†Presented in part at the Anaesthetic Research Society, Sheffield Meeting, July 7–8, 1995 (*British Journal of Anaesthesia* 1995; 75: 653P).

Subjects and methods

This study was approved by the local Ethics Committee. Ten ASA I or II patients undergoing surgery anticipated to last at least 120 min gave written informed consent.

The closed-loop system comprised an IBM compatible personal computer (PC) interfaced to a Datex Relaxograph for monitoring neuromuscular block and a Graseby Medical 3400 infusion pump for administration of atracurium. The PC was programmed to use the developed fuzzy control strategy and co-ordinate communication with the two devices via serial links. System safety was given close attention before commencing any clinical research. A hierarchical alarm structure was used so that any concurrently active alarm conditions were dealt with appropriately. System hardware and software integrity were monitored carefully offline in real-time using a simulation device attached to the Datex Relaxograph.

Patients received a standardized anaesthetic. After premedication with temazepam, anaesthesia was induced with alfentanil 10 mg kg^{-1} and a sleep dose of propofol followed by a propofol infusion of 10 mg kg^{-1} h^{-1}. The patient's lungs were then ventilated manually with nitrous oxide in oxygen while the automated drug delivery system was prepared. Stimulating electrodes for a Datex Relaxograph were placed over the ulnar nerve of the non-infused hand and sensing electrodes placed over the hypothenar area. The initial T1 set point was entered as 10% of baseline, a file name was entered for data storage and the concentration of atracurium (2 mg ml^{-1}) was entered so that the computer could convert the controller output from mass rate (mg h^{-1}) to volume flow rate (ml h^{-1}). In addition, the patient's weight was entered for calculation of the atracurium loading dose. When the computer system was satisfied that no alarm conditions were active, it delivered a loading dose of atracurium 0.33 mg kg^{-1} at 1200 ml h^{-1} to facilitate tracheal intubation. Anaesthesia was maintained with a propofol infusion of 8–10 mg kg^{-1} h^{-1}, the patient's lungs ventilated with 66% nitrous oxide in oxygen and morphine administered as appropriate. Neuromuscular block was controlled by the closed-loop fuzzy atracurium controller throughout the operation.

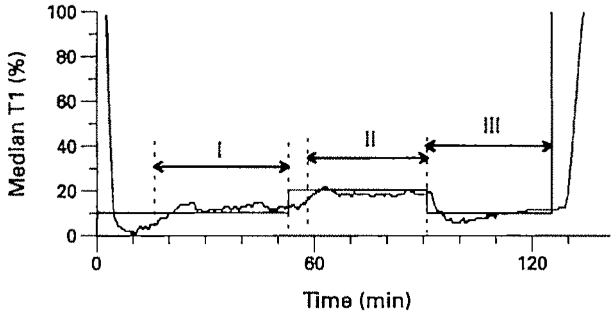

Figure 1 Sample clinical trace showing the definition of phases I, II and III used for the performance analysis. Note that these phases include transients.

The time taken after administration of the atracurium loading dose for T1 to start recovering and reach at least 5% of baseline was used to assess patient sensitivity to atracurium and thus determine its initial infusion rate. If this recovery time was fast (slow) the patient was judged insensitive (sensitive) to atracurium and therefore required a high (low) initial infusion rate. If T1 was above the initial 10% set point when neuromuscular block started to recover, the computer was programmed to give an additional 5-mg bolus over 3 min and repeat as necessary until T1 was less than the initial 10% T1 set point level. When T1 had recovered to 5–10%, the fuzzy controller commenced operation.

The fuzzy controller used the median of the last three T1 values. The Datex Relaxograph performed a train-of-four stimulation every 20 s to calculate the T1 error values at 1-min intervals which the fuzzy controller then used. The controller remained active at the initial 10% set point level for at least 30 min (phase I). The set point was then increased to 20% by keyboard entry and then returned to 10% again for two further periods of at least 30 min duration (phases II and III) (fig. 1). When the set point was reduced from 20% to 10%, an additional bolus dose of atracurium was administered equal to 10% of the value of the current mg h^{-1} integral (I) component of the fuzzy controller output. This was introduced to represent the situation where a prompt increase in neuromuscular block is required to improve surgical conditions while avoiding the problem of overshooting the degree of block required. During all phases the atracurium infusion rate was subject to an upper limit of 100 mg h^{-1}. In addition, the atracurium infusion was temporarily stopped if the median T1 value was more than 5% below the set point.

To assess the performance of the fuzzy controller, raw T1 values were analysed (i.e. not three-term median T1 values) to allow comparison of performance with previously reported controllers. T1 errors, defined as the raw T1 value minus the set point T1 value, were calculated for each phase with each patient. These T1 errors were analysed for each phase as follows: mean (SD); root mean square

Table 1 Control performance analysis (mean (SD) [range]) for the first 30 min of each phase only. This fixed period of analysis provides less variable, and therefore more meaningful, ISE and ITAE values

Phase	Mean error (%)	SD (%)	RMSD (%)	ISE (%) (min)	ITAE (min^2)	PC (%)
I	1.1 (1.4)	2.4 (0.68)	3.0 (0.62)	2.7 (1.1)	11 (2.5)	70 (22)
	[−0.9–2.9]	[1.7–3.6]	[2.0–4.2]	[1.2–5.0]	[7.0–14]	[34–89]
II	−0.43 (1.2)	1.5 (0.29)	1.9 (0.36)	1.1 (0.44)	6.7 (1.8)	39 (29)
	[−1.7–2.0]	[1.1–2.0]	[1.5–2.8]	[0.6–2.1]	[4.4–10]	[11–92]
III	0.28 (0.94)	3.4 (0.88)	3.5 (0.85)	3.2 (1.8)	8.4 (3.9)	47 (18)
	[−1.1–1.8]	[2.3–5.3]	[2.5–5.4]	[1.4–7.6]	[3.3–13]	[23–71]

deviation (RMSD); point count (PC), proportion of T1 errors above the T1 set point (i.e. those with positive value); integral square error (ISE); and integral time absolute error (ITAE) (appendix).

The latter two calculations are standard control engineering performance measures [6]. The first, ISE, is similar to RMSD, a measure of variation about the set point. The second, ITAE, is a measure which penalizes errors more heavily the further they are from the time origin of each phase. Both of these measures are sensitive to the period of analysis (appendix). We therefore selected the first 30 min of each phase for analysis. Clearly, for good control performance we need values for each of these calculations to be close to zero, except PC which needs to be close to 50%. Mean (SD) mg kg^{-1} h^{-1} atracurium infusion rates were also calculated for each phase. These values were then analysed for the 10 patients and expressed as mean (SD) and range.

Results

Ten patients (four male) were studied. Mean age was 59 (range 35–75) yr, mean weight 72 (45–110) kg. No phase III was possible for patient No. 4 because the operation ended earlier than expected. Mean duration of phase I was 45 (30–85) min, phase II 35 (28–57) min and phase III 47 (33–78) min. There was a wide range for duration of phases I and III. As some performance measures are sensitive to the magnitude of the period of analysis (appendix), we considered only the first 30 min of each phase.

Table 1 shows good control performance with a mean error of 1.1% and 0.28% above the 10% set point for phases I and III, respectively, and 0.43% below the 20% point for phase II. This is mainly consistent with the point count (PC) measure; more often above the set point in phase I with PC = 70%, more often below in phase II with PC = 39% and marginally more often below in phase III with PC = 47%. The SD values were 2.4%, 1.5% and 3.4% for phases I, II and III, respectively. This variation is low, particularly when it is considered that analysis includes transient phases. This implies that stable neuromuscular block was achieved. The SD and RMSD values were similar for each phase confirming that the mean error was close to zero. The ISE and RMSD performance measures are similar calculations and accordingly provide similar values for each phase. The ITAE performance measure was similar for phases I, II and III with values of 11, 6.7 and 8.4 min^2, respectively.

Table 2 Mean atracurium infusion rates for the 10 patients in the first 30 min of each phase only (mean (SD) [range])

Phase	Mean	SD
I	0.40 (0.08) [0.30–0.58]	0.23 (0.05) [0.16–0.30]
II	0.38 (0.10) [0.20–0.50]	0.22 (0.06) [0.10–0.32]
III	0.34 (0.08) [0.19–0.46]	0.22 (0.07) [0.12–0.35]

The range of the mean atracurium infusion rates which the fuzzy controller accommodated successfully in phases I, II and III were 0.30–0.58, 0.20–0.50 and 0.19–0.46 mg kg^{-1} h^{-1} (table 2). The SD was consistently high at 0.23, 0.22 and 0.22 mg kg^{-1} h^{-1} for phases I, II and III, respectively.

Discussion

Several different computer systems for feedback control of atracurium infusions have been reported. The periods used for performance analysis in these studies differ. Most have analysed only steady state performance [7–11]. We included transient phases in our performance analysis. Unlike previously reported clinical studies we tested the controller sensitivity to set point changes. Most studies have used EMG to monitor neuromuscular block. However, various different maintenance anaesthetics were used, some of which potentiate the effects of neuromuscular blockers. It is therefore not possible to provide a valid comparison of performance across these different atracurium controllers in terms of mean, SD and RMSD. However, there appears to be no statistically or clinically significant difference in reported controller performances. The main advantage the fuzzy controller offers over previously reported controllers is its simplicity and its friendly or intuitive designer interface. For example, a possible fuzzy control rule drawn from expert experience in the control of atracurium-induced neuromuscular block or just plain common sense could be:

> "IF T1 is greater than the set point by a LARGE amount
> AND T1 is moving towards the set point but only SLOWLY
> THEN set the atracurium infusion rate to a HIGH level."

The first line of this rule is a proportional (P) controller component, the second a differential (D) component. These antecedent components are fuzzy rule inputs. The final line is the fuzzy rule output.

This friendly designer interface for the fuzzy controller implies there is no need to understand complex mathematical formulae nor is there a need to interpret pharmacokinetic data. The fuzzy controller simply takes the T1 measurement and goes through some basic processing steps:

1. Input scaling

Scale each of the error inputs, that is proportional, differential and integral components.

2. Fuzzification

Assign fuzzy sets centred about these scaled values. This transforms error inputs from the real world to the fuzzy domain.

3. Fuzzy inferencing

Determine the degree of membership (DOM) of each error input with overlapping fuzzy sets. These calculated DOM values are used in combination with the fuzzy rules to calculate the DOM value for each fuzzy rule output.

4. Defuzzification

Combine the outputs of the fuzzy rules using a weighting method such as "centre of gravity". This transforms data from the fuzzy domain back to the real world.

5. Output scaling

This defuzzified value is scaled to give the real output value in terms of mg h^{-1} atracurium infusion rate.

Each of these steps requires simple calculations only. This low computational cost means it is simple to implement in terms of hardware and software.

The only other atracurium controller to report the point count (PC) performance measure also found that T1 was below a 20 % set point (our phase II) for most of the time (PC = 25 %) [9]. This may be a reflection of the non-linear atracurium dose–response characteristic in this region.

No previous clinical study has analysed the performance of an automated atracurium drug delivery system using ISE and ITAE but we report them here in the hope that future performance assessments will use them. It is noted that ITAE and ISE performance measures are sensitive to the duration of analysis (appendix). It is therefore important to compare these values over the same period (30 min in our study). The ISE is similar to the commonly reported RMSD as a measure of variation about the set point. However, ITAE has greater value because it measures the accuracy of the controller in reducing any error from the set point in proportion to the length of time as the controller commenced operation after receiving a new set point.

The consistently high SD atracurium infusion rate (table 2) indicates high controller activity, that is fluctuating infusion rates. This controller over-activity was not expected from computer simulation studies and suggests that the fuzzy PD (dynamic) component of the controller needed further testing with computer simulation under high system noise level conditions. Interestingly, however, Young and Hsiao [12] suggested that this pseudo-bolus action is required to promptly bring second compartment concentrations to desired levels in a three-compartment pharmacokinetic open model of neuromuscular blocking agents. The apparent over-activity of this fuzzy controller might be overcome by reducing the output scaling factor of the dynamic (PD) component of the fuzzy controller.

It may be argued that the fuzzy controller reported here could easily be implemented as a simple PID controller without the need for fuzzy logic. This would imply simply limiting the ranges for the PID error components in a piece-wise linear manner. This is true with this particular fuzzy controller but overlooks the potential for fuzzy logic controllers to provide a smooth and arbitrarily non-linear control surface with no additional computational burden. This holds particular promise with self-organizing fuzzy logic controllers which can modify the fuzzy rulebase online so as to match the needs of each individual patient, which may change during the course of an operation.

Clinically this system was useful. It provided stable surgical operating conditions, minimized the amount of neuromuscular blocker required by each patient, reduced the need for the anaesthetist to spend time controlling neuromuscular block, and allowed reliable antagonism of neuromuscular block at the end of surgery.

In conclusion, this simple fuzzy controller with fixed variables provided stable control of neuromuscular block and its performance was insensitive to set point changes.

Appendix

FORMULAE FOR PERFORMANCE ANALYSIS

The T1 error used for analysis was defined as follows:

$$E_n = T1_n - SP_n$$

where $T1_n$ = Relaxograph reading and SP_n = T1 set point for sample number n.

This error was then analysed in the following ways:

(i) Mean (M) and standard deviation (SD) of the T1 error,

$$M = \frac{\sum_{n=1}^{N} E_n}{N}$$

$$\mathrm{SD} = \sqrt{\frac{\sum_{n=1}^{N} (E_n - M)^2}{N-1}}$$

(ii) Root mean square deviation (RMSD) of T1 error,

$$\mathrm{RMSD} = \sqrt{\frac{\sum_{n=1}^{N} E_n^{2}}{N-1}}$$

(iii) Point count (PC), proportion of T1 samples above the T1 set point,

$$PC = \sqrt{\frac{N + \sum_{n=1}^{N} sgn(E_n)}{2 \times N}}$$

where $\mathrm{sgn}(E_n) = 1$ if E_n is > 0, else $\mathrm{sgn}(E_n) = -1$.

(iv) Integral square T1 error (ISE),

$$ISE = \int E_n^2 \times dt \approx \sum_{n=2}^{N} (E_n^2 \times (t_n - t_{n-1}))$$

(v) Integral time absolute T1 error (ITAE)

$$\mathrm{ITAE} = \int t \times |E_n| \times dt \approx \sum_{n=1}^{N} (t_n \times |E_n| \times (t_n - t_{n-1}))$$

Comparison of arterialized venous with arterial blood propofol concentrations during sub-anaesthetic infusions in volunteers

K. R. JOHNSTON, M. D. VICKERS AND W. W. MAPLESON

Summary

We have compared propofol concentrations in arterial and arterialized venous blood (from the radial artery at the wrist and a vein in the opposite forearm) in five volunteers during a sub-anaesthetic increasing infusion regimen designed to produce pseudo-steady-state arterial concentrations of 0.06, 0.17 and 0.43 μg ml^{-1}. As in a previous study, we found no statistically significant difference between sampling sites ($P = 0.66$). However, changes in the method of arterialization yielded a reduction in the observed variability, with the arterialized venous propofol concentration lying within ±23% (95% reference interval) of the corresponding arterial concentration compared with 1 ±43%, as reported previously. (*Br. J. Anaesth.* 1996; **76**: 401–404)

Key words

Anaesthetics i.v., propofol. Measurement techniques, drug concentration. Pharmacology, steady-state infusions.

It is generally argued that studies on the uptake and distribution of anaesthetic agents and their effects on the central nervous system when administered by the i.v. or inhalation routes require estimation of the arterial concentration of the agents [1–3]. Relating central nervous system effects to arterial drug concentrations by repeated sampling presents ethical and practical difficulties in both patient and volunteer studies. The technique of arterialization, whereby forearm blood flow is increased by external heating to minimize the effect of tissue extraction and time lag, allows venous blood to be sampled as an alternative to direct arterial cannulation. The technique has been used previously for indirect estimation of arterial $P\text{CO}_2$ [4] and has been validated for halothane [3].

In a study of depression of the peak velocity of saccadic eye movements by sub-anaesthetic infusions of propofol in volunteers, Gao, Mapleson and Vickers [1] measured propofol concentrations in samples of arterialized venous blood as an alternative to arterial sampling. The measured concentrations differed substantially from predicted values and concern was expressed by the authors that some of the systematic deviation observed may have resulted from the site of blood sampling. Subsequently, direct comparison of arterialized venous and arterial blood propofol concentrations in a group of patients receiving similar, low-dose infusions was reported by Okell, Mapleson and Vickers [5]. The results of this study indicated that individual arterialized venous propofol concentrations may differ from corresponding arterial concentrations by as much as 1±43% (95% reference interval [6]). Such wide variability brought into question the acceptability of arterialized venous blood sampling as an investigative tool for propofol assay.

The present study was designed to evaluate the effect of improvement in the method of arterialization of forearm blood flow when comparing arterialized venous with arterial blood propofol concentrations during similar, sub-anaesthetic propofol infusions.

Subjects and methods

Approval was granted by the District Ethics Committee for the administration of sub-anaesthetic infusions of propofol in volunteers undergoing radial arterial cannulation for other research purposes. A medical questionnaire was completed, physical examination undertaken and written informed consent obtained from all participants. Each volunteer was weighed before administration of the propofol infusion. Five healthy, non-smoking volunteers (three male) completed the investigation.

INFUSION AND SAMPLING SITES

Using local anaesthesia, an 18-gauge cannula (1.2 mm o.d.) was placed in a suitable vein on the dorsum of the non-dominant hand for infusion of propofol.

For arterial blood sampling, a 20-gauge (1.0 mm o.d.) cannula (Venflon (R) 2 Viggo) was inserted using local anaesthesia into the radial artery of the same hand at the wrist. The cannula was connected via a short sampling line and three-way tap to a continuous flushing system (CFS Intraflo (R) II), pressurized with heparinized normal saline (1.0 u. ml^{-1}).

For sampling venous blood, a 14-gauge (2.0 mm o.d.) cannula was inserted using local anaesthesia into a large superficial vein of the dominant (arterialized) forearm, near the antecubital

Table 1 Sequence of administration of propofol to produce the three pseudo-steady-states. *Predicted arterial concentration at the end of each 25-min period

Infusion	Dose ($mg\ kg^{-1}\ h^{-1}$)	Duration (min)	Predicted concentration* ($\mu g\ ml^{-1}$)
(Bolus)	($0.03\ mg\ kg^{-1}$)	—	
1st	0.25	25	0.06
Loading	1.0	5	
2nd	0.6	20	0.17
Loading	2.3	5	
3rd	1.5	20	0.43

fossa. This cannula was connected to a source of heparinized saline via a sampling line and three-way tap. The ability to aspirate blood freely from the venous cannula without the use of a tourniquet or exposing the arm was confirmed at frequent intervals. The cannula was flushed periodically with 2-ml boluses of heparinized saline to maintain patency throughout the study period.

TECHNIQUE OF ARTERIALIZATION

The dominant arm was wrapped in an electric heating blanket in such a way that blood samples could be obtained without disturbing its position. No constricting bands were allowed on the sampling arm, which was placed horizontally at right angles to the body, as described previously [2, 3], to prevent venous obstruction. Forearm skin temperature was measured with a K-type (NiCr-NiAl) thermocouple (Digitron 1408-K) embedded in a bead of heat-conducting compound (RS55-431-1) and then taped to the skin with adhesive tape. The method used in a previous study by Okell, Mapleson and Vickers [5] raised questions as to the adequacy of "arterialization" because of the close proximity of the thermocouple and heating blanket. In order to ensure that we estimated true forearm skin temperature, for this study the thermocouple was insulated from the warming blanket by interposing polyurethane foam (5 × 5 × 2 cm) and adhesive aluminium foil. We assumed that venous blood had become arterialized when forearm skin temperature had increased to greater than 38 °C.

INFUSION REGIMEN

When arterialization of forearm blood had been achieved, the sub-anaesthetic infusion of propofol (Diprivan, Zeneca) was started using a syringe-driver type infusion device (Ohmeda 9000). The standard 1 % formulation ($10\ mg\ ml^{-1}$) was used; an initial bolus dose was followed by a stepwise increasing infusion regimen, identical to that used in previous studies [1, 2]. The infusion regimen (table 1) is based on a three-compartment computer model [7] using the pharmacokinetic microconstants reported by Gepts and colleagues [8]. This regimen is predicted to attain a pseudo-steady-state propofol concentration in the central compartment at the end of each of the three, 25-min periods. Appropriate allowance was made in the initial propofol bolus for the deadspace of the infusion system.

BLOOD SAMPLING AND ASSAY

At the end of each 25-min period, blood was obtained simultaneously from arterial and venous sampling cannulae, without the use of tourniquets. Appropriate deadspace volumes of blood were discarded (5 ml arterial and 10 ml venous). Each sample (venous and arterial) was divided into two identical aliquots, mixed with potassium oxalate and stored at 4 °C (a total of 12 aliquots per volunteer). Coded aliquots were assayed for blood propofol concentrations at another institution using high-pressure liquid chromatography with fluorescence detection, according to the method of Plummer [9]. The within-batch coefficient of variation (CV) reported for this method is 1.3–5.5 % and the between batch CV 2.9–12.3 %.

STATISTICAL ANALYSIS

Statistical analysis was by analysis of variance using Genstat 5, [10] release 1.3, running on a DEC mainframe computer under the Ultrix operating system OSF/1 V2.0B.

Analysis of variance was performed in terms of log concentration because this was needed to obtain similar variance at all three infusion rates, that is variability was consistent in terms of percentage of mean (coefficient of variation) rather than in absolute terms (SD). Analysis of variance distinguished four sources of variation: between subjects, between steady states, between sampling sites and between aliquots. The variations between steady states and between sampling sites were partitioned into systematic and random effects. The systematic effects were the differences between the mean concentrations for each steady state and for each sampling site.

Results

One outlying measurement (table 2) (50-fold higher than predicted) was treated as a "missing value" which Genstat handles appropriately. The analysis

Table 2 Measured whole blood propofol concentrations at the end of each 25-min period ($\mu g\ ml^{-1}$). *Outlier treated as missing value

		Concentration ($\mu g\ ml^{-1}$)			
Subject No.	Period	Arterialized venous		Arterial	
1	1	0.16	5.7*	0.25	0.20

	3	0.39	0.44	0.43	0.37

Table 3 Analysis of variance of logarithms of the measured concentrations

Source of variation	Degrees of freedom	Sums of squares	Mean square	Variance ratio	P
Between					
Subjects (random)	4	0.28743	0.07186		
Steady states					
Systematic	2	3.29769	1.64885	134.4	< 0.001
Random	8	0.09814	0.01227		
Sampling sites					
Systematic	1	0.00155	0.00156	0.2	0.66
Random	14	0.10809	0.00772		
Between aliquots (random)	29	0.06989	0.00241		
Total	58	3.81743			

(table 3) shows that, although the three 25-min periods produced very different "steady state" concentrations ($P < 0.001$), the difference between sampling sites was not significant ($P = 0.66$).

From the mean squares in table 3, the SD between aliquots (the analytical error in terms of the log concentration) can be estimated [11] to be $\sqrt{0.00241} = 0.0491$ which, taking antilogs, corresponds to a coefficient of variation (CV) of 12.0%.

The mean difference in log concentration between sampling sites (mean arterialized venous − mean arterial) was −0.0102, that is −2.3%. The SD between sampling sites, after allowing for the contribution from analytical error, can be estimated [11] to be $\sqrt{\{(0.00772-0.00241)/2\}} = 0.0515$ which, again taking antilogs, corresponds to a coefficient of variation of 12.6%. The standard error of the difference of log concentration between the two sampling sites is then given by $0.0515 \times \sqrt{(2/15)} = 0.0188$, where 15 is the number of venous–arterial pairs in the study. From these results it can be calculated that the 95% confidence interval for the mean difference (arterialized venous − arterial) (av − a) is −11.0% to +7.2%, and that individual av − a differences may range (95% reference interval) [6] from −22.6% to +23.2%.

Discussion

Although the mean difference between arterialized venous and arterial concentrations was small and not significant, the confidence interval shows that the true mean difference might be of the order of 10% in either direction. Furthermore, the 95% reference interval shows that, in addition to the uncertainty arising from the analytical error, its concentration may (with 95% probability [6]) be between 23% less than the true arterial concentration and 23% greater.

Our previous study [5] also found a small, non-significant difference between arterialized venous and arterial concentration. The method of statistical analysis was slightly different from that used here; in particular, constancy of variance was achieved by expressing all measured concentrations as a percentage of the mean of the two arterial samples (in each set of two arterial and two venous). When those data were re-analysed in the same way as here (i.e. using log concentration) the mean arterialized venous concentration was further below the mean arterial concentration (−5.6% instead of our −2.3%) with a wider confidence interval (−17% to +7% compared with our −11% to +7%) and a much wider reference interval (−36% to +39% compared with our −23% to +23%). Therefore, it seems likely that the foam pad and foil, which were placed between the thermocouple and the warming blanket in this study, but not in the previous one [5], are essential.

Although the use of the foam pad reduced the scatter of the arterialized venous to arterial differences, the remaining 95% reference interval of ±23% must still imply that, at least at these low concentrations, measurement of arterialized venous concentration is of limited value in estimating the arterial concentration in an individual subject. However, it should be acceptable for mean concentrations measured in substantial numbers of subjects for research purposes. As found in previous studies [2, 4, 5], it is practicable to use the heating pad in patients.

The analytical error in the present study (CV of 12%) is at the upper limit of that claimed by Plummer [9] for the between-batch CV for the method and approximately twice that claimed for the within-batch CV, but very similar to the 11% found by Weaver and colleagues [12] for propofol concentrations up to 20 $\mu g\ ml^{-1}$ measured by the same method in sheep blood.

As found in the previous study [5], mean measured concentrations were greater than predicted: 0.15 (95% confidence interval 0.13–0.17) compared with a predicted value of 0.06; 0.23 (0.19–0.27) compared with 0.17; and 0.53 (0.45–0.63) compared with 0.43.

Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement†

B. M. WEISS, D. R. SPAHN, H. RAHMIG, R. ROHLING AND T. PASCH

Summary

Radial artery tonometry provides continuous measurement of non-invasive arterial pressure (CNAP) by a sensor positioned above the radial artery. An inflatable upper arm cuff enables intermittent oscillometric calibration. CNAP was compared with invasive radial artery pressure recordings from the opposite wrist in 22 high-risk surgical patients with an inter-arm oscillometric mean arterial pressure difference ⩽ 10 mm Hg. Oscillometric, tonometric and invasive digital pressure values, and invasive and CNAP waveforms were obtained by the same instrument (Colin BP-508). Correlation coefficients (r) of invasive *vs* oscillometric values ($n = 481$ pairs) were 0.83, 0.90 and 0.92, and mean absolute errors of oscillometry were 7.6, 4.7, and 2.6 mm Hg for systolic, diastolic and mean arterial pressures, respectively. Correlation was poor for systolic ($r = 0.80$), diastolic ($r = 0.77$) and mean ($r = 0.84$) invasive *vs* CNAP values ($n = 1375$). Compared with oscillometry, mean absolute errors of 15.2, 10.9 and 9.4 mm Hg for systolic, diastolic and mean CNAP, respectively, were significantly ($P < 0.001$) higher. Mean prediction errors of CNAP, compared with invasive values, were −5.8 (SD 14.2) mm Hg for systolic, +7.2 (8.3) mm Hg for diastolic and +3.9 (8.8) mm Hg for mean arterial pressure. Individual patient accuracy of CNAP was assessed as good (individual prediction error ⩽ 5 (8) mm Hg and individual absolute error ⩽ 10 mm Hg) in seven patients, as acceptable (⩽ 10 (12) and ⩽ 15 mm Hg) in 11 patients, and as inadequate in four of 22 patients. Individual accuracy of oscillometry was good or acceptable in all 22 patients. The trend in CNAP changes (difference between consecutive measurements) was sufficiently accurate during induction of anaesthesia, as only 47 (7.6%), 14 (2.3%) and 27 (4.4%) of 616 systolic, diastolic and mean CNAP values differed by more than 10 mm Hg of invasive pressure trends. We conclude that: intermittent oscillometry provides accurate arterial pressure monitoring; CNAP measurements offer a reliable trend indicator of pressure changes during induction of anaesthesia and may be considered an alternative to invasive pressure measurements, should arterial cannulation be difficult in an awake patient; and accuracy of absolute CNAP values is only moderate and unpredictable, thus radial artery tonometry should not replace invasive monitoring in high-risk patients during major surgical procedures. (*Br. J. Anaesth.* 1996; **76**: 405–411)

Key words

Arterial pressure. Arterial pressure, measurement. Measurement technique, arterial pressure. Measurement techniques, tonometry. Measurement techniques, oscillometry.

The principles of tonometry are based on compressing and partial flattening (applanation) of a superficial artery against the underlying structures, preferably bone. The flattened surface of the arterial segment "balances" the pressure-induced circumferential stress on the arterial wall and the forces exerted by arterial pressure become perpendicular to wall tension. The ongoing intra-arterial forces, sensed by a pressure transducer attached firmly on the skin surface above the artery, are translated into arterial pressure waveforms [1, 2]. Radial artery tonometry was incorporated recently in anaesthesia monitoring instruments. Using an inflatable upper arm cuff, the calibration (oscillometry) for tonometric pressure values is provided intermittently. In addition to oscillometric pressure, continuous non-invasive arterial pressure (CNAP) waveform and tonometric digital pressure values are displayed continuously and updated automatically. In anaesthetized patients, the method was found to provide accurate, reliable online information, even during induced hypotension [3, 4]. Other investigators reported poor accuracy of radial artery tonometry and limited ability to detect significant changes more rapidly than with oscillometry alone [5]. Also, a limited ability to capture the pulse pressure signal in

paediatric patients was observed [6]. An accurate technique of CNAP measurement, however, could replace invasive arterial pressure monitoring in some patients, avoiding the risks of arterial cannulation. In addition, arterial cannulation can be difficult in the awake state, and CNAP monitoring may be a temporary alternative, allowing cannulation later under the more favourable condition of general anaesthesia.

The purpose of the study was to evaluate radial artery tonometry in patients with concomitant cardiac, vascular, pulmonary and renal diseases undergoing non-thoracic surgical procedures.

Patients and methods

The study was approved by the Institutional Ethics Committee. After obtaining informed consent, we studied patients undergoing abdominal or transurethral surgical procedures in the supine or lithotomy position, requiring invasive arterial pressure monitoring with no history of recent radial artery cannulation. The anaesthetic technique was chosen independent of the investigation. Premedication comprised oral midazolam and patients were placed in the supine position on an operating table. A circulating water mattress and warmed i.v. infusions were used to maintain normothermia. The arms were placed on armholders at the level of the heart, abducted approximately 45–70° from the body. Arterial pressure was measured oscillometrically on both arms, using an adult size, inflatable upper arm cuff and a multifunctional monitoring instrument (BP-508, Colin Medical Instrumentations, Komaki, Japan). Three patients with an inter-arm mean arterial pressure difference exceeding 10 mm Hg (average of three measurements) were excluded. Patient characteristics (19 males and three females), inter-arm oscillometric differences and concomitant diseases are summarized in table 1.

A radial artery cannula (20-gauge, 32 mm) was inserted during local anaesthesia and connected to low compliance tubing (diameter 1.0–1.5 mm, length 165 cm, two stopcocks). A disposable pressure transducer (Deltran, Utah Medical, Midvale, UT, USA) was used. This set was tested previously *in vitro* with a pressure waveform generator. Almost identical values for mean and trough pressure were found, and peak pressure was overestimated by a mean of 2.0 (SD 0.8) mm Hg, compared with values obtained by a micromanometer pressure transducer [7]. The pressure transducer was connected to the pressure module (with a low-pass filter for frequencies greater than 25 Hz) of the Colin instrument. The level of the right atrium was used for zero calibration.

Table 1 Patient characteristics ($n = 22$) (mean (SD) [range])

Age (yr)	66.3 [25.5–91.1]
Weight (kg)	74.0 (14.3) [42.5–91.0]

The upper arm cuff and the housing with a multi-element array sensor (SA-250, Colin, Komaki, Japan), attached above the radial artery, were placed on the contralateral arm. The dimensions of the sensor housing were 7.0 × 4.0 × 3.7 cm, with weight 90 g. The wrist was placed in a brace in an extended position and the brace and sensor housing were wrapped, as recommended by the manufacturer. The intermittent oscillometric measurements served as the reference (occlusive calibration) and defined the range and values for tonometric CNAP. Automatic recalibration occurred independently of the preset interval whenever the device registered distortion of the CNAP curve. The instrument displayed on the screen: digital oscillometric pressure values, selected time interval and time elapsed since the previous calibration; invasive and CNAP curves on the same scale; and synchronously, the updated invasive and tonometric digital values for systolic, diastolic and mean arterial pressures. One of the 30 elements of the sensor transducer identified automatically maximal pulse amplitude signals from the flattened radial artery. A small graphical display (tonogram) on the screen indicated the position of the "active transducer" as a vertical line and as a bar. Within given limits, automatic repositioning of the active element–transducer and optimal pulse amplitude identification occurred, otherwise manual repositioning was required. Another graphical display and digital value indicated so-called signal strength. Signal strength is calculated automatically by the device as the ratio between the peak-to-peak amplitudes of tonometric pressure to the amplitudes of cuff oscillations. According to the manufacturer, signal strength should be 50–100 amplitude units. Inadequate sensor placement and a signal strength less than 50 amplitude units required repositioning of the sensor. The pressure applied on the wrist by the sensor (hold-down pressure), controlled through a microprocessor and set by a pneumatic bladder within the housing, was displayed on the screen. Initial signal strength and hold-down pressure values were recorded in each patient, and controlled throughout the procedure.

Comparative measurements were started before induction of anaesthesia and lasted until the patient was prepared to leave the operating room. Oscillometric calibration was preset at 5-min intervals during induction of anaesthesia and at 10-min intervals for the rest of the procedure. Invasive and tonometric CNAP values were documented every 30–60 s during induction of anaesthesia and every 3–5 min for the remainder of the procedure. The built-in printer automatically and continually recorded the time of day and a pair of oscillometric and invasive pressure values *or* a pair of invasive and tonometric CNAP values. All values were later checked and incomplete or artefactual pairs (collected during blood aspiration, flushing, repositioning of the sensor or unstable signal strength) were excluded from analysis. As the waveform recording was not provided by this instrument software, both CNAP and invasive pressure curves were printed continually on a multichannel paper recorder (Servomed, Hellige, Freiburg, Germany). The oscillometric signal and scale could not be recorded, and the CNAP trace was centred manually within the channel and the amplitude adjusted to that of invasive pressure.

The time periods of induction of anaesthesia and surgical procedure, actual time interval between oscillometric calibrations and actual frequency of CNAP collection were recorded for each patient. Invasive pressure was considered the reference. Oscillometric and corresponding invasive pressure pairs and, separately, tonometric CNAP and corresponding invasive pressure pairs were analysed. Pressure differences were calculated for each pair of systolic, diastolic and mean values. Mean (SD) pressure differences (prediction error or bias) were derived for oscillometry and tonometry, cumulatively for all data and individually for each patient. Absolute error (precision) was calculated as the sum of squared pressure differences, divided by the number of measurements, cumulatively for all data and individually for each patient [8]. Percentage error was derived from (mean pressure difference/mean of average pressure) × 100. Oscillometric and tonometric errors were compared by the Student's *t* test and $P < 0.05$ was considered statistically significant. To evaluate the correlation between the measured and calculated variables, linear regression analysis, with coefficient of correlation (*r*) and 95 % confidence intervals for the single observations, was used. The average pressure of each pair and the mean of the average were calculated for oscillometric and invasive, and for tonometric and invasive pairs. Each tonometric prediction error was plotted against the average pressure value of the two measurements, and the mean error (bias) and limits of agreement (±2 SD) were drawn [9]. Each patient's individual prediction error of tonometric and oscillometric systolic, diastolic and mean arterial pressure was defined arbitrarily as good ($\leqslant 5$ (8) mm Hg), acceptable (5 (8) < errors $\leqslant 10$ (12) mm Hg) or poor (> 10 (12) mm Hg). Individual mean absolute errors of $\leqslant 10$, 11–15 and > 15 mm Hg were arbitrarily classified as good, acceptable and poor, respectively. Bias and precision of systolic, diastolic and mean arterial pressures were combined to assess oscillometry and, separately, tonometry in each patient, according to an arbitrary score (two errors for three pressures: 2 = good, 1 = acceptable and 0 = poor error). Good monitoring required a score of 9–12 points, acceptable monitoring 5–8 points, and 0–4 points indicated a poor function of tonometric CNAP. A pressure difference between two consecutive measurements (trend of changes) was derived for the invasive and CNAP methods during induction of anaesthesia. The critical difference between the two trends was arbitrarily set at 10 mm Hg. Data are presented as mean (SD) unless otherwise stated.

Results

The mean period of measurement was 153 (87) min and the mean duration of surgery 109 (75) min. We studied five patients during spontaneous breathing, using regional anaesthesia in two patients and general anaesthesia in three. General anaesthesia, neuromuscular block and controlled ventilation were used in 17 patients, in seven patients combined with a continuous extradural block. Single or multiple i.v. injections of ephedrine, nitroglycerin, or both, were given to 12 patients, one patient received a dopamine infusion of 1–3 $\mu g\ kg^{-1}\ min^{-1}$ for 2.5 h, and in nine patients vasoactive drugs were not given. Intraoperative blood loss was estimated as less than 10 % of circulating blood volume in 13 patients, less than 20 % in two patients, less than 50 % in three patients and exceeding 50 % in four patients. Blood volume was substituted, as required, with crystalloid and colloid solutions, and blood transfusions.

According to the tonogram, and axial and signal strength indicators, correct sensor positioning was obtained initially in all patients. Initial values of signal strength and hold-down pressure were 96.5 (21.8) amplitude units and 78.0 (32.7) mm Hg, respectively. Protection of the sensor position, as a result of the abducted arm and the weight and volume of the sensor housing itself, was found to be difficult on occasion. In several patients repositioning of the sensor was required during the study. In one patient tonometric CNAP ceased to function, the warnings and repeated oscillometric measurements indicated a function failure, and then CNAP monitoring returned automatically. The function of the device was not disturbed by the intraoperative use of electrocautery. The CNAP curve looked acceptable, compared with the simultaneous invasive pressure curve, during normal heart rate and cardiac arrhythmia.

We analysed a total of 481 pairs of oscillometric and invasive pressure (21.9 (12.6) pairs per patient), and 1375 pairs of tonometric and invasive pressure (62.5 (28.4) pairs per patient). During induction of anaesthesia (30.7 (18) min) and for the remainder of the procedure, oscillometric calibration was performed every 6.1 (3.1) min and 8.5 (2.5) min, respectively, and tonometric CNAP data were collected every 1.0 (0.5) min and 4.7 (2.0) min, respectively. Pressure differences and dispersion of errors showed a normal distribution. Cumulatively (table 2), oscillometric measurements were more accurate than tonometric CNAP. Absolute errors of CNAP were significantly larger than corresponding absolute errors of oscillometry. Average CNAP errors and linear regression analysis (*r*, mean prediction line) of the pooled data showed small discrepancies and a significant correlation with invasive pressure values. The confidence interval range, however, exceeded 50 mm Hg for systolic and 30 mm Hg for diastolic and mean (fig. 1) arterial pressures. The limits of agreement (2 SD) between

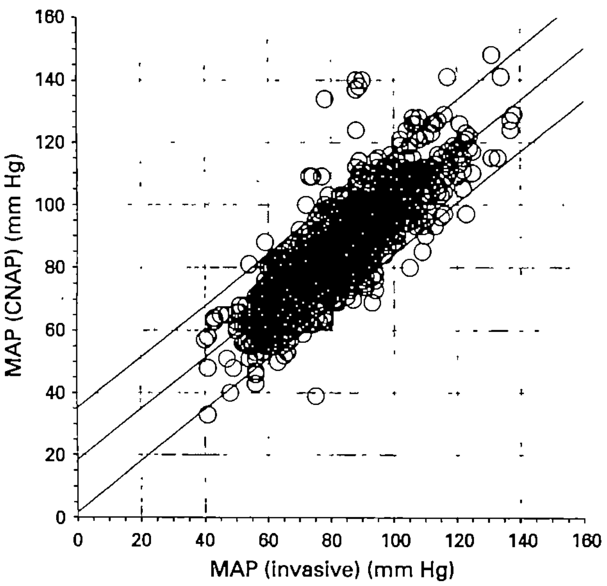

Figure 1 Linear regression analysis with scatterplot for mean arterial pressure (MAP) of the invasive *vs* the CNAP method ($n = 1375$, $r = 0.84$). Mean prediction line and 95% confidence intervals for the single observations, with a range of 33 mm Hg, are shown.

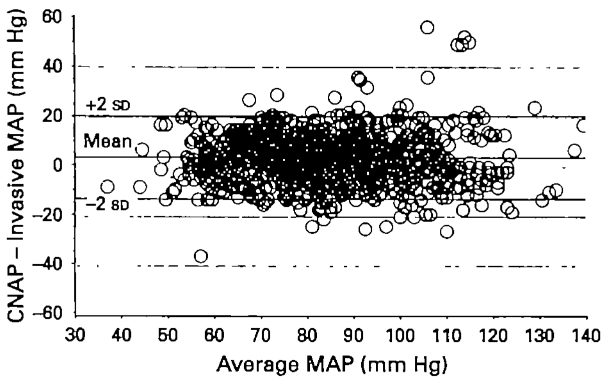

Figure 2 Scatterplot of pressure differences and average pressure for mean arterial pressure (MAP) of the invasive *vs* the CNAP method ($n = 1375$). Mean prediction error (bias) and limits of agreement (2 SD = 16.5 mm Hg) between the two methods are shown, according to Bland and Altman [9].

the invasive and CNAP methods exceeded 54 mm Hg for systolic and 30 mm Hg for diastolic and mean (fig. 2) arterial pressures.

According to individual bias and precision of oscillometry, 14 (11%) of 132 (two criteria, three pressures, 22 patients) values were in the poor category. Globally, intermittent non-invasive monitoring was assessed as good in 16 and as acceptable in six patients. According to each patient's individual bias and precision of tonometry, 50% of systolic values showed poor accuracy, diastolic values were predominantly in the acceptable category and the majority of the mean CNAP values showed good agreement with invasive measurements (table 3). CNAP monitoring was assessed as good in four patients, acceptable in 14 and poor in four of 22 patients. These four patients with inadequate tonometric accuracy could not be distinguished from the other 18 patients in terms of concomitant diseases, inter-arm oscillometric pressure difference (in one case it was among the lowest of all patients), bias and precision of oscillometry, course of the procedure (blood loss, vasoactive drugs) and sensor performance (signal strength, hold-down pressure). Individual inter-arm pressure difference did not correlate with individual oscillometric ($r = 0.13$) or tonometric ($r = 0.25$) prediction errors. A strong correlation between oscillometric and tonometric prediction errors ($r = 0.86$, fig. 3), and a moderate correlation between oscillometric and tonometric absolute errors ($r = 0.48$) were found, but the confidence interval range for both analyses exceeded 15 mm Hg.

The correlation of trends in mean arterial pressure changes with the invasive and CNAP methods ($n = 616$, 28 (16) pairs per patient) during induction of anaesthesia showed a confidence interval range within 20 mm Hg (fig. 4). The difference between the two trends exceeded 10 mm Hg in 47 (7.6%) measurements for systolic pressure in 16 patients, in 14 (2.3%) measurements for diastolic pressure in seven patients and in 27 (4.4%) measurements for mean arterial pressure in 12 patients. These discrepancies occurred predominantly in one of 22 patients.

Discussion

Comparison of non-invasive and invasive arterial pressure methods results inevitably in disagreement [10]. Measurements at different arterial sites are confounded by differences in velocity of pressure wave propagation, unequal impedance, reflections and resonances, in addition to differences in blood

Table 3 Accuracy of tonometric CNAP according to each patient's individual prediction error (bias) and individual absolute error (precision). *Prediction error of ≤ 5 (8) mm Hg was arbitrarily defined as good, 5 (8) < error ≤ 10 (12) mm Hg as acceptable and > 10 (12) mm Hg as poor. Absolute errors of ≤ 10, 11–15 and > 15 mm Hg were defined correspondingly. Data are number of patients (%) for each category (total = six criteria in 22 patients = 132 (100%))

	Prediction error (bias)			Absolute error (precision)

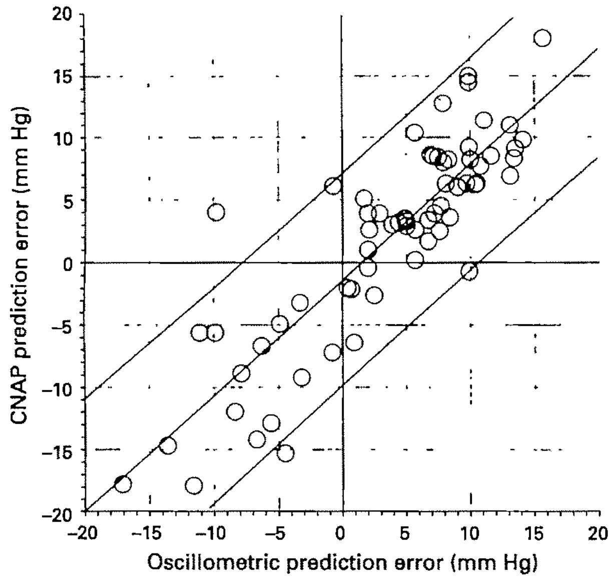

Figure 3 Linear regression analysis with scatterplot of individual oscillometric mean prediction error *vs* individual tonometric (CNAP) mean prediction error for systolic, diastolic and mean arterial pressures ($n = 66$, $r = 0.86$). Mean prediction line and 95% confidence intervals for single observations, with a range of 17 mm Hg, are shown.

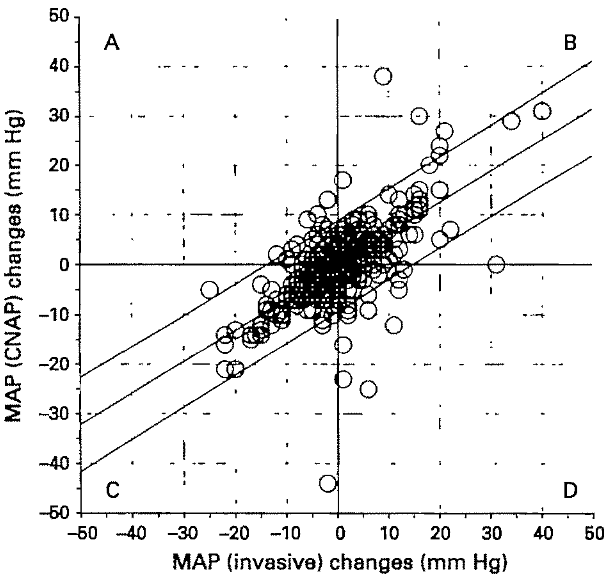

Figure 4 Linear regression analysis with scatterplot of trends in mean arterial pressure (MAP) changes (difference between consecutive measurements) for the invasive and CNAP methods during induction of anaesthesia ($n = 616$, $r = 0.66$). Mean prediction line and 95% confidence intervals for the single observations, with a range within 20 mm Hg, are shown. Data in the B and C quadrants indicate the changes in the two methods in the same direction, and data in the A and D quadrants indicate changes in the opposite direction. In 27 instances (4.4%), predominantly in one of 22 patients, the difference between the two trends exceeded 10 mm Hg.

flow distribution within the arterial system [11]. Furthermore, the basic principles of non-invasive methods share no similarities with, and only superficially resemble, the invasive method [1–6, 10, 12–14]. Although the intra-arterial measurement should theoretically be considered the "gold standard", its precision is dependent on a variety of technical factors [3–7, 10–17]. Also, numerous, poorly controlled patient variables, external influences and cardiocirculatory changes during a dynamic period of anaesthesia and surgery further accentuate the difference between the methods of pressure measurement [3–6, 10–24]. As a rule, pressure values from different methods over time show bidirectional variations in one subject and even more variation when the data are summarized for a group of patients. Different principles of measurement at different arterial sites, and different types of capturing, speed and interpretation of "pressure signals" explain the absence of exclusive or even predominant pressure over- or underestimation by a non-invasive method. The present study indicates that, compared with contralateral invasive radial artery pressure: intermittent oscillometry provides accurate arterial pressure monitoring; CNAP measurements by radial artery tonometry offer a reliable trend indicator of pressure changes during induction of anaesthesia; radial artery tonometry may be considered a valid alternative to invasive pressure measurements, if arterial cannulation is difficult in an awake patient; and accuracy of absolute CNAP values is only moderate and unpredictable, thus it should not replace invasive monitoring in high-risk patients during major surgical procedures.

Other CNAP methods (finger photoplethysmomanometry, dual photometry and pulse wave-delay, brachial artery displacement) have been evaluated previously during anaesthetic and surgical procedures [23–29]. Using various criteria, each method has been shown to be insufficiently accurate for most subjects or for most of the time, or both, and none could be recommended as an alternative to invasive pressure monitoring. Radial artery tonometry had promise as an accurate and simple method of CNAP recording, with narrow limits of agreement and high precision compared with simultaneous invasive measurements [1]. A high level of accuracy was obtained during controlled hypotension but invasive pressure was measured in some cases with a resonance overshoot eliminator, without explaining the reasons and criteria for its use [4]. Such a device has not been tested adequately under clinical conditions [7, 16, 17], and thus cannot be considered a requirement for high-fidelity reproduction of invasive arterial pressure. More recently, Siegel, Brock-Utne and Brodsky analysed a large number of invasive and tonometric CNAP pairs, and reported discrepancies between invasive and CNAP readings [5]. These authors concluded that tonometric CNAP is unable to detect changes in arterial pressure more rapidly than intermittent oscillometry, as accuracy of the tonometric sensor is limited.

For this investigation, a mixed group of high-risk surgical patients, undergoing various non-thoracic surgical procedures, was selected for testing tonometric CNAP. Both non-invasive methods, oscillometry and tonometry, on average underestimated systolic and overestimated diastolic and mean arterial pressures. Compared with intermittent oscillometry, radial artery tonometry exhibited inferior accuracy. By pooling (mixing of all "good and bad" data) and cumulatively analysing all pressure pairs, the coefficients of correlation, mean prediction and percentage errors (2–9 mm Hg and 2–13 %, respectively) of oscillometry and tonometry indicated almost excellent agreement with invasive radial artery pressure. These data alone, however, may not reveal a bidirectional spread and real discrepancy of non-invasive *vs* invasive values. One and 2 SD of the errors, and 95 % confidence intervals revealed some disagreement for all patients (table 2, figs 1, 2). Using the absolute error (precision), a rigorous and overall indicator of accuracy, oscillometry showed a narrow SD range of 1–13 mm Hg for systolic, diastolic and mean arterial pressures. Aware of inherent limitations of a CNAP method, the cumulative tonometric precision with an SD range of 6–20 mm Hg could eventually indicate that radial artery tonometry is a clinically useful technique during anaesthesia and surgery.

Standards for non-invasive arterial pressure measuring devices and specific requirements during anaesthesia are inadequately defined. They are extrapolated from studies in healthy volunteers or non-surgical patients under steady-state conditions. The American National Standard of the Association for the Advancement of Medical Instrumentation recommended that the maximal bias of non-invasive arterial pressure, obtained from at least 85 patients, should not exceed 5 (8) mm Hg from a non-invasive reference method [30]. The British Hypertension Society expanded the procedure for evaluation of arterial pressure measuring devices, and considered the 5 (8)-mm Hg criterion too liberal. A grading system was proposed according to the percentage of readings ⩽ 5, ⩽ 10 and ⩽ 15 mm Hg from a non-invasive reference method [31]. Both standards and procedures are not applicable directly to anaesthesia and the intraoperative environment, and both are too rigorous (albeit theoretically desirable) for evaluation of a non-invasive (*vs* invasive) method of arterial pressure measurements. In this study only the mean pressure value measured oscillometrically (table 2) fulfilled the American standard for minimal bias (SD) [30]. Adopting the British criteria [31], even oscillometric mean arterial pressure (with 50 % of pressure differences within 5 mm Hg and 84 % within 10 mm Hg) would be only partially acceptable.

Another approach to the evaluation of non-invasive techniques was considered necessary. To provide more insight into the individual performance of oscillometry and tonometry, the data were pooled and analysed separately for each patient (instead of pooling the data of all patients according to the amount of error). It is a question of judgment if the good or acceptable criteria (table 3) are individually good or acceptable and if systolic, diastolic and mean arterial pressures are of equal importance (as presumed for this analysis) for monitoring high-risk surgical patients. Oscillometry showed a high level of individual accuracy and intermittent monitoring was found to be good or acceptable in all 22 patients. With CNAP monitoring a relevant number of individual pressures (26 %) failed to fulfil our liberal definition of "acceptable" (bias ⩽ 10 (12) mm Hg, precision ⩽ 15 mm Hg). The criteria appeared to be too rigorous for systolic pressure (inversely, tonometry particularly failed to identify the peak pressure) but diastolic and mean arterial pressures were also found in the poor category in some patients (table 3). The CNAP method was assessed as a failure in four (18 %) of 22 patients. Adapting the same individual bias criteria to the results of Siegel, Brock-Utne and Brodsky [5], radial artery tonometry was good in six, acceptable in eight and poor in two of their 16 patients, similar to the findings of this study. Most probably, it is not the amount of error *per se* but the unknown direction of pressure changes which makes tonometric monitoring unreliable (e.g. 2 SD of ±27.3 for systolic CNAP indicates a range of 95 % confidence intervals or clinical uncertainty of more than 54 mm Hg) and any subsequent decision for intervention difficult and potentially harmful. Obviously, CNAP monitoring should be interrupted more frequently by oscillometric calibration.

It is not clear why tonometric CNAP specifically failed in four of our 22 patients, indicating the general unpredictability of the method during anaesthesia and surgery. The inter-arm pressure difference, obtained before induction of anaesthesia, showed no correlation with oscillometric and tonometric errors obtained later during the procedure. Nevertheless, it should not be dismissed as irrelevant for dynamic comparison over a longer period. The oscillometric and tonometric errors correlated well on average (fig. 3), but the confidence intervals revealed a considerable degree of disagreement between the two methods. It might be assumed that the combination of factors, such as inter-arm pressure difference and a bidirectional relationship of the oscillometric to invasive, oscillometric to tonometric and tonometric to invasive arterial pressure values, individually influenced the accuracy of each non-invasive method.

Haemodilution induces a hypercoagulable state

T. G. RUTTMANN, M. F. M. JAMES AND J. F. VILJOEN

Summary

It has been suggested that haemodilution with saline may increase whole blood coagulation. This study was conducted in two parts. First, we investigated the effect of *in vitro* dilution of blood with saline on whole blood coagulation as measured by the thrombelastogram (TEG). Blood (4 ml) was diluted with 0.9% saline 1 ml and coagulation compared with that of an undiluted control specimen obtained concurrently from the same subject. In the second part, the study was repeated using a modified gelatin colloidal solution (Haemaccel) as the diluent. The *r* time, *k* time and *r*+*k* time were decreased relative to control in both diluent groups. The alpha angles were increased compared with control in both groups while maximum amplitude was unchanged in the Haemaccel diluted group. We conclude that haemodilution *per se* increases the coagulability of whole blood *in vitro*, but that saline haemodilution has a more marked effect on final clot strength. (*Br. J. Anaesth.* 1996; **76**: 412–414)

Key words

Blood, coagulation. Fluids, i.v. Measurement techniques, thrombelastography.

Haemodilution with i.v. fluids decreases the concentration of clotting factors in blood and, intuitively, it would be anticipated that this should induce some degree of impairment of coagulation. There is, however, some evidence that moderate haemodilution with crystalloid solutions may induce a hypercoagulable state [1]. Thrombelastography (TEG) is a technique first developed by Hartert in 1948 [2]. It had little clinical use for many years until it was re-evaluated in 1974 [3]. Subsequently, it was developed further [4] and applied and validated in liver transplantation [5] and cardiac surgery [6].

TEG is essentially a graphic method of displaying the stages in the formation of a whole blood clot (thrombosis) and as such provides a visual pattern of functional clotting status [7]. It has been used to measure coagulation in clinical anaesthesia [8] and we therefore investigated whether or not haemodilution with crystalloid and colloid solutions *in vitro* altered TEG measurements.

Methods

The TEG involves two mechanical parts, a cuvette and a piston. Freshly drawn blood (0.36 ml) is placed in the cuvette which oscillates through 4°45′ at 37 °C. The piston is suspended in the blood sample by a torsion wire which is tranduced to a chart recorder. When no clot exists, the motion of the cuvette does not affect the piston and the chart records a straight line. As strands of fibrin form they attach to the piston and it becomes coupled to the motion of the cuvette, and hence the shearing elasticity of the evolving blood clot is transmitted to the thermal paper.

The TEG pattern is divided into component variables. Reaction time (*r*) is the interval between the start of recording and the time at which the amplitude of the tracing is 2 mm. It reflects the function of the intrinsic clotting pathway. Coagulation time (*r*+*k*) is the time required for the amplitude to reach 20 mm and provides information on not only intrinsic factors but also platelets and fibrinogen, which are also represented by the clot formation rate ($\alpha°$). Maximum amplitude (MA) is the greatest amplitude achieved on the thrombelastogram and is a measure of clot strength and elasticity, again reflecting the properties of platelets and fibrinogen in addition to factor XIII.

The experiment was conducted in two parts. In the first part, blood samples were obtained from 20 healthy, conscious volunteers. Blood was obtained from a free-flowing forearm vein in a 10-ml syringe and separated into two aliquots of 4 ml each in polypropylene plastic tubes. Isotonic saline 1 ml was added to one sample while the other was left undiluted and served as a control. Specimen tubes containing each sample were inverted several times to ensure thorough and similar mixing of blood in each tube. The control samples were inverted in a similar way to those of the diluted group to ensure that, as far a possible, each sample was treated in a similar manner. Specimens from each sample tube (0.360 ml) were then added to the thrombelastograph and simultaneous traces recorded of the normal blood sample and the saline diluted sample. The TEG trace was recorded for 1 h and *r* and *k* times, alpha angle ($\alpha°$), and MA were measured for each sample.

In the second part of the study, the method described above was repeated, except that the test samples were diluted with 1 ml of a modified gelatin colloidal solution (Haemaccel). Again, one sample

was used for testing the effect of haemodilution while the other served as a control.

Data from each diluent group were compared with those obtained from the matched controls in each limb of the experiment and any differences noted were analysed for statistical significance using a paired Student's t test.

Results

The results are shown in tables 1 and 2. In the first part of the study there were statistically significant differences between the saline-treated and untreated samples in all variables measured by the thromb-elastograph. There was a highly significant decrease in r and k times, a highly significant increase in the α angle and a more moderate, although still significant, increase in MA.

In the second part of the study, there were statistically significant differences between the Haemaccel-treated and untreated samples for all variables measured by the thrombelastograph, except for MA, which was not affected by dilution with Haemaccel. There was a highly significant decrease in r and k times, and a highly significant increase in the α angle.

Discussion

In 1950, Tocantins, Carroll and Holburn [1] suggested that saline dilution of blood may render it hypercoagulable. This was supported by an *in vivo* study in rats [9]. In 1980, Janvrin, Davies and Greenhalgh [10] demonstrated an increase in the coagulability of whole blood and an increased incidence of postoperative deep vein thrombosis (DVT) in patients treated with i.v. crystalloid during surgery compared with a group who received no i.v. fluid. An *in vivo* study noted that patients receiving crystalloids demostrated an increase in coagulability, as measured by the TEG [11]. This was not attributed directly to the crystalloid infusions. Indeed, some authors have used saline dilution as a control when investigating the effects of other substances on coagulation [12].

We performed an *in vitro* study on human blood using the TEG to compare the dynamic coagulation profile of 20 % haemodilution with either crystalloid or colloid with that of an undiluted control. We have shown that haemodilution with both solutions causes a decrease in r and k times, reflecting increased intrinsic coagulability and platelet and fibrinogen activity. The α angle, reflecting speed of clot formation, was increased significantly in both test groups. Maximum amplitude showed a moderate increase in the saline group, reflecting an increase in clot strength, again indicating increased fibrin and platelet activity, but this effect was not apparent in the colloid diluted group. Mean k time and $r+k$ time for both test groups were shorter than the minimum values quoted by Mallet and Cox [8], although the other measurements were within their quoted ranges. The changes demonstrated in our study represent an increase of 20–40 % in the initiation of coagulation and the speed of clot formation induced by haemodilution, with a lesser effect on the development of clot strength. This implies that moderate haemodilution with either crystalloid or colloid could cause blood to clot more readily, with minimal effects on the strength of the final clot formed. What the effect of greater or lesser degrees of haemodilution might be has not been examined in this study, but Tocantins, Carroll and Holburn [1] suggested that the effect increases with whole blood dilutions of up to 40 % and that the changes in the speed and character of thrombus formation were as a result of haemodilution rather than the properties of saline itself. By repeating the study using a colloid solution as diluent, we have shown similar decreases in r and k times and an increase in α angles, thereby offering further evidence that the documented changes are brought about by dilution rather than by the nature of the actual diluent itself.

Although the intuitive assumption is that haemodilution would increase bleeding tendencies through dilution of coagulation factors, in reality the reserve capacity of the coagulation system under normal conditions is probably so great that dilution is of no relevance unless large volumes are used. Smaller quantities of infused fluids, however, may well activate the coagulation process in several ways, the mechanisms for which would need to be examined if this *in vitro* observation were to be confirmed *in vivo*.

The mechanism by which haemodilution causes this increase in coagulation is far from clear. Tocantins, Carroll and Holburn [1] showed that the nature of the crystalloid diluent was not important, and that all crystalloid solutions produced similar effects; our own unpublished data confirm this impression. They suggested also that haemodilution disturbed the relationship of thrombin and antithrombin resulting in a relative decrease in the concentration of antithrombin, but Monkhouse [9] considered this explanation insufficient to account for his own observations in rats. By performing an *in vitro* study, we have eliminated extraneous factors such as heparinization, stress response, tissue damage and endothelial injury, all of which could affect coagulation in an *in vivo* study. All of the changes we have been able to demonstrate have thus been a direct consequence of the addition of diluent to normal blood.

Our results confirm that the addition of either saline or Haemaccel to a 20% dilution (equivalent to 1000 ml of an i.v. fluid in an average 70-kg person) *in vitro* renders blood hypercoagulable, affecting aspects of the intrinsic coagulation cascade from initial fibrin formation (decreased *r* time), rapidity of fibrin build-up and cross-linkage (decreased *k* time), and speed of clot formation (increased α angle). Final absolute clot strength (MA) was increased only with saline haemodilution and was unchanged with Haemaccel haemodilution. As the TEG measures only the function of the intrinsic pathway, great care was take not to initiate coagulation via the extrinsic pathway.

An in vivo study using the TEG supported by other estimations of coagulation status is necessary to establish coagulation profiles for a range of surgical patients treated with perioperative i.v. fluid solutions.

Effect of tramadol on depth of anaesthesia

J. F. COETZEE, J. S. MARITZ AND J. C. DU TOIT

Summary

We have studied 51 patients who were anaesthetized with propofol and suxamethonium followed by 0.7% isoflurane and 66% nitrous oxide in oxygen to see if tramadol caused lightening of anaesthesia. A two-channel EEG was recorded and music was played via headphones. Two groups received tramadol 200 and 100 mg i.v. and the third group received saline. Tramadol caused significant, dose-dependent activation of the EEG, evidenced by increased frequencies and decreased amplitudes, but these changes were small and probably unimportant. Derived EEG variables did not approach values known to be associated with near-awakening during isoflurane anaesthesia. No patient moved on skin incision and there were no incidences of free recall. (*Br. J. Anaesth.* 1996; **76**: 415–418)

Key words

Analgesics opioid, tramadol. Anaesthetics volatile, isoflurane. Memory. Anaesthesia, depth.

Tramadol is a relatively new, centrally acting opioid agonist that modifies spinal pain transmission by inhibiting monoamine reuptake. It has been suggested that it is unsuitable for intraoperative use after a 65% incidence of awareness in 20 patients who received tramadol infusions during nitrous oxide anaesthesia supplemented by intermittent administration of low concentrations of enflurane [1]. A recent editorial [2] described the possible risk of awareness associated with intraoperative tramadol administration as a "major drawback" and suggested that "...the risk of intraoperative awareness may represent significant disadvantages for tramadol". The purpose of this study was to determine if single doses of tramadol administered to patients during isoflurane–nitrous oxide anaesthesia resulted in unacceptable lightening of anaesthesia.

Patients and methods

Institutional approval and informed consent were obtained from 51 non-obese, ASA I–II patients, 18–69 yr old, with body weights 42–103 kg. All patients were undergoing orthopaedic and gynaecological surgery. Premedication comprised diazepam 10 mg orally. After attachment of ECG electrodes and preoxygenation, anaesthesia was induced with propofol 1.5–2.0 mg kg^{-1} and the trachea intubated after administration of suxamethonium 1.0 mg kg^{-1}. Patients' lungs were ventilated mechanically, maintaining end-expired carbon dioxide concentration at 4.2–4.8%. Anaesthesia was maintained with 66% nitrous oxide in oxygen and the isoflurane vaporizer was adjusted to maintain an end-expired isoflurane concentration of 0.7% (Siemens Sirecust 734G). No additional doses of neuromuscular blockers were given and recovery from suxamethonium block was confirmed using a nerve stimulator with the stimulating electrodes applied to the skin over the median nerve at the elbow.

The electroencephalogram (EEG) was monitored with a two-channel monitor (Ceregraph, Somchem Ltd, Somerset West, South Africa) using bilateral frontal–ipsilateral mastoid montages via standard silver–silver chloride ECG electrodes. Good electrical contact was ensured by abrading the skin and cleansing with ether. Measured electrode–skin impedances were less than 5 kΩ. The Ceregraph monitor performs power spectral analysis by fast Fourier transform (FFT) on digitized EEG data and stores the derived quantitative descriptors of EEG frequency and amplitude on computer disk: these included 95th percentile power frequency (95%PF), median power frequency (MF) [3] delta ratio (DR) [4], relative delta power (RDP) and root mean square of the EEG signal voltage (RMS).

After maintaining stable end-expired isoflurane concentrations of 0.7% for 20 min, music was played via earphones. Before being placed on the patient, the earphones were applied to an investigator who adjusted the volume control so that the music was heard clearly without experiencing discomfort. The music content was applicable to the patient's cultural background. Patients were allocated randomly to one of three groups (n = 17) who received isotonic saline 4 ml (saline group), tramadol 100 mg (group T100) or tramadol 200 mg (group T200) i.v. The EEG was recorded for another 20 min, after which skin incision was performed. Patient movement within 1 min of incision was recorded. The saline group received morphine 0.2 mg kg^{-1} during operation for postoperative analgesia. A blinded investigator vis-

ited the patients on the first postoperative day to enquire about intraoperative recall, including hearing music.

DATA ANALYSIS

Every 4 s the Ceregraph monitor calculated the quantitative EEG descriptors derived from FFT of the previous 8-s epoch and stored these values in an ASCII file on computer disk. During subsequent offline analysis, values for the various EEG descriptors (95%PF, MF, etc.) were tabulated at the following times: before administration of tramadol or saline (0 min), and at 5, 10, 15 and 20 min. Each value was obtained by calculating the mean of 20 readings from the data in the ASCII file. Preliminary analysis of the tabulated data included descriptive statistics (mean, SD, SEM, median) and tests for normality distribution (Komolgorov–Smirnov test). Plots of the mean values of the various EEG descriptors over time were inspected to determine visually if level shifts occurred after administration of tramadol or saline. Distribution-free methods of analysis were used to test if level shifts were significant as follows.

Level shifts within groups

For each EEG descriptor, four successive differences for each subject were calculated: that is the differences in descriptor values between 0–5, 5–10, 10–15 and 15–20 min. The null hypothesis of no level shift stated that the expected values of these differences were zero. A permutation test, that is a distribution-free version of the Hotelling T^2, was performed, as described by Maritz [5]. The end-result of the test is a statistic whose distribution under the null hypothesis is chi-square with 4 degrees of freedom.

Inter-group comparison of level shifts

For each subject, the value of the EEG descriptor at time zero was subtracted from the mean of the values recorded at 5, 10, 15 and 20 min to give a "mean level shift". One-way analysis of variance was performed between groups on these mean level shift values. In addition, a *t* test was performed on the mean level shift of each group to determine if that shift differed significantly from zero.

Comparison of trend profiles between the groups

The trend profiles of the EEG descriptors obtained at 5, 10, 15 and 20 min were considered. In order to determine if the trend profiles over time differed between groups, the null hypothesis states that the expected values of the differences defined above (5–10, 10–15 and 15–20 min) are identical in the three groups. Pairwise comparisons of group profiles were made via a trivariate, two-sample permutation test, that is a distribution-free version of the Hotelling two-sample T^2 was performed that produces a statistic whose distribution under the null hypothesis is chi-square with 3 degrees of freedom. $P = 0.05$ was regarded as indicating statistical significance.

Table 1 Patient data for the three groups (mean (SD or range))

Group	Age (yr)	Weight (kg)
T100	39 (20–61)	67.6 (13.1)
T200	34 (18–55)	62.8 (15.1)
Saline	40 (19–69)	74.3 (16.1)

Results

Patient data are presented in table 1: ages and weights did not differ significantly between groups. No patient moved on skin incision and there were no episodes of intraoperative recall or recollection of music.

EEG CHANGES WITHIN EACH GROUP AFTER TRAMADOL ADMINISTRATION

There were no significant EEG changes in the saline group (table 2). In contrast, both tramadol groups showed significantly increased EEG frequencies and decreased amplitudes within 5 min of drug administration and these appearances were maintained throughout the measuring period. These changes were expressed by increased MF, DR and 95%PF and decreased RMS and RDP.

INTER-GROUP COMPARISON OF MEAN EEG CHANGES AFTER TRAMADOL ADMINISTRATION

After tramadol administration, mean EEG changes in group T200 were significantly different from those of the saline group but did not differ from those of group T100. In group T100, mean level shifts of all EEG descriptors did not differ significantly from those of the saline and T200 groups.

INTER-GROUP COMPARISON OF TREND PROFILES AFTER TRAMADOL ADMINISTRATION

The post-injection trend profiles of all EEG descriptors were similar in the saline and T200 groups. The 95% PF and left RMS in group T100 differed significantly from those of the two other groups.

Discussion

Administration of tramadol during stable, light nitrous oxide isoflurane anaesthesia resulted in increased EEG frequencies (increased MF, DR and 95%PF, and decreased RDP) and decreased EEG amplitude (decreased RMS). These changes were maintained throughout the 20-min measurement period. Lightening of anaesthesia usually leads to increasing EEG frequencies of lower amplitude and two of the descriptors used in this study have been shown to indicate near-awakening during isoflurane–nitrous oxide anaesthesia [3, 4]. Schwilden and Stoeckel [3] concluded that there was an increased probability of patient awareness if the MF exceeded 5–6 Hz. Long and colleagues [4] found that near-

Table 2 Mean (SD) values for the various univariate EEG descriptors of the three groups obtained at different times. Stage 0 = Before injection, stages 5, 10, 15 and 20 = 5, 10, 15 and 20 min after injection, respectively. There were 17 subjects in each group. Results from the right side only are presented, because left-sided values were similar. 95% PF = 95th percentile power frequency, MF = median power frequency, RDP = relative delta power, DR = delta ratio, RMS = root mean square of the EEG signal voltage

awakening occurred at DR values of approximately 2. The EEG changes caused by administration of tramadol in our patients, although statistically significant, were subtle and small, the values not approaching those that have been found to occur during near-awakening. The EEG changes may therefore be clinically insignificant.

It is possible that the effects of tramadol may be dose-dependent, as indicated by the tendency towards different post-injection profiles in group T100 (95%PF and RMS) and by the observation that the mean level shifts of group T100 were not different from the two other groups, whereas the mean level shift in group T200 differed significantly from that of the saline group.

All patients in the study remained sufficiently anaesthetized so that they did not move during skin incision and the initial stages of the operative procedures. Furthermore, there was no evidence of intraoperative conscious recall, either spontaneously or on enquiry. It may be argued that inability to recall music and lack of movement on surgical stimulation are insensitive indicators of awareness during anaesthesia. Lehmann, Horrichs and Hoeckle [1] found free recall of conscious awareness by playing music to their patients and similarly we endeavoured to seek *conscious* awareness without amnesia in our patients. This should be distinguished from the more subtle manifestations of wakefulness during anaesthesia, namely conscious awareness with amnesia and subconscious awareness with amnesia [6], which would have required detection by different methods, such as the isolated forearm technique [7, 8] or cued word lists [9].

Movement on skin incision is not concerned directly with consciousness but is a generally accepted sign of inadequate anaesthesia. If the groups who had received tramadol had demonstrated a greater incidence of movement on skin incision than the saline group, this may have suggested that tramadol antagonized anaesthesia. The absence of this sign was also an important monitor of the ethics of the study, because a high incidence of movement on skin incision in the tramadol groups may have necessitated termination of the study.

The three methods of monitoring depth of anaesthesia, that is minor EEG changes, lack of movement on skin incision and absence of spontaneous conscious recall, suggest that tramadol, in doses up to 200 mg i.v., given to adults during stable, light isoflurane–nitrous oxide anaesthesia, did not lead to clinically significant lightening of anaesthesia in this study.

LABORATORY INVESTIGATIONS

Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function

S. DALMAS, S. C. U. MARSCH, D. M. PHILBIN, D. J. GAVAGHAN, W. A. RYDER AND P. FOËX

Summary

We have determined the effects of alterations in preload on ischaemia-induced diastolic dysfunction in anaesthetized beagles instrumented to measure left ventricular pressure and regional dimensions. Low-flow regional ischaemia decreased peak lengthening rates in ischaemic (mean −26 (SEM 6) mm s^{-1}, $P < 0.01$) and non-ischaemic (−8.6 (3.4) mm s^{-1}, $P < 0.05$) myocardium. Peak lengthening rates and the time constant of isovolumic relaxation (τ) were not affected by alterations in preload. Absolute values of τ failed to distinguish between ischaemia and control. The ischaemia-induced decrease in peak negative dP/dt was preload dependent and caused mainly by a concomitant decrease in peak left ventricular pressure. We conclude that indices derived from segmental lengthening are sensitive to ischaemia and insensitive to preload, in contrast with indices derived from left ventricular pressure. It remains to be determined if monitoring of early segmental lengthening will improve detection and assessment of perioperative myocardial ischaemia. (*Br. J. Anaesth.* 1996; **76**: 419–427)

Key words

Heart, ischaemia. Heart, myocardial function. Heart, ventricles. Blood, volume. Dog.

Myocardial ischaemia has profound effects on both systolic and diastolic cardiac performance. There is, however, clinical and experimental evidence that diastolic function is particularly sensitive to myocardial ischaemia. Dodek, Kassebaum and Bristow reported repeated episodes of pulmonary oedema in patients with a normal heart size [1]. Moreover, despite the absence of systolic dysfunction, diastolic dysfunction may occur in a high proportion of patients with coronary artery disease, both at rest and during pacing-induced ischaemia [2, 3]. In experimental models of myocardial ischaemia, diastolic dysfunction precedes contractile dysfunction [4] or may even be the predominant, if not only, sequel of ischaemia [5].

Given the impact of myocardial ischaemia on cardiac morbidity and mortality [6], early detection and rigorous treatment of ischaemic episodes might lead to improvement in perioperative outcome. Recent advances in technology allow non-invasive assessment of diastolic function using echocardiography (segmental re-extension), pulsed wave Doppler echocardiography (filling pattern), or both. However, even mild alterations in preload (change in end-diastolic pressure ±4–5 mm Hg) were reported to mimic or mask diastolic dysfunction as derived from the mitral inflow velocity profile [7, 8]. As rapid and substantial changes in preload cannot be excluded in the perioperative period, preload-induced modifications have to be taken into account in order to interpret indices of diastolic function. It is currently not known if and how alterations in preload affect regional segmental lengthening or interact with ischaemia-induced alterations in the pattern of left ventricular relaxation and lengthening.

The aim of the present investigation was to determine the effects and interactions of alterations in circulating blood volume on global and regional indices of left ventricular diastolic function in the absence and presence of myocardial ischaemia.

Materials and methods

EXPERIMENTAL PREPARATION

The study conformed to the United Kingdom Animals Act (Scientific Procedures, 1986, Home Office licence No. PPL 30/00887). Nine beagles of both sexes (mean weight 14.4 (SEM 1.2) kg) were premedicated with morphine 1.0 mg kg^{-1} i.m. Anaesthesia was induced with sodium thiopentone 10 mg kg^{-1} i.v. and maintained with 1.0–1.5% halothane and nitrous oxide in oxygen ($FI_{O_2} = 0.4$).

Correspondence to P.F.

Inspiratory and end-tidal gas concentrations were measured continuously (gas analyser M1025A, Hewlett-Packard, Bracknell, UK) and mechanical ventilation was adjusted to maintain the end-tidal carbon dioxide concentration at 4.5–5.5%. Mid-oesophageal temperature was maintained at 36–37 °C using a Servo-controlled heating element incorporated into the operating table. Ringer's lactate 5 ml kg^{-1} h^{-1} was infused continuously through an i.v. cannula inserted in the left hind leg. A left thoracotomy was performed, the fifth and sixth ribs excised, and the heart isolated and suspended in a pericardial cradle.

INSTRUMENTATION

Instrumentation included limb lead II of the electrocardiogram (subcutaneous electrodes); an 8-French gauge fluid-filled cannula in the left common carotid artery for withdrawal of blood; a 7-French gauge pulmonary artery catheter (Swan–Ganz, American Edwards Laboratories, Anasco, Puerto Rico) inserted into the pulmonary artery via the left jugular vein; a micromanometer-tipped 8-French gauge catheter (Millar, Houston, TX, USA) inserted into the aortic arch via the right femoral artery for measurement of systemic pressures; a second micromanometer-tipped 8-French gauge catheter in the left ventricle (inserted via a stab wound in the apical dimple) for measurement of ventricular pressures; Doppler flow probes (Triton, San Diego, CA, USA) placed around the proximal ascending aorta and the left anterior descending coronary artery (LAD) distal to its first diagonal branch; a snare positioned distal to the flow probe on the LAD and attached to a micrometer controlled occluder; and two pairs of piezoelectric crystals (5 MHz, 2 mm in diameter, Triton Technologies, San Diego, CA, USA) implanted approximately 1 cm apart in a circumferential plane via small epicardial stab wounds in the subendocardium of a near apical (ischaemic area, supplied by the LAD) and a basal area (non-ischaemic area, supplied by the left circumflex coronary artery) for ultrasonic measurement of segmental length.

After completion of surgery and instrumentation, arterial blood-gas analysis was performed, and ventilation adjusted if necessary. Halothane was discontinued, a bolus dose of fentanyl 100 μg kg^{-1} administered, and a continuous infusion of fentanyl 2 μg kg^{-1} min^{-1} commenced and maintained throughout the study. After a stabilization period of 1 h, 200 ml of arterial blood (four aliquots with 50 ml each) was obtained and kept at body temperature in a heated water bath while 200 ml of Dextran (5%, average molecular weight 70000) was infused into the femoral vein. A period of 30 min was then allowed for the haemodynamic state to stabilize before the circulating blood volume was increased stepwise: after recording baseline haemodynamic variables, 50 ml of blood was infused in the femoral vein over 30 s and further haemodynamic variables were recorded 1 min after completion of the infusion. Infusion of the following aliquot was started 3 min after completion of the previous infusion. This was repeated three times (total volume infused 200 ml). The 200 ml of blood was then withdrawn over a period of 15 min. After a stabilization period of 10 min, the snare around the LAD was tightened until the onset of obvious systolic lengthening, as assessed by the apical circumferential length–ventricular pressure loop (tilt of the loop to the right) which was displayed continuously on an oscilloscope. After completion of baseline recordings 10 min after the onset of ischaemia, the circulating blood volume was increased in a manner identical to that described for the control stage.

DATA COLLECTION AND ANALYSIS

ECG, pressure (aortic, left ventricular, airway), flow (aortic, coronary) and myocardial segment lengths signals were converted using an analogue-digital converter (AT-MIO-16, National Instruments Corporation, Austin, TX, USA) and displayed continuously on the screen of an IBM AT personal computer using the real-time mode software designed in this department. After every volume modification, data were recorded at a sampling frequency of 500 Hz during a period of three respiratory cycles and stored on the hard disk. Cardiac output was measured in triplicate by thermodilution (COM-2 Baxter, Santa Ana, USA) before the start of volume modification at each stage.

At the end of the experiment, the animals were killed with an overdose of halothane. A fine catheter was inserted into the LAD and 5 ml of Evans blue dye injected. In all animals necropsy confirmed the subendocardial placement of the crystals within or outside the blue stained region.

Data analysis was performed on an IBM AT personal computer using the play-back mode of the above-mentioned software. To minimize the respiratory effects on haemodynamic variables, end-expiratory data were used for analysis. The first derivative of left ventricular pressure (dP/dt) was obtained by electronic differentiation. End-diastole was defined as the first upward (positive) deflection of the left ventricular dP/dt signal. End-systole was defined as the first return to zero of the aortic flow signal.

REGIONAL WALL MOTION

Length measures were normalized to an initial end-diastolic length of 10 mm. The following variables were used to quantify regional wall motion: end-diastolic length (EDL); end-systolic length (ESL); minimum diastolic length (L_{min}); and maximum length during systole (L_{max}). Total shortening was defined as $EDL - L_{min}$ (mm). Systolic shortening was defined as $EDL - ESL$ and expressed as a percentage of total shortening. Post-systolic shortening was defined as $ESL - L_{min}$ and expressed as a percentage of total shortening. Thus systolic and post-systolic shortening together = 100%. Systolic lengthening was defined as $L_{max} - EDL$ and expressed as a percentage of EDL.

TIME CONSTANT OF ISOVOLUMIC RELAXATION

The time constant of isovolumic relaxation (τ) was obtained by the method described originally by Weiss, Frederiksen and Weisfeldt [9]: the slope of the natural logarithm of left ventricular pressure (P) *vs* time (t) relation (from peak $-\mathrm{d}P/\mathrm{d}t$ to the ventricular pressure that exceeds end-diastolic pressure by 10 mm Hg) was obtained by a least squares linear regression and τ was defined as the negative inverse of that slope:

$$\ln P = At + c$$
$$\tau = 1/-A$$

where A = slope and c = intercept of the $\ln P$ *vs* t relation.

The rationale for the use of a method which assumes an asymptotical pressure–stress decay to zero rather than an asymptotical decay to an unknown baseline pressure–stress was that values yielded by the former approach are much closer to the "true" time constant of isovolumic relaxation obtained by preventing filling and thus allowing the ventricle to relax completely [10].

LENGTHENING

The base value of lengthening was defined as L_{min} and the interval between the preceding R wave of the ECG and L_{min} was defined as the R–L_{min} interval. The peak lengthening rate (PLR) was obtained by electronic differentiation and the interval between the preceding R wave of the ECG and PLR was defined as the R–PLR interval. Relaxation time (RT) was defined as the interval between peak negative $\mathrm{d}P/\mathrm{d}t$ and the time when lengthening rate had decreased to 50% of PLR [11]. The end of the rapid lengthening phase was defined as the time when the lengthening rate had decreased to less than 2 mm s^{-1} (normalized units and hence equal to a lengthening rate of 0.2 (end-diastolic length) per second). The segmental length at this time was termed L_{ms} (length at minimum speed). Thus L_{ms} divides segmental re-extension into a rapid and slow portion [12]. The fraction of lengthening occurring during the rapid lengthening period (RL%) was expressed as a percentage of total lengthening:

$$\mathrm{RL\%} = [(L_{ms} - L_{min})/(\mathrm{EDL} - L_{min})] \times 100$$

STATISTICS

All values are expressed as mean (SEM). Data were analysed on an IBM AT personal computer using SPSS, a commercially available statistical analysis program (SPSS for Windows, Release 5, SPSS Inc, Chicago, IL, USA). $P < 0.05$ was considered to represent statistical significance. Means of the two different stages were compared by a paired Student's *t* test. Combined effects of volume loading and the experimental interventions (control, ischaemia) on global and regional haemodynamics were assessed using GLIM (generalized linear interactive modelling, version 3.77 update 2, The Royal Statistical Society, London, UK). Interactive modelling was performed by forward stepwise multiple linear regression ($P < 0.05$ for inclusion or exclusion of a variable as obtained by F-test) for the following equation:

$$\text{Variable} = \text{constant} + V \times (\text{infused volume in ml}) + S_i(\text{ischaemia}) + I_i(\text{interaction volume/ischaemia})$$

where V, S, and I = maximum likelihood variable estimates. The constant and the term S are expressed in the units of the variable concerned, while the terms V and I are expressed in units of the variable concerned per millilitre volume infused. A significant term for V indicates a correlation between volume loading and dependent variable; a significant term for S indicates a parallel shift of the regression line compared with baseline; a significant term for I indicates a difference in slope. For all variables tested, models assuming a liner relationship between dependent variable and volume yielded a better fit (as indicated by residual sum of squares) than models assuming a log-linear relationship.

Results

GLOBAL FUNCTION

Infusion of 200 ml of blood increased left ventricular end-diastolic pressure from 6.7 (0.6) to 11.3 (0.9) mm Hg during control experiments and from 7.7 (0.8) to 13.2 (1.6) mm Hg during ischaemia. The combined effects of myocardial ischaemia and volume loading on global cardiac function are shown in table 1.

EFFECTS OF MYOCARDIAL ISCHAEMIA ON REGIONAL WALL MOTION

During ischaemia, coronary blood flow velocity in the LAD was reduced to 16 (4)% of control. In the ischaemic area (LAD supply) this resulted in a marked reduction in total shortening; systolic shortening was replaced almost completely by haemodynamically ineffective post-systolic shortening (table 2). Myocardial ischaemia did not affect regional wall motion in the remote non-ischaemic area.

PEAK NEGATIVE $\mathrm{d}P/\mathrm{d}t$

Combined effects of ischaemia and alterations in circulating blood volume on peak negative $\mathrm{d}P/\mathrm{d}t$ ($-\mathrm{d}P/\mathrm{d}t$) are shown in figure 1. Note the significant and independent effects of both volume loading and myocardial ischaemia. Figure 2 demonstrates that a highly significant correlation ($r > 0.95$, $P < 0.001$) between peak negative $\mathrm{d}P/\mathrm{d}t$ and peak left ventricular pressure (LVP) was preserved during myocardial ischaemia. Assessing the combined effects of ischaemia, peak LVP and alterations in circulating blood volume on $-\mathrm{d}P/\mathrm{d}t$, general linear interactive modelling yielded the following variable estimates (SEM):

$$-\mathrm{d}P/\mathrm{d}t\,(\text{mm Hg s}^{-1}) = -105\,(321) + [24\,(2) \times \text{LVP}] - [1.5\,(0.7) \times \text{volume}] - [267\,(102)\text{ if ischaemic}].$$

Table 1 Effect of volume loading on global haemodynamics (mean (SEM)) during control and myocardial ischaemia. For the sake of clarity only three of the five stages of the loading procedure are shown. Variable estimates (SEM) were obtained using general linear interactive modelling (see text). None of the interactive terms (not displayed) proved to be significant at the 0.05 level for any variable. $*P < 0.05$, $**P < 0.01$. Example: the model predicts systolic arterial pressure at the 200 ml level during ischaemia as follows: 151 mm Hg + 200 (9×10^{-2}) mm Hg − 17 mm Hg = 152 mm Hg

		Volume infused (ml)			Variable estimates		
		0	100	200	Constant	Volume ($\times 10^{-2}$)	Ischaemia
Heart rate (beat min^{-1})	Control	121 (8)	118 (8)	123 (6)	125 (3)	0	0
	Ischaemia	132 (12)	129 (9)	127 (8)			
Systolic arterial pressure (mm Hg)	Control	146 (8)	161 (9)	168 (9)	151 (5)	9 (4)*	−17 (5)**
	Ischaemia	134 (10)	143 (8)	150 (7)			
Diastolic arterial pressure (mm Hg)	Control	92 (5)	106 (6)	111 (6)	97 (4)	7 (3)**	0
	Ischaemia	93 (8)	100 (7)	105 (6)			
LV end-diastolic pressure (mm Hg)	Control	6.7 (0.6)	8.7 (0.6)	11.3 (0.9)	7.0 (0.6)	2.3 (0.5)**	1.4 (0.6)*
	Ischaemia	7.7 (0.8)	10.5 (1.2)	13.2 (1.6)			
Peak positive d*P*/d*t* (mm Hg s^{-1})	Control	3289 (396)	3274 (372)	3399 (353)	3280 (132)	0	−638 (187)**
	Ischaemia	2527 (245)	2663 (217)	2778 (252)			

Peak LVP was the single most important predictor ($F_{(1,88)} = 164$) and accounted for 66% of the overall variance (volume 4%, ischaemia 2%, residual variance 29%).

TIME CONSTANT OF ISOVOLUMIC RELAXATION

The time constant of isovolumic relaxation (τ) increased consistently during ischaemia which resulted in a significant difference between control and ischaemia when assessed by paired comparison. However, when the combined effects of ischaemia and alterations in circulating blood volume on τ were assessed by general linear interactive modelling, the term "ischaemia" failed to reach statistical significance. Thus absolute values for τ could not distinguish between control and ischaemia. Only when values for τ were normalized to an initial value of 100% did a significant effect of myocardial ischaemia become apparent (variable estimate + 6.5 (1.5)%, $P \leqslant 0.01$). Alterations in circulating blood volume had no significant effect on τ (for both absolute values and percentage changes) during both baseline and ischaemia (fig. 3).

REGIONAL LENGTHENING

In the control stage, there was a significant inter-regional difference in peak lengthening rate (apex 68 (11) mm s^{-1}; base 45 (5) mm s^{-1}; $P < 0.05$), relaxation time (apex 123 (6) ms; base 88 (4) ms; $P < 0.05$) and R–PLR interval (apex 325 (14) ms; base 290 (11) ms; $P < 0.05$).

The combined effects of ischaemia and volume loading on regional indices in ischaemic and non-ischaemic myocardium are shown in tables 3 and 4. Note that despite a significant increase in the $R–L_{mm}$ interval in the ischaemic area, the interval between R wave and peak lengthening rate (R–PLR) remained unchanged. Likewise, the decrease in $R–L_{mm}$ of the remote non-ischaemic area was accompanied by an unchanged R–PLR interval. Myocardial ischaemia was associated with a decrease in PLR in both ischaemic and remote non-ischaemic myocardium and in neither area did volume loading modify PLR during the control and ischaemic stages.

Discussion

Myocardial ischaemia affected the lengthening pattern in both ischaemic and remote non-ischaemic myocardium: in ischaemic myocardium the beginning of the lengthening period was delayed and PLR was reduced markedly while in remote non-ischaemic myocardium, lengthening started earlier and there was a moderate decrease in PLR. These changes were not modified by alterations in circulating blood volume. Moreover, alterations in circulating blood volume did not affect the time constant of isovolumic relaxation, both in the presence or absence of myocardial ischaemia. A highly significant correlation between peak negative d*P*/d*t* and peak LVP was preserved during the ischaemic period and peak LVP was the most important predictor of peak negative d*P*/d*t*.

GLOBAL DIASTOLIC FUNCTION

A decrease in peak negative d*P*/d*t* and an increase in both time constant of isovolumic relaxation (τ) and end-diastolic pressure are well established features of myocardial ischaemia both in humans and in a variety of experimental models [3–5, 13, 14].

PEAK NEGATIVE d*P*/d*t* (−d*P*/d*t*)

In the absence of myocardial ischaemia, −d*P*/d*t* is influenced by left ventricular contractility, end-systolic volume and mean aortic pressure [15, 16]. Consistent with the present findings, Gaasch and colleagues observed an increase in −d*P*/d*t* when an increase in preload, caused by volume expansion, was accompanied by an increase in afterload [17]. In contrast, an isolated increase in preload (increase in afterload prevented by aortic unloading) resulted in unchanged values for −d*P*/d*t*. Bahler and Martin observed a decrease in −d*P*/d*t*, associated with a decrease in peak systolic LVP, following a decrease

Table 2 Effect of volume loading on regional wall motion in ischaemic myocardium (mean (SEM)) during control and myocardial ischaemia. For the sake of clarity only three of the five stages of the loading procedure are shown. Systolic shortening and post-systolic shortening are expressed as a percentage of total shortening (TS) and add up to 100%. Variable estimates (SEM) were obtained using general linear interactive modelling (see text). The interactive term ($V \times I$) indicates an effect of volume loading during the ischaemic state. $^{*}P < 0.05$, $^{**}P < 0.01$

		Volume infused (ml)			Variable estimates			
		0	100	200	Constant	Volume ($\times 10^{-2}$)	Ischaemia	Interaction ($V \times I$)
Systolic lengthening (%)	Control	0	0	0	0 (0.3)	0	14.1 (4)**	−3.2 (1)*
	Ischaemia	14.7 (1.7)	10.9 (1.9)	7.9 (1.3)				
Total shortening (mm)	Control	3.06 (0.36)	3.02 (0.34)	2.99 (0.25)	3.03 (0.13)	0	−1.540 (45)**	0
	Ischaemia	1.34 (0.24)	1.48 (0.23)	1.61 (0.5)				
Systolic shortening (% of TS)	Control	98 (2)	97 (2)	98 (2)	97 (1)	0	−94 (5)	0

Post-systolic shortening (% of TS)	Control	2 (2)	3 (2)	2 (2)	2 (1)	0	95 (6)**	0
	Ischaemia	97 (1)	97 (1)	97 (1)				

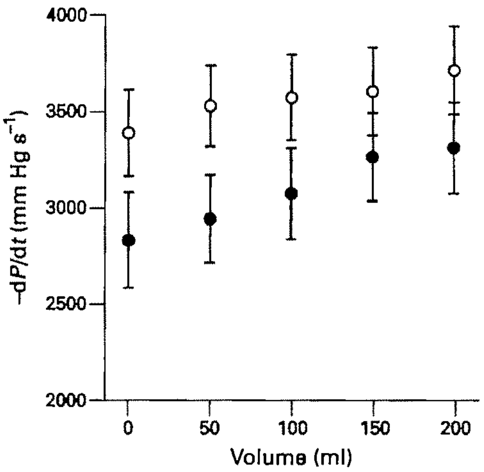

Figure 1 Combined effects of myocardial ischaemia and alterations in circulating blood volume on peak negative dP/dt ($-dP/dt$) during control (○) and myocardial ischaemia (●) (mean, SEM). Both ischaemia and volume loading had a significant and independent effect on $-dP/dt$. Variable estimates as obtained from general linear interactive modelling (GLIM) predicted: dP/dt (mm Hg s^{-1}) as 3452 (132) +(2.0 (0.9) × volume in ml) − (612 (132) if ischaemic) (see text for further explanation).

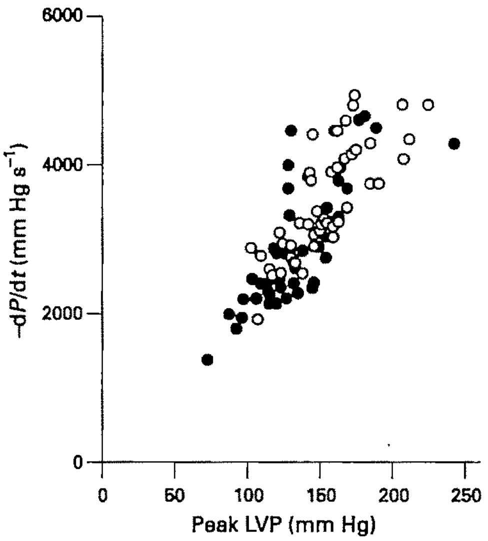

Figure 2 Correlation between peak negative dP/dt ($-dP/dt$) and peak left ventricular pressure (LVP) during control (○) and regional myocardial ischaemia (●).

in preload induced by caval occlusion [11]. In addition to confirming their finding of a highly significant correlation between $-dP/dt$ and peak LVP in normally perfused myocardium, our study has demonstrated that this correlation was well preserved during myocardial ischaemia. Using interactive statistical modelling we demonstrated that peak LVP was the most important predictor of $-dP/dt$. Thus the decrease in peak negative dP/dt, associated with myocardial ischaemia, appears to reflect mainly an ischaemia-induced decrease in developed pressure rather than direct impairment of early relaxation.

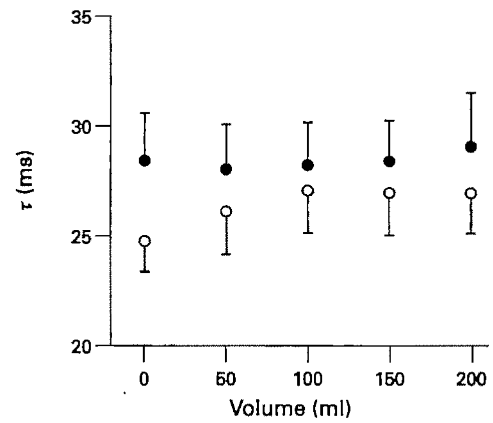

Figure 3 Combined effects of myocardial ischaemia and alterations in circulating blood volume on the time constant of isovolumic relaxation (τ) (mean, SEM). Although τ increased consistently during myocardial ischaemia, absolute values did not distinguish between control (○) and ischaemia (●), as indicated by the overlapping error bars.

TIME CONSTANT OF ISOVOLUMIC RELAXATION

Although a consistent increase in the time constant of isovolumic relaxation (τ) occurred, absolute values for τ failed to distinguish between control and myocardial ischaemia. Only when values for τ were normalized to an initial value of 100% could generalized linear interactive modelling detect a significant effect of myocardial ischaemia. These statistical findings may be explained by the comparatively small number of animals in our study and the large inter-individual variance of τ. A similar inter-individual variance of τ was found in a previous clinical investigation which failed to demonstrate a significant difference in τ between patients with and without coronary artery disease [8]. Although load-dependence of τ has been reported repeatedly [17–20] there is controversy as to whether alterations in preload affect τ: Raff and Glantz found that volume loading increased τ and that the end-diastolic pressure was an independent predictor of τ, as assessed by multiple linear regression analysis [19]. In contrast, Karliner and colleagues reported that volume loading had no effect on τ [18]. Moreover, Bahler and Martin found that τ remained unchanged after a reduction in preload caused by caval occlusion [11]. In addition, Gaasch and colleagues [17, 20] demonstrated that volume loading did not affect τ provided that left ventricular systolic pressure

Table 3 Effect of volume loading on segmental lengthening in ischaemic myocardium (mean (SEM)) during control and myocardial ischaemia. For the sake of clarity only three of the five stages of the loading procedure are shown. Variable estimates (SEM) were obtained using general linear interactive modelling (see text). None of the interactive terms (not displayed) proved to be significant at the 0.05 level for any variable. R–PLR = Interval between preceding R wave of the ECG and the peak lengthening rate, $R\text{–}L_{min}$ = interval between the preceding R wave of the ECG and the minimum segment length, RL = fraction of total lengthening during the rapid lengthening phase. $^{**}P < 0.01$

remained unchanged (increase in afterload prevented by aortic unloading), whereas an increase in τ was observed when volume loading increased both end-diastolic and peak systolic left ventricular pressure. However, despite an increase in peak systolic pressure in the present investigation, alterations in circulating blood volume did not affect τ. The load-dependence, if any, of the time constant of isovolumic relaxation during myocardial ischaemia has not been investigated thoroughly. Our results demonstrated that modest alterations in preload had no significant effect on the ischaemia-induced increase in τ.

REGIONAL DIFFERENCES IN DIASTOLIC FUNCTION

In agreement with a previous report [12], the present investigation demonstrated that baseline PLR was higher in the apex than in the base. In addition, we found a significantly shorter relaxation time at the base compared with the apex. Similarly, an isolated increase in left atrial pressure after mitral valve opening has been found to be associated with a significantly greater effect on the segmental PLR in apical compared with mid-wall or posterior myocardium [21]. Taken together, findings from the present and previous [12, 21] investigations indicate that inter-regional differences in segmental wall motion are not confined solely to the ejection period [22].

In the absence of myocardial ischaemia, alterations in circulating blood volume had no effect on PLR or on the percentage of lengthening during the rapid phase in both apical and basal myocardium. Similar findings were reported by Lew and LeWinter [12]. In contrast, Bahler and Martin demonstrated that acute reductions in preload (caval occlusion) were associated with proportional reductions in the peak rate of early diastolic re-extension and in the relaxation time measured in the internal short axis (midway between the apex and base) [11]. In addition, Ishida and colleagues found a 20% increase in peak transmitral flow rate after volume loading had increased end-diastolic pressure over a range similar to that of the present study (9.4–13.3 mm Hg) [23]. However, these apparently contradictory findings may simply result from assessment of regional function in a circumferential plane in the present study. Assuming that at the site of the crystals, the left ventricle may be regarded as a cylindrical annulus, changes in the area of the cavity and hence intra-cavitary volume (V), are proportional to the square of the measured subendocardial circumferential length ($V = kL^2$). Thus the change in volume ($\mathrm{d}V$) which corresponds to any change in length ($\mathrm{d}L$) depends on the instantaneous length ($\mathrm{d}V/\mathrm{d}t = 2kL \times \mathrm{d}L/\mathrm{d}t$). Accordingly, in the presence of an unchanged peak segmental lengthening rate the peak rate of volume change is proportional to $2L$. Thus the 10% increase in segmental length, brought about by volume modification under control conditions, is compatible with a 20% increase in $\mathrm{d}V/\mathrm{d}t$ found by Ishida and colleagues [23] in their study involving similar modification of left ventricular end-diastolic pressure.

DIASTOLIC FUNCTION OF ISCHAEMIC MYOCARDIUM

A decrease in the peak rate of regional wall thinning or PLR, or both, was demonstrated in an area subjected to exercise-induced ischaemia, pacing-induced ischaemia or flow deprivation as a result of coronary occlusion [24–27]. Whereas the effect of alterations in preload on re-extension in normally perfused myocardium has been investigated [11, 12], the present study is the first to demonstrate that moderate alterations in preload have no significant effect on ischaemia-induced changes in the pattern of segmental lengthening in ischaemic myocardium.

In the ischaemic area, myocardial ischaemia was associated with a reduction in the fraction of lengthening during the rapid phase. This finding, which was not influenced significantly by alterations in circulating blood volume, is compatible with a decrease in the early-to-late peak transmitral flow velocity (E-to-A ratio) which is found commonly in patients with coronary artery disease [28]. In contrast, the relaxation time [11] proved to be insensitive to both ischaemia and volume modification.

DIASTOLIC FUNCTION OF REMOTE NON-ISCHAEMIC MYOCARDIUM

Our results are in agreement with the findings of an earlier study from our laboratory that demonstrated an earlier onset and a decrease in maximal lengthening rate of non-ischaemic segments during coronary occlusions in anaesthetized dogs [29]. In contrast, Nonogi and colleagues demonstrated an increase in PLR of the non-ischaemic area during exercise-induced ischaemia in patients with coronary artery disease [30]. No such increase in PLR was found by Nakamura and colleagues during pacing-induced angina in patients with coronary artery disease [26]. In the anaesthetized pig, Takahashi, Levine and Grossman found a significant increase in PLR in non-ischaemic myocardium during pacing-induced ischaemia but not during coronary occlusions [27]. Their findings suggest that an increase in heart rate, caused by pacing or exercise, may have an independent effect on PLR in remote non-ischaemic myocardium. Whereas the effects of preload on systolic function in remote non-ischaemic myocardium have been investigated previously [31] the present study is the first to demonstrate the combined effects of myocardial ischaemia and alterations in preload on the regional lengthening pattern of remote non-ischaemic myocardium.

CRITIQUE OF METHODOLOGY

The present investigations were performed in acutely instrumented animals with an open chest and an open pericardium. Therefore, the effects of myocardial ischaemia occurred in the presence of, and may have been modified by, an acute surgical preparation. Our findings were obtained in a model of low-flow ischaemia and, therefore, cannot necessarily be extrapolated to demand-induced ischaemia. At present regional myocardial ischaemia can neither qualitatively nor quantitatively be defined using indices of diastolic (dys)function; we therefore defined ischaemia using a systolic wall motion abnormality (systolic lengthening) and ensured the presence of severe myocardial ischaemia during the whole loading procedure. However, as the extent of systolic dysfunction (segmental shortening) was more marked than that of diastolic dysfunction (segmental shortening), further studies are necessary to determine if and how our findings may be modified in the settings of mild or moderate ischaemia. In agreement with a previous study from our laboratory [32], we found that systolic lengthening was related inversely to preload. As it is unlikely that our loading procedure altered the passive properties of severely ischaemic myocardium, our observation may relate to the combined effects of preload and stretch caused by the shortening of non-ischaemic segments during the period of isovolumic contraction: in the presence of a low preload the ischaemic segment is situated on the flat part of its pressure–length relation and further lengthening is easily accomplished during isovolumic contraction. In contrast, further lengthening is difficult to achieve when a high preload has already placed the ischaemic segment on the steep part of its pressure–length relation.

The regional pattern of lengthening was obtained from sonomicrometers implanted in a circumferential plane. Depending on the ventricular region, uniaxial measurements may underestimate the extent of both shortening and re-extension [33]. However, shortening and lengthening in the apical region of the anterior wall occurs predominantly in a circumferential plane [33]. To the best of our knowledge, the preferential plane(s) of regional deformations in basal areas of the anterior wall have not been described and, therefore, inter-regional comparisons have to be interpreted with caution.

General linear interactive modelling was used to assess the combined effects of myocardial ischaemia and alterations in circulating blood volume on dependent variables. In addition to identifying significant terms and interactions, this statistical method yields variable estimates which allow quantitative assessment of independent predictors. For example, the parameter estimates for the combined effects of ischaemia, peak ventricular pressure, and volume on $-dP/dt$ (see results) indicate that a similar decrease in $-dP/dt$ may be achieved by imposing myocardial ischaemia (-267 mm Hg s^{-1}) or by lowering the peak ventricular pressure by 11 mm Hg (-11×24 mm Hg s^{-1}).

IMPLICATIONS

As left ventricular diastolic function appears to be particularly sensitive to myocardial ischaemia, monitoring diastolic function may prove to be appropriate to detect and monitor perioperative myocardial ischaemia. However, in the perioperative period alterations in preload are common and, therefore, indices of diastolic function should be insensitive to alterations in circulating blood volume. Previous studies have demonstrated that moderate alterations in preload (changes in end-diastolic pressure ±4–5 mm Hg), caused by nitroglycerin or ventriculography, may mimic or mask diastolic dysfunction, as assessed by indices derived from the mitral inflow velocity profile [7, 8]. The present results suggest that indices derived from left ventricular pressure measurements are also of limited value: peak negative dP/dt is preload-dependent and appears to reflect ischaemia-induced changes in contractility rather than relaxation. Absolute values for τ, although preload-independent, failed to distinguish between ischaemia and control. However, our findings demonstrate that the pattern of segmental lengthening, while being sensitive to myocardial ischaemia, is not affected by alterations in preload. This suggests that the non-invasive monitoring of early segmental lengthening rather than flow profile or indices derived from left ventricular pressure may be useful for the detection and assessment of myocardial ischaemia. Further studies are necessary to determine if in the presence of other types of ischaemia (e.g. moderate low-flow ischaemia, demand-induced ischaemia) segmental lengthening is also sensitive to ischaemia and insensitive to alterations in preload. Moreover, clinical investigations (e.g. perioperative echocardiography) need to demonstrate if monitoring of the regional pattern of early lengthening is feasible and offers any advantage over the currently used monitoring of regional contractile function.

Effects of carbon dioxide embolism with nitrous oxide in the inspired gas in piglets†

J.-B. NYARWAYA, S. PIERRE, J.-X. MAZOIT, V. UMBRAIN, M. ROMAIN, K. SAMII AND A. D'HOLLANDER

Summary

We have compared cardiorespiratory variables in anaesthetized piglets whose lungs were ventilated with oxygen in nitrous oxide (N_2O group) or nitrogen (N group) after right ventricular carbon dioxide boluses (0.5 or 1 ml kg^{-1}; $n = 12$) or slow graded injections ($n = 6$). Boluses affected all variables studied significantly ($P < 0.05$) except mean systolic arterial pressure. Significant changes in PE'_{CO_2} ($P = 0.012$) and Pa_{O_2} ($P = 0.048$) values were observed in the N_2O group. Changes in Pa_{CO_2} were related to volumes of injected carbon dioxide ($P = 0.044$). Boluses of 1.0 ml kg^{-1} induced severe circulatory collapse in two piglets in the N_2O group. Slow embolization altered respiratory variables significantly ($P < 0.001$)). Pa_{O_2} decreased significantly in the N_2O group ($P < 0.0001$). Mean pulmonary arterial pressure increased significantly over time ($P = 0.0001$) and lasted longer in the N_2O group ($P < 0.05$). Volumes and time required to induce a 50% increase in mean pulmonary arterial pressure differed significantly between groups ($P < 0.05$). We conclude that nitrous oxide worsened the effects of rapid and slow carbon dioxide emboli on cardiopulmonary variables. Rapid carbon dioxide embolism altered respiratory and haemodynamic variables, while slow carbon dioxide embolism changed only respiratory variables. (*Br. J. Anaesth.* 1996; **76**: 428–434)

Key words

Carbon dioxide, embolism. Anaesthetics gases, nitrous oxide. Embolism, carbon dioxide. Pig.

Cases of carbon dioxide embolism with life-threatening consequences have been reported during laparoscopic surgery [1, 2]. As with air embolism, a variety of factors including the volume of the bolus [3, 4], its rate of entry into the vascular compartment and the inspired gas composition [5–8] are likely to determine the consequences of carbon dioxide embolism. In an *in-vitro* experiment, Nunn [5] noticed that air bubbles enlarged when infused in blood obtained from a patient whose lungs had been ventilated with nitrous oxide–oxygen mixtures. Steffey, Johnson and Eger [9] observed that breathing nitrous oxide resulted in significantly greater and prolonged increases in mean pulmonary artery pressure (PAP) after i.v. injection of carbon dioxide in anaesthetized dogs. These observations [5, 9] suggest that nitrous oxide diffuses from the surrounding blood and alveolar space into the carbon dioxide bubbles as they travel through the venous and pulmonary circulation.

In the present study we have examined the influence of volume and rate of entry into the right ventricle of carbon dioxide emboli, and the role of the inspired gas (nitrous oxide–oxygen *vs* nitrogen–oxygen) on both haemodynamic state and gas exchange in anaesthetized piglets. Two different experimental conditions were studied: boluses and slow graded infusions of carbon dioxide. These models were intended to mimic either an acute carbon dioxide embolism or a progressive gas embolism, as might be produced by carbon dioxide passing through a venous tear during laparoscopic procedures.

Materials and methods

We studied domestic piglets (Belgian Pietrain) of both sexes ($n = 18$) weighing 23–27 kg after obtaining approval from the Animal Research Committee of Erasme University Hospital, Brussels.

Fasting animals were premedicated with azaperone 1 mg kg^{-1} i.m. and anaesthetized with a combination of ketamine 20 mg kg^{-1} i.m., atropine 0.05 mg kg^{-1} i.m. and midazolam 0.1 mg kg^{-1} i.m. [10]. Tracheal intubation was facilitated with administration of pancuronium 0.5 mg kg^{-1} [11] supplemented with propofol 2–5 mg kg^{-1} [12]. The lungs were ventilated with a Servo Elema 900B ventilator (Siemens, Solna, Sweden). Anaesthesia was maintained with propofol 25 mg kg^{-1} h^{-1} i.v., fentanyl 10 µg kg^{-1} h^{-1} i.v. and pancuronium 0.4 mg kg^{-1} h^{-1} i.v. Fluid infusion of 0.9% NaCl 10 ml kg^{-1} h^{-1} was given via a cannula in the external vein of the ear. Inspired gas composition, end-tidal partial pressure of carbon dioxide (PE'_{CO_2}) and

ventilation rate were monitored continuously using a Datex Capnomac AGM-103 monitor (Datex, Helsinki, Finland). Tidal volume, temperature and pulse oximetry (Sp_{O_2}) were monitored using a Datex Cardiomap Ultima SV monitor (Datex, Helsinki, Finland).

The saphenous artery was cannulated for recording of systemic artery pressure and sampling for arterial blood-gas analysis. Both external jugular veins were dissected for the introduction of catheters. A flow-directed thermodilution catheter (7.5 Fr, Edwards Swan-Ganz, Baxter Healthcare Co, Irvine, CA, USA) was placed in the pulmonary artery for continuous monitoring of PAP and measurements of cardiac output (CO). A second flow-directed thermodilution catheter (7.5 Fr, Edwards Swan-Ganz, Baxter Healthcare Co, Irvine, CA, USA) and a double-lumen catheter (7 Fr, Deltacath, Becton Dickinson, USA) were introduced into the right ventricle and auricle, respectively, via the opposite external jugular vein. The position of the catheters was confirmed by the presence of an appropriate pressure-wave pattern on the monitor. Systolic arterial pressure (SAP) and PAP were measured continuously using electronic transducers (Uniflow, Baxter Healthcare Co, Uden, Holland) connected to a monitoring system (Sirecust 404-1, Siemens AG, Erlangen, Germany) with zero pressure at the thoracic mid-level as the reference. A 2-MHz Doppler ultrasonic flow transducer (Sonicaid Model D206, Oxford Sonicaid Ltd, Chichester, UK) was positioned above the right heart chambers so that a 10-ml saline injection delivered to the right ventricle would produce an audible change in sound.

A record of the ECG, ultrasonic Doppler signal, $P\text{E}'_{CO_2}$, SAP and PAP was obtained on a six-channel recorder (Model 800, Gould Electronic, Baillanvilliers, France) for later analysis of these variables. Arterial blood-gas values were determined using an ABL 500 (Radiometer, Copenhagen, Denmark). Measurements of CO were performed in triplicate using a SAT-1 cardiac output computer (American Edwards Lab., Irvine, CA, USA) with 10-ml injections of 0.9 % NaCl via one port of the double-lumen catheter.

The fractional inspired concentration of oxygen ($F\text{I}_{O_2}$) was set at 0.32–0.35 and ventilation adjusted to maintain the arterial partial pressure of carbon dioxide (Pa_{CO_2}) at 4.5–6 kPa. The animal's core temperature was monitored via a pulmonary artery thermocouple and maintained at 38–39.5 °C throughout the experiment. Acquisition of baseline data began after a stabilization period of at least 30 min after completion of the surgical procedure. Variables monitored included Sp_{O_2}, Sa_{O_2}, Pa_{O_2}, $P\text{E}'_{CO_2}$, Pa_{CO_2}, heart rate (HR), mean SAP, mean PAP and CO.

STUDY 1: RAPID CARBON DIOXIDE BOLUS INJECTION

Twelve piglets were allocated randomly in one of two groups to undergo ventilation with either oxygen–nitrogen (N_2 group, $n = 6$) or oxygen–nitrous oxide (N_2O group, $n = 6$) mixture. The carbon dioxide gas was delivered from a container with outflow pressure and volume regulated by a manometer connected to a 50-ml leak-free syringe. A three-way stopcock enabled the syringe to be connected between the outflow tubing of the carbon dioxide container and the distal port of the 7.5-French gauge thermodilution catheter for embolization. Before embolization, the syringe was flushed five times with carbon dioxide. The injection was then performed manually over a 30-s period. Animals were injected successively with two carbon dioxide volumes (0.5 and 1 ml kg^{-1}) following a crossover design.

STUDY 2: SLOW GRADED INJECTIONS

A manually regulated flowmeter (Aalborg Instruments, Monsey, NY, USA) mounted between the manometer of the carbon dioxide container and the distal port of the 7.5-French gauge flow-directed catheter was used to adjust the volume infused per minute. Piglets were embolized with a gradual increase in carbon dioxide flow while the lungs were ventilated with either oxygen–nitrogen (N_2 group, $n = 6$) or oxygen–nitrous oxide (N_2O group, $n = 6$). The infusion was discontinued when mean PAP increased by 50 % from baseline. Initially, piglets were embolized with a carbon dioxide flow of 7.5 ml min^{-1}. At each increment, the embolized carbon dioxide volumes were increased by 10 graduations and the infusion was maintained for 3 min at a constant pressure of 14.7 psi. A calibration chart allowed determination of the infused carbon dioxide flows according to readings wherein 10, 20, 30, 40, 50, 60, 70, 80, 90, 100 corresponded to 7.5, 12.6, 17.5, 24, 31, 39.4, 49, 58.4, 69.5, 82.1 ml min^{-1}, respectively.

Between the experimental sequences, the blood-gas variables studied were allowed to return to control values. Ventilation with different gas mixtures was separated by 1 h of ventilation with 100 % oxygen to ensure adequate washout of nitrous oxide and nitrogen. Thereafter, a 30 min-period of washing with either nitrogen or nitrous oxide was allowed before the next experiment was performed.

STATISTICAL ANALYSIS

Study 1

All variables were analysed using a three-way (time, nitrous oxide *vs* nitrogen, 0.5 *vs* 1 ml kg^{-1}) analysis of variance (ANOVA) with one-way (time) for repeated measurements. The Newman–Keuls test was used for multiple comparisons where appropriate.

Study 2

A two-way (time and nitrous oxide *vs* nitrogen) ANOVA with one-way for repeated measurements (time) was carried out. The Newman–Keuls test was used for multiple comparisons when applicable. The volume of carbon dioxide required to induce an increase of 50 % in mean PAP, duration of injection and the time to recovery of basal $P\text{E}'_{CO_2}$ values were compared between groups using the Wilcoxon test for paired data [13].

Data are expressed as mean (SD). Changes were considered statistically significant at $P < 0.05$.

Results

Baseline values of the variables after anaesthesia are shown in table 1.

Table 1 Baseline values of studied variables (36 measurements) recorded from six groups of piglets ($n = 6$ in each group) after anaesthesia and ventilation of the lungs with 35% oxygen and either nitrogen or nitrous oxide

	Mean	Range	SD
HR (beat min^{-1})	119	110–130	6
Mean SAP (mm Hg)	96	83–110	10
Mean PAP (mm Hg)	20	17–24	2
CO (litre min^{-1})	3080	2800–3500	240
Sp_{O_2} (%)	96	95–97	1
Sa_{O_2} (%)	97	96–97	1.5
Pa_{O_2} (kPa)	17.4	15.2–18.4	1.1
$P\text{E}'_{CO_2}$ (kPa)	5	4.6–5.3	0.3
Pa_{CO_2} (kPa)	5.3	5.3–5.6	0.1

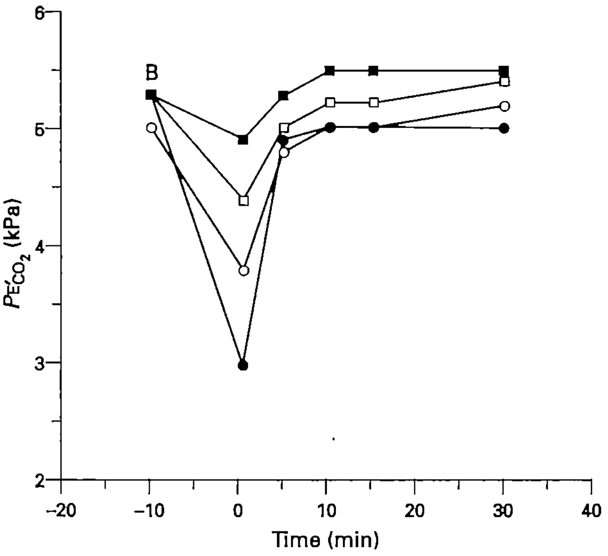

Figure 1 Effect of carbon dioxide embolism on $P\text{E}'_{CO_2}$ in the N_2 group after 0.5 ml kg^{-1} (■) and 1 ml kg^{-1} (□) boluses, and in the N_2O group after 0.5 ml kg^{-1} (●) and 1 ml kg^{-1} (○) boluses against time.

STUDY 1

In all animals, precordial sensor-detected carbon dioxide embolism occurred in less than 5 s after injection of carbon dioxide boluses.

Changes in gas exchange

After embolization, $P\text{E}'_{CO_2}$ decreased significantly over time ($P = 0.001$, ANOVA) and these reductions were more severe in the N_2O group than in the N_2 group ($P = 0.012$, ANOVA). However, there were no statistically significant differences between the two volumes of carbon dioxide boluses (0.5 *vs* 1 ml kg^{-1}).

At $T + 30$ s, the changes in $P\text{E}'_{CO_2}$ were decreased significantly in all groups ($P < 0.05$, Newman-Keuls test) (fig. 1). In three piglets in the N_2 group, analysis of recording charts showed an increase in $P\text{E}'_{CO_2}$ up to a mean of 0.3 kPa after embolization with 0.5 ml kg^{-1}. These initial increases lasted about 20 s and were followed by typical post-embolic $P\text{E}'_{CO_2}$ decreases (fig. 2).

Changes in Sp_{O_2} and Sa_{O_2} were time related ($P = 0.001$, ANOVA). Decreases in Sp_{O_2} and Sa_{O_2} values were greatest at $T + 0.5$ min ($P < 0.05$, Newman–Keuls test) compared with other times. Sp_{O_2} decreased by 5% and 9% after 0.5 and 1 ml kg^{-1} boluses, respectively, but only in the N_2O groups (fig. 3). Sa_{O_2} and Sp_{O_2} did not differ significantly with different inhaled gas mixtures and volumes of carbon dioxide boluses.

Alterations in Pa_{O_2} were significant in relation to time ($P = 0.0001$) and were more severe in the N_2O than in the N_2 group ($P = 0.048$, ANOVA). In the N_2 and N_2O groups, Pa_{O_2} decreased to 81% and 71% from baseline after 0.5 ml kg^{-1} carbon dioxide boluses, while after embolization with 1 ml kg^{-1} decreases to 72% and 59% were observed. With 1 ml kg^{-1} carbon dioxide boluses, decreased Pa_{O_2} persisted for 30 min in the N_2O group.

Differences in Pa_{CO_2} were significant in relation to time ($P = 0.0001$, ANOVA) and to volumes of carbon dioxide boluses ($P = 0.044$, ANOVA). In both groups, Pa_{CO_2} values returned to baseline 30 min after embolization and no significant difference was observed in relation to gas mixture.

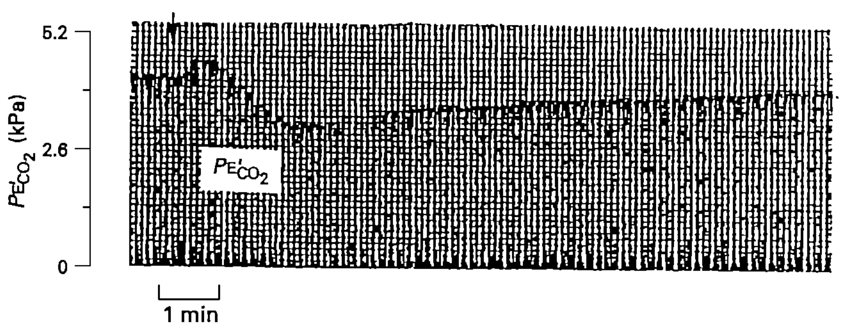

Figure 2 A typical tracing showing an increase in $P\text{E}'_{CO_2}$ and a subsequent decrease after right intraventricular embolization with 0.5 ml kg^{-1} following ventilation with an oxygen–nitrogen mixture in piglet No. 5. The arrow indicates the beginning of the right intraventricular emergence of the carbon dioxide bubbles.

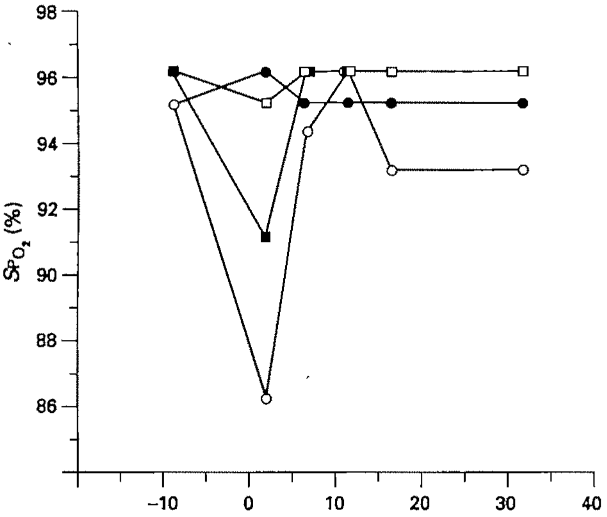

Figure 3 Evolution of Sp_{O_2} from baseline values against time in the N_2 groups after 0.5 ml kg^{-1} (■) and 1 ml kg^{-1} (□), and in the N_2O groups after 0.5 ml kg^{-1} (●) and 1 ml kg^{-1} (○) carbon dioxide boluses. All values are mean ($n = 6$ in each group).

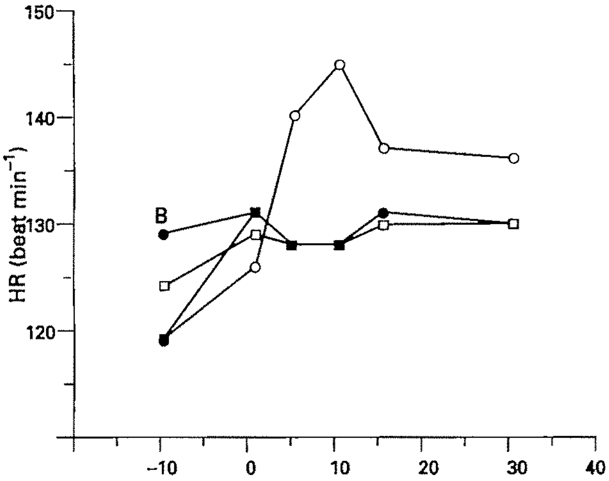

Figure 4 Changes in heart rate (HR) from baselines values in the N_2 groups after 0.5 ml kg^{-1} (□) and 1 ml kg^{-1} (■) and in the N_2O groups after 0.5 ml kg^{-1} (●) and 1 ml kg^{-1} (○) against time. Note there are increases only in the N_2O groups compared with baseline. All values are mean ($n = 6$ in each group).

Cardiovascular changes

HR changed significantly over the post-embolization periods ($P = 0.029$, ANOVA). At $T+5$ min and $T+10$ min, these differences were significant ($P < 0.05$, Newman–Keuls test) (fig. 4) compared with other periods. No significant changes were observed in MAP values.

Mean PAP changed significantly in relation to time ($P < 0.0001$, ANOVA). These changes were observed at $T+30$ s and $T+5$ min ($P < 0.05$, Newman–Keuls test).

Changes in CO were observed over time ($P < 0.0001$, ANOVA) and differences were significant at $T+30$ s and $T+5$ min ($P < 0.05$, Newman–Keuls test). In the N_2O group, two piglets suffered cardiovascular collapse after embolization with 1 ml kg^{-1} carbon dioxide volumes.

There were no statistically significant differences in relation to the gas mixture used for ventilation and to the two volumes of carbon dioxide boluses (table 2).

Table 2 Statistical significance of changes in the variables studied after rapid carbon dioxide embolization ($n = 6$ in each group)

	Time	N_2 *vs* N_2O	0.5 *vs* 1 ml kg^{-1}
$P\acute{E}_{CO_2}$	0.001	0.012	ns
Sp_{O_2}	0.0001	ns	ns
Sa_{O_2}	0.0001	ns	ns
Pa_{O_2}	0.0001	0.48	ns
Pa_{CO_2}	0.0001	ns	0.044
HR	0.04	ns	ns
Mean SAP	ns	ns	ns
Mean PAP	0.01	ns	ns
CO	0.001	ns	ns

STUDY 2

An increase in mean PAP of 50 % was used as the reference for completion of embolization. Compared with the N_2O group, the N_2 group required higher cumulative infused carbon dioxide volumes (247 (189) ml *vs* 72 (60) ml) and a longer delay to reach a 50 % increase in mean PAP (15.5 (7.6) min *vs* 6.5 (3) min, $P < 0.05$: paired Wilcoxon test) (fig. 5).

Changes in gas exchange

After embolization, $P\acute{E}_{CO_2}$ changed significantly with time ($P = 0.001$, ANOVA). At $T+30$ s, $P\acute{E}_{CO_2}$ showed significant decreases of 20 % in the N_2 group *vs* 27 % in the N_2O group ($P < 0.05$, Newman–Keuls test). The time to regain baseline $P\acute{E}_{CO_2}$ values was longer in the N_2 group than in the N_2O group (11.5 (7.6) min *vs* 7 (4) min, $P < 0.05$: unpaired Wilcoxon's test). The chart recording of $P\acute{E}_{CO_2}$ during slow embolization showed a plateau profile, despite the stepwise variation in the delivery of carbon dioxide flows used for embolization (fig. 6).

We found significant post-embolic decreases in Sp_{O_2} and Sa_{O_2} over time ($P < 0.0001$) in both groups and the differences were significant at $T+30$ s ($P < 0.05$, Newman–Keuls test).

Values of Pa_{O_2} decreased significantly ($P < 0.0001$, ANOVA) by 70 % and 63 % from baseline in the N_2 and N_2O groups ($P < 0.05$, Newman–Keuls test), respectively, at $T+30$ s.

Post-embolic increases of 24 % in Pa_{CO_2} ($P < 0.0001$, ANOVA) were noted at $T+30$ s in both groups.

Cardiovascular changes

There were no statistically significant changes in HR, mean SAP and CO with time (table 3). Only mean PAP values changed significantly over time ($P = 0.01$, ANOVA). At $T+30$ s and $T+5$ min, mean PAP values were significantly greater than those recorded at other times ($P < 0.05$, Newman-Keuls test). Thirty minutes after termination of

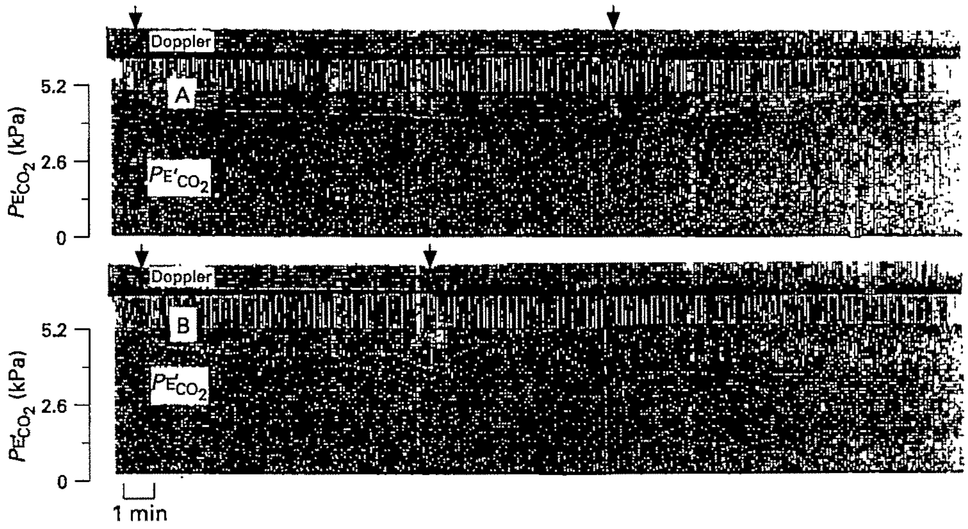

Figure 5 Typical tracings showing changes in PE'_{CO_2} and the Doppler signal after slow right intraventricular embolization with slow graded carbon dioxide infusion during ventilation with oxygen–nitrogen (A) or oxygen–nitrous oxide (B) in piglet No. 3. The arrows indicate the beginning and end of right intraventricular emergence of the carbon dioxide bubbles.

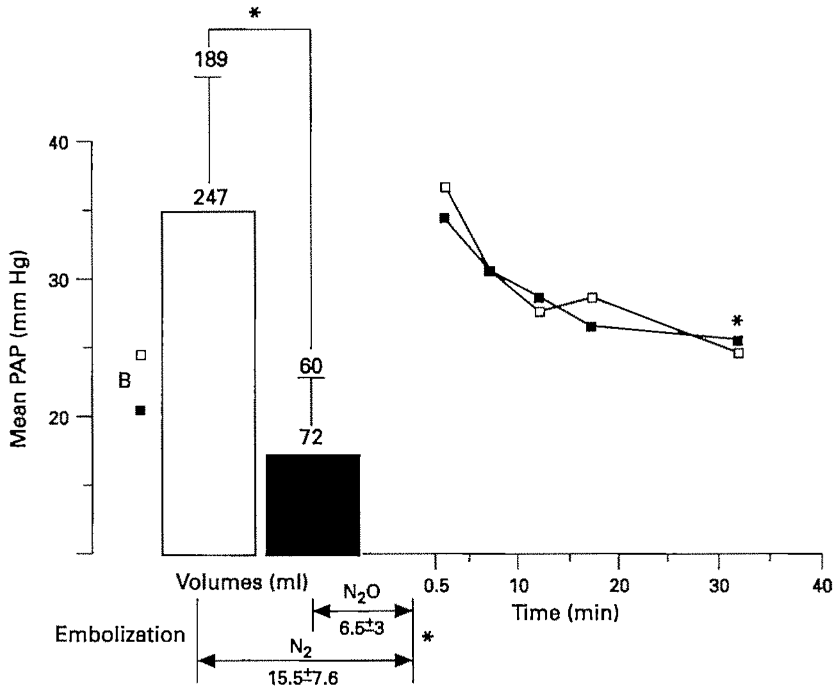

Figure 6 Evolution of mean PAP from baseline values (B) after slow intraventricular embolization with graded carbon dioxide infusion during ventilation with oxygen–nitrogen (□) or oxygen–nitrous oxide (■). Injected volumes in the nitrous oxide (□) *vs* the N_2 group (■) and time (N_2O *vs* N_2) required to obtain a 50% increase in mean PAP are shown. All values are mean (SD), * $P < 0.05$ ($n = 6$ in each group).

Table 3 Statistical significance of changes in the variables studied after slow carbon dioxide embolization ($n = 6$ in each group)

	Time	O_2/N_2 *vs* O_2/N_2O
PE'_{CO_2}	0.001	ns
Sp_{O_2}	0.001	ns
Sa_{O_2}	0.001	ns
Pa_{O_2}	0.001	ns
Pa_{CO_2}	0.001	ns
HR	ns	ns
Mean SAP	ns	ns
Mean PAP	0.001	ns
CO	ns	ns

embolization, residual mean PAP increases were still significantly higher (21% *vs* 10% from baseline values, $P < 0.05$) in the N_2O group than in the N_2 group (fig. 5).

Discussion

We have shown that after rapid and progressive carbon dioxide embolism in piglets, cardiorespiratory alterations were worsened by the presence of nitrous oxide in the gas mixture used for mechanical ventilation. These findings confirm the results of previous studies which demonstrated that nitrous oxide amplifies the effects of venous air [6–8] or carbon dioxide embolism and prolongs the delay to recover from the physiological insults [9]. In agreement with previous studies [7, 9], nitrous oxide reduced the volume required to induce predetermined changes.

Continuous $P\text{E}'_{CO_2}$ monitoring showed some particular trends in addition to the commonly observed sharp decrease after gas embolism. First, abrupt and transient increases in $P\text{E}'_{CO_2}$ were observed after rapid boluses of low volume. This observation confirms the biphasic trend of $P\text{E}'_{CO_2}$ recordings reported previously after carbon dioxide embolism during laparoscopic surgery [2, 14, 15]. Second, while mean PAP continued to increase during progressive embolization, $P\text{E}'_{CO_2}$ values decreased steadily and demonstrated a plateau profile. Moreover, $P\text{E}'_{CO_2}$ values returned to baseline earlier than those of mean PAP and reached a higher level than baseline after slow embolization in the N_2 group. These variations in response differed markedly compared with those reported previously after air embolism [16]. Therefore, it must be emphasized that during progressive carbon dioxide embolism, $P\text{E}'_{CO_2}$ monitoring may not allow either early and reliable detection of carbon dioxide embolism or provide relevant quantitative information about the size of the carbon dioxide emboli. The other non-invasive monitorings, including HR and Sp_{O_2}, demonstrated changes in values and trends similar to those reported after laparoscopic carbon dioxide embolism.

For invasive monitoring, only Pa_{O_2} changed significantly in relation to volume of carbon dioxide boluses and the inspired gas mixture during rapid carbon dioxide embolization. After both rapid and progressive infusions, an increase in mean PAP was observed constantly, immediately after injection of carbon dioxide. In agreement with previous studies on the effects of air [6, 8] and carbon dioxide emboli [9], the rate of increase in mean PAP was related closely to the rate of injection, the volume of the carbon dioxide bolus and the nature of the gases used for ventilation. During slow carbon dioxide embolization, although mean PAP was increased by 50% from baseline, no significant changes in CO were observed. In the presence of N_2O, the trends in mean PAP showed higher values without any significant differences. However, its residual values were significantly higher in the piglets whose lungs were ventilated with oxygen–nitrous oxide. This finding confirms the known sensitivity of mean PAP monitoring in detecting gas embolism [16].

Although this model is not strictly similar to the clinical situation, the right intraventricular site for injection was chosen in an attempt to create a better quantitative experimental design for carbon dioxide embolization to observe the relationship between different patterns (volume and rate) and effects. It is well known that gas bubbles introduced into the jugular vein, superior vena cava and right atrium move downwards in some parts of the cardiac cycle and upwards in others [17], and that some fraction of the injected carbon dioxide is absorbed before reaching the pulmonary vasculature.

The haemodynamic changes induced by slow embolization differ from those observed with carbon dioxide boluses, where decreases in CO may be caused mainly by a "bubble-lock" in the right side of the heart. This observation suggests that mechanical block of portions of the pulmonary circulation is only partial but sufficient to contribute to alterations in pulmonary gas exchange. As the arteriole is the major determinant of PAP, one can speculate that an arteriolar effect may be reflected in these changes in PAP [18]. The present study suggests that the post-embolic vascular change may be greater and more prolonged in the presence of nitrous oxide than nitrogen. However, the magnitude of the post-embolic disturbances, may be determined by the combined effect of the size and number of carbon dioxide bubbles. First, a low volume embolism may allow carbon dioxide microbubbles to reach the alveolar capillaries with high alveolar elimination of carbon dioxide and increase in $P\text{E}'_{CO_2}$. This is in agreement with previous reports of an abrupt but transient increase followed by a progressive decrease during carbon dioxide embolism during laparoscopic surgery [2, 14, 15]. Second, larger carbon dioxide bubbles may induce widespread arteriolar block and pulmonary blood flow redistribution resulting in ventilation-to-perfusion ($V\text{A}/Q$) ratio alterations including an increased $V\text{A}/Q$ ratio in the embolized lung [19] associated with opening of intrapulmonary arteriovenous shunts and decreased $V\text{A}/Q$ ratio in the non-embolized area. The majority of air bubbles ejected from the right ventricle are likely to reach the non-dependent branches of the pulmonary arteries [20, 21]. In terms of regional ventilation-to-perfusion distribution, this implies that inhalation of nitrous oxide would worsen the shift of blood flow to dependent regions with a larger pulmonary shunt and greater deadspace resulting in greater decreases in Pa_{O_2} and $P\text{E}'_{CO_2}$ values during rapid embolization.

When differences in solubility and diffusion are considered, the present study agrees with the principle that inhalation of nitrous oxide aggravates existing air and carbon dioxide embolism [22]. The greater partial pressure of carbon dioxide in bubbles compared with surrounding blood and the alveoli results in a direct transfer of carbon dioxide from bubbles to blood with post-embolic increases in Pa_{CO_2} and higher elimination to alveolar space producing an initial increase in $P\text{E}'_{CO_2}$. Furthermore, the progressive return to baseline values observed in the present study is in agreement with Kunkler and King [23] who demonstrated that carbon dioxide bubbles equilibrated rapidly with the surrounding blood gases and revealed large amounts of other gases, by analysis performed within few seconds on undissolved emboli. Second, considering the greater physiological changes observed in the presence of nitrous oxide, transfer of nitrous oxide into carbon dioxide bubbles may be speculated. The Fick equation to spherical bubble flow in the bloodstream suggests that the rate of gas diffusion is directly proportional to Krogh's coefficient (the product of solubility and diffusion) and the partial pressure gradient of diffusion for that gas [8]. The higher Krogh's coefficient for carbon dioxide than for nitrous oxide and nitrogen suggests that carbon dioxide outflow should be faster than inflow of nitrous oxide and nitrogen for a given partial pressure. Therefore, the magnitude of changes observed during nitrous oxide ventilation may be associated with initial entry of nitrous oxide into the carbon dioxide bubbles until equilibration with the surrounding blood and to the resultant longer lifespan for bubbles, allowing a larger number to induce a cumulative effect. In contrast with nitrous oxide, diffusion of nitrogen into carbon dioxide bubbles would be slower, therefore carbon dioxide bubbles might dissipate more rapidly after embolization.

We conclude that during procedures at risk of carbon dioxide embolism, significant gas exchange alterations should be considered as clinically relevant even in the absence of haemodynamic disturbances. Anaesthetists should keep in mind the study of Eger and Saidman [24] demonstrating that the relationship between nitrous oxide blood concentration and the volume increase of air bubbles is exponential and that for a concentration of between 50% to 75% a two- to four-fold increase may be attained. The present study suggests additional limitations about routine $P\text{E}'_{\text{CO}_2}$ monitoring during laparoscopic surgery. The assumptions that $P\text{E}'_{\text{CO}_2}$ monitoring may reliably detect carbon dioxide embolism during laparoscopy with carbon dioxide insufflation should be reconsidered. Because of the increasing number of surgical laparoscopic procedures which may potentially lead to severe gas embolism [1, 2], the presence of Doppler monitoring should be mandatory, as it has been found to be the most sensitive and specific for detection of gas embolism [16, 25].

REVIEW ARTICLE

Sevoflurane—a long-awaited volatile anaesthetic

I. SMITH, M. NATHANSON AND P. F. WHITE

In evaluating any newly introduced anaesthetic, it is worth comparing its properties with those of a theoretical "ideal" volatile agent which would have a low solubility in blood to allow for rapid equilibration between delivered concentration and the effect site in the central nervous system (CNS). This would facilitate rapid induction of anaesthesia, allow easier titration of anaesthetic dose to the desired effect during the maintenance period and permit rapid emergence and recovery at the end of anaesthesia. An ideal anaesthetic should also be easy to deliver and devoid of perioperative side effects and toxicity.

Desflurane (Suprane) was the last new volatile anaesthetic introduced into clinical practice in 1992. Although relatively insoluble and easy to titrate during the maintenance period, desflurane is not a practical induction agent because of its irritant effects on the airway. The theoretically improved control over depth of anaesthesia during the maintenance period afforded by desflurane is complicated by its tendency to induce cardiovascular stimulation when the delivered concentration is increased rapidly [16, 85). In addition, desflurane requires unusually complex vaporizer technology for its administration.

Sevoflurane has been in clinical use in Japan since 1990 and has recently gained approval for use in Great Britain, the United States and much of the rest of the world. This review considers the clinical properties of sevoflurane in relation to existing volatile anaesthetics (table 1) and the "ideal" volatile agent.

History of sevoflurane

Research to develop a safe, non-inflammable inhaled anaesthetic agent began in the 1930s when chemists discovered that the substitution of fluorine for other halogens "lowers the boiling point, increases stability, and generally decreases toxicity" [5]. This work was continued by McBee, who used his knowledge of fluorine chemistry gained from working on the "Manhattan" atomic bomb project, to investigate a number of fluorine-containing compounds, none of which was eventually suitable for clinical use. In 1951, Suckling synthesized halothane, and soon the search for other clinically useful fluorine-containing anaesthetics began in earnest. Sevoflurane (fig. 1) was first synthesized in 1968 by Regan at Travenol Laboratories, Illinois, while he was investigating a series of halomethyl polyfluoroisopropyl ethers. The compound was initially reported by his co-workers in 1971 [83]. The group at Travenol went on to describe the results of animal experiments which characterized the important clinical properties of the new anaesthetic [84]. Development was later to be impeded by apparent toxic effects, eventually shown to be a consequence of flawed experimental design [36]. The first volunteer trials, reported by Holaday and Smith in 1981, were encouraging [37]. However, further work was slow because of the problems of biotransformation and stability with soda lime. The volatile anaesthetic isoflurane was felt at the time to be a more suitable drug for commercial development [8]. Baxter Travenol sold the rights to sevoflurane to Anaquest (Ohmeda/BOC), who in turn sold these to Maruishi Company. Maruishi continued research and development, eventually releasing sevoflurane for clinical use in Japan in May 1990. By the end of 1993, an estimated 1 million patients had received sevoflurane [18]. The continuing search for an inhaled agent with rapid induction, emergence and recovery characteristics has stimulated the recent re-examination of sevoflurane. The considerable resources necessary to introduce another volatile anaesthetic into the western marketplace have resulted in the purchase and subsequent development of sevoflurane by a multinational company, namely Abbott Laboratories.

Physical properties of sevoflurane

Sevoflurane is related structurally to isoflurane and enflurane (fig. 1), and not surprisingly shares many of the physical properties of these dugs; (interestingly, desflurane is even more closely related structurally to isoflurane, yet desflurane has quite unique physical properties). Sevoflurane has a boiling point of 58.6 °C and a saturated vapour pressure (SVP) of 160 mm Hg at 20 °C. These values are similar to those of halothane, enflurane and isoflurane. The blood:gas partition coefficient of sevoflurane is 0.69 [78]. This is approximately half

that of isoflurane (1.43) and compares favourably with the blood:gas solubility of both desflurane (0.42) and nitrous oxide (0.44). The low blood:gas solubility of sevoflurane should provide for rapid induction of, and recovery from, anaesthesia.

The minimum alveolar concentration (MAC) of sevoflurane is reported to be between 1.71 % [43] and 2.05 % [73]. This value was reduced to 0.66 % in an adult population by addition of approximately 60 % nitrous oxide [43]. The MAC value of sevoflurane, and therefore the typical maintenance concentration, is almost identical to that of enflurane. The MAC for sevoflurane, in common with other anaesthetics, is somewhat higher in children. Typical values are 2.6 % (reduced to 2.0 % by nitrous oxide) in children and 3.3 % in neonates [51].

Clinical properties of sevoflurane

INDUCTION OF ANAESTHESIA

While it is unlikely that inhalation induction of anaesthesia will replace the use of rapid-acting i.v. induction agents, insertion of an i.v. needle (or cannula), and even injection of i.v. anaesthetics (e.g. methohexitone, etomidate, propofol), may cause considerable discomfort, especially in children. While the use of local anaesthetics can reduce this discomfort, poor veins and a lack of co-operation can make i.v. induction of anaesthesia impractical for many patients. Induction of anaesthesia by mask may be preferable in some of these patients, assuming that this could be accomplished rapidly and smoothly. Finally, inhalation induction may be desirable on those occasions when there is a danger of airway obstruction following rapid loss of consciousness.

Anaesthetic vapours with a low blood:gas solubility coefficient should permit rapid induction of anaesthesia as the alveolar concentration equilibrates rapidly with the inspired (delivered) concentration. Based on solubility characteristics, inhalation induction should take longest with halothane, and become increasingly more rapid with enflurane, isoflurane, sevoflurane and desflurane, respectively. However, the ability to deliver an inspired concentration sufficiently high to induce anaesthesia is limited by the effects of the anaesthetic vapour on the patient's airway. In practice, agents such as enflurane, isoflurane and desflurane are irritating to the airway, resulting in coughing, breath-holding, excessive salivation and even laryngospasm. As a result, the rate of equilibration is reduced and induction is slower than would be predicted from the blood:gas solubility value alone. For example, inhalation induction with desflurane resulted in airway complications in 30–40 % of healthy, day-case patients, with occasional prolonged or failed inductions [82], while desflurane appears to be even more irritant in children, with up to 58 % of cases coughing [92].

In contrast, sevoflurane is pleasant-smelling and relatively non-irritating to the airways, permitting a high inspired concentration to be inhaled without side effects or discomfort. When a group of unpremedicated patients undergoing major gynaecological surgery were allowed to breathe 5 % sevoflurane in an oxygen–nitrous oxide mixture, anaesthesia was induced within 109 ± 25 s [76]. Anaesthesia was induced successfully in all 25 patients, none of whom coughed, experienced apnoea, laryngospasm or other airway-related side effects. Yurino and Kimura studied a group of unpremedicated volunteers in whom anaesthesia was induced by breathing oxygen–nitrous oxide to which sevoflurane was added, beginning at 0.5 % and increasing to a maximum of 4.5 % in increments of 0.5 % every 3–4 breaths [90]. Using this traditional (stepwise) technique, anaesthesia was induced in 108 ± 19 s. Laryngospasm and breath-holding were not observed, and while coughing occurred in 12.5 % of subjects, this was described as "mild" and did not adversely affect haemoglobin oxygen saturation [90]. When 4.5 %

sevoflurane was administered to a similar group of volunteers as a single, vital capacity breath, loss of consciousness was achieved in only 54 ± 10 s, while the incidence of coughing was reduced to 6.3 % [90]. Compared with isoflurane, vital capacity single breath induction with 1.7 MAC of sevoflurane was more rapid (120 ± 24 *vs* 145 ± 39 s) and associated with significantly fewer respiratory complications [89]. For example, coughing occurred in 43 % of patients breathing isoflurane compared with none with sevoflurane. In addition, one patient (4.8 %) in the isoflurane group developed laryngospasm, and the technique was abandoned in another patient because of excessive involuntary movements [89]. The majority of patients (60 %) found sevoflurane to be "pleasant smelling", while 75 % found isoflurane "unpleasant" [89]. The use of even higher concentrations of sevoflurane (up to 8 % on the newest vaporizers) permits even more rapid induction of anaesthesia. Using 7.5 % sevoflurane as a single vital capacity breath allowed loss of consciousness in 41 ± 16 s [91]. However, coughing was more common (25 %) when 7.5 % sevoflurane was used in a tidal breathing induction technique, resulting in slower induction of anaesthesia (52 ± 13 s) [91].

Inhalation induction is practised more commonly in children than in adults, and halothane has been considered the drug of choice. Early clinical experience from Japan suggested that inhalation induction with sevoflurane was "smoother" compared with halothane in children [61]. Most early investigations have reported inhalation induction times in children to be similar, irrespective of whether sevoflurane or halothane were administered [63, 67]. However, in at least one investigation, the average concentration of halothane administered was considerably higher (in terms of MAC-multiples) compared with sevoflurane, which may have distorted the results obtained [63]. Lerman and colleagues achieved an average time to loss of the eyelash reflex of 54 s in infants (< 1 yr) and 73–80 s in children aged 3–12 yr when a traditional induction sequence was used in a non-comparative evaluation [51]. Sevoflurane was administered in oxygen, commencing at 1.5 %, and increased by 1.5 % every 3 breaths. Premedication was not administered, and the incidence of airway-related complications was very low in all age groups [51]. Continuing the induction sequence, tracheal intubation was possible with deep sevoflurane anaesthesia after 4–5 min [51]. Smooth and uneventful tracheal intubation requires a sevoflurane concentration approximately 33 % above the MAC value [39]. However, insertion of the less stimulating laryngeal mask airway is possible at 1 MAC of sevoflurane [80].

Recent investigations in the paediatric population have demonstrated more rapid induction of anaesthesia with sevoflurane compared with halothane [1, 20, 32, 81]. For example, children receiving a stepwise induction technique lost their eyelash reflex in 1.7 min with sevoflurane compared with 2.2 min with halothane ($P < 0.001$) [1]. Similarly, Epstein and colleagues completed induction of anaesthesia in children in 97 ± 31 s using sevoflurane compared with 120 ± 36 s with halothane ($P < 0.05$) [20]. Even more rapid induction was reported in children aged 1–12 yr by Greenspun and co-workers [32]. Loss of the eyelash reflex occurred in 1.0 ± 0.2 min with sevoflurane compared with 1.4 ± 0.4 min with halothane ($P = 0.0002$), using a similar induction technique to the two previous studies [32]. Taivainen and colleagues also achieved induction times of 1 min with sevoflurane, administering concentrations up to 7 % [81]. Significantly more children rated their induction with sevoflurane as "pleasant" compared with halothane (56 % *vs* 20 %) and expressed a preference for a similar technique in the future (76 % *vs* 44 %) [81]. Although Sarner and colleagues did not detect any difference in induction times when comparing sevoflurane in oxygen with sevoflurane–nitrous oxide and halothane–nitrous oxide, omission of nitrous oxide increased the incidence of excitatory activity on induction with 5–35 % sevoflurane [72].

Therefore, sevoflurane appears to be a practical and well-tolerated inhalation induction agent in all age groups investigated to date. In children, it will challenge halothane as the inhalation induction agent of choice. Although the use of sevoflurane for inhalation induction in adults is likely to be more limited, it provides a viable alternative to i.v. induction techniques. Before sevoflurane can be recommended for use in association with the "difficult airway", its safety in partial airway obstruction and in patients with irritable airways needs to be investigated.

MAINTENANCE OF ANAESTHESIA

Anaesthetists are familiar with the titration of volatile agents to maintain an appropriate "depth" of anaesthesia. The rapidity with which alteration in the anaesthetic vaporizer dial setting results in a change in the level of anaesthesia is determined by the difference between the anaesthetic concentration delivered by the vaporizer and the concentration in the CNS [18]. The ratio of these two concentrations is influenced by the extent of rebreathing, which in turn depends on the type of anaesthetic circuit and the total fresh gas flow, in addition to anaesthetic uptake from the alveoli. For a given degree of rebreathing, the less soluble volatile agents allow for more rapid and precise control of anaesthetic depth, as their uptake from the alveoli is less than for agents with a higher blood:gas solubility. Although large alterations in the administered anaesthetic concentration may induce airway irritation in lightly anaesthetized, spontaneously breathing patients, this is rarely a problem after i.v. induction of anaesthesia or when neuromuscular blockers and controlled ventilation are used.

As the ratio between the delivered and alveolar concentration of sevoflurane is four times less than that achieved with isoflurane at a given fresh gas flow, greater precision in the control of anaesthetic depth should be achieved with this new agent [18]. Because it is even less soluble than sevoflurane, desflurane results in a delivered:alveolar concentration difference that is five times smaller than isoflurane. However, rapid increases in the delivered concentration of desflurane can induce transient increases in heart rate, arterial pressure, or both [16, 85]. While these changes do not appear to pose a significant hazard to most patients, the phenomenon may deter anaesthetists from adjusting the depth of anaesthesia as rapidly as the physical properties of desflurane would allow in patients with pre-existing cardiovascular disease. In contrast, these excitatory phenomena are not observed when the level of sevoflurane anaesthesia is adjusted rapidly [16].

The pharmacodynamic effects of sevoflurane on the various organ systems appear to be similar to those of other commonly used halogenated ethers. Sevoflurane produces dose-dependent ventilatory depression [14] and also reduces respiratory drive in response to hypoxia and increases in carbon dioxide partial pressure, comparable with levels achieved with other ether anaesthetics. It relaxes bronchial smooth muscle, although perhaps not as effectively as halothane. Sevoflurane decreases mean arterial pressure predominantly through decreased peripheral resistance, with cardiac output being well maintained over the normal anaesthetic maintenance range. A degree of myocardial depression occurs at higher concentrations, as a result of an effect on calcium channels [33]. Sevoflurane does not sensitize the myocardium to the arrhythmogenic effects of catecholamines [65]. Sevoflurane has little effect on normal myocardial blood flow, is a less potent coronary arteriolar dilator than isoflurane [35], and does not appear to cause "coronary steal" [44]. In contrast with other halogenated ethers, sevoflurane appears to be associated with a lower heart rate [16, 26], which helps to reduce myocardial oxygen consumption and assists myocardial perfusion. In addition, the lack of an anaesthetic-specific increase in heart rate may facilitate the determination of "depth of anaesthesia".

Sevoflurane has CNS effects similar to those of isoflurane and desflurane. Intracranial pressure increases at high inspired concentrations of sevoflurane (analogous to isoflurane); however, this effect is minimal over the 0.5–1-MAC range [74]. Sevoflurane is not associated with convulsive or epileptic activity [74]. Renal and hepatic blood flow are well preserved with sevoflurane, and organ toxicity has not been observed to date. There are limited data on sevoflurane in the obstetric population [30]. However, sevoflurane appears to have similar uterine effects to isoflurane, and no differences in maternal or fetal outcome were observed when equianaesthetic concentrations (0.5 MAC) of these two agents were compared during elective Caesarean section [30]. Sevoflurane produces clinically useful neuromuscular block and potentiates neuromuscular blockers to a similar degree to other anaesthetics. It can trigger malignant hyperpyrexia in susceptible individuals, and at least four cases have been reported to date [15].

EMERGENCE AND RECOVERY CHARACTERISTICS

The low blood:gas solubility of sevoflurane should permit rapid elimination from the CNS. When sevoflurane and isoflurane were compared as anaesthetic maintenance agents after induction of anaesthesia with midazolam and thiopentone in healthy patients undergoing elective operations, the average times from end of anaesthesia to eye opening on command were 18.6 ± 2.0 min for isoflurane and 7.5 ± 0.5 min for sevoflurane ($P < 0.001$) [26]. When propofol was used as the induction agent before operations lasting approximately 2.5 h, emergence from sevoflurane–nitrous oxide anaesthesia (4.1 ± 2.2 min) was still significantly more rapid compared with isoflurane–nitrous oxide (6.7 ± 2.2 min) [76].

Recovery from the newer volatile anaesthetic agents appears relatively unaffected by the duration of anaesthetic exposure, whereas recovery from more soluble agents increases in direct proportion to the length of anaesthetic administration [19]. While emergence times from sevoflurane remained reasonably constant over a range of anaesthetic durations from 1–7 MAC-h in healthy patients undergoing elective surgery, emergence times from isoflurane demonstrated a five-fold difference over a similar range of exposure times [26]. Nevertheless, Quinn and colleagues failed to detect any difference in emergence times between sevoflurane and isoflurane after operations lasting 3 h [68]. However, sevoflurane was associated with faster emergence compared with isoflurane using a similar technique for gynaecological operations of shorter duration, suggesting that the use of intraoperative opioid analgesics may have masked differences between the two groups in the former study, which also involved very small numbers of patients [68].

Rapidly eliminated anaesthetic agents are used most commonly for day-case anaesthesia, where rapid, clear-headed recovery may allow for earlier discharge of patients. In a randomized (non-blinded) investigation, Fredman and colleagues [23] compared a variable rate continuous infusion of propofol with sevoflurane for maintenance of anaesthesia in combination with nitrous oxide after induction of anaesthesia with propofol in a group of patients undergoing day-case gynaecological or ENT operations. The investigation also included a third group of patients who received sevoflurane–nitrous oxide for both induction and maintenance of anaesthesia. There were no significant differences in early or intermediate recovery times between the three treatment groups (table 2). Pencil and paper tests also failed to detect any significant differences between the three treatment groups in terms of postoperative sedation or psychomotor impairment [23]. In a similar investigation during day-case surgery procedures lasting approximately 90 min, emergence from sevoflurane anaesthesia required 10.4 ± 6.5 min compared with 11.0 ± 11.0 min after propofol anaesthesia [38]. In common with the study of Fredman and colleagues [23], both groups of patients received propofol for induction and nitrous oxide for maintenance of anaesthesia [38].

When sevoflurane was compared with desflurane for maintenance of anaesthesia in a group of women undergoing day-case laparoscopic sterilization, mean time to eye opening after desflurane (4.8 (SD 2.4) min) occurred significantly earlier compared with sevo-

flurane (7.8 (3.8) min) (table 3) [64]. In this preliminary investigation, anaesthesia was induced with propofol and fentanyl, and the volatile anaesthetic agents were titrated to maintain haemodynamic stability in an attempt to ensure comparable levels of anaesthesia (fig. 2) [64]. Despite more rapid emergence from desflurane anaesthesia, subsequent recovery end-points (e.g. orientation, ambulation and hospital discharge) did not differ between the two anaesthetic groups. There were also no differences in subjective feelings or psychomotor function during the recovery period, suggesting that any differences between these two anaesthetic agents are of minimal clinical significance when used for day-case anaesthesia [64].

Sevoflurane and desflurane have also been compared as anaesthetic maintenance agents in children [86]. In this study, anaesthesia was induced in both groups with halothane, which was then discontinued and the maintenance anaesthetic introduced. In common with the findings of Nathanson and colleagues, [64] in adults, emergence was delayed in children anaesthetized with sevoflurane compared with desflurane. However, the more rapid emergence after desflurane (5 ± 2 min *vs* 11 ± 4 min) was associated with a significantly higher incidence (55 %) of agitation and excitement in these children [86]. Although early recovery was also delayed after sevoflurane (19 ± 7 min *vs* 11 ± 4 min for desflurane), later recovery events were similar after both maintenance anaesthetics [86].

When halothane is used for induction of anaesthesia in children, it is often used subsequently as the anaesthetic maintenance agent. In comparison with halothane, the use of sevoflurane for induction and maintenance of anaesthesia permitted significantly more rapid eye opening (4.3 ± 1.1 *vs* 9.5 ± 2.7 min) after the end of anaesthesia [63]. The difference in recovery times persisted throughout the postoperative period, and allowed the children who had received sevoflurane to be discharged home almost 50 min earlier than those exposed to halothane (88 ± 23 *vs* 137 ± 21 min, respectively) [63]. The postoperative effects of halothane may be prolonged. In one group of paediatric inpatients, psychomotor performance on the Trieger dot test was significantly better for at least 6 h after sevoflurane anaesthesia compared with halothane [81]. Epstein and colleagues reported significantly faster emergence from sevoflurane anaesthesia compared with halothane (9.9 ± 2.9 min *vs* 12.5 ± 4.7 min), despite a higher MAC-multiple of sevoflurane concentration at the end of anaesthesia [20]. Similar findings were observed in another group of children undergoing minor surgical procedures with halothane or sevoflurane anaesthesia [67]. Tracheal extubation was possible 5 min earlier in children anaesthetized with sevoflurane compared with halothane ($P < 0.01$), while response to commands occurred 15 min earlier after sevoflurane [67]. However, a rigid hospital procedure prevented differences in discharge times from being detected in this investigation [67]. After ENT operations, discharge times did not differ following sevoflurane or halothane anaesthesia, despite more rapid awakening and early recovery with sevoflurane [32]. However, the requirements for postoperative opioid analgesia may have masked differences between the groups, while hospital discharge may also have been delayed by a relatively high incidence of postoperative vomiting in both groups of children [32]. In contrast, another clinical investigation demonstrated earlier hospital discharge after anaesthesia with sevoflurane compared with halothane, despite similar emergence times with both agents [72].

Metabolism and toxicity

In contrast with other recently introduced volatile anaesthetics, sevoflurane is a comparatively unstable molecule. It undergoes a moderate degree of metabolism (approximately 5 %) [6] and also breaks down in the presence of soda lime and Baralyme at elevated temperatures [79]. Both processes result in potentially toxic products. However, unlike other anaesthetic ethers, sevoflurane does not possess a CF_2H group, and so (similar to halothane) does not result in the production of carbon monoxide in association with excessively dry carbon dioxide absorbants [22].

Sevoflurane is metabolized by the liver to produce hexafluoroisopropanol and inorganic fluoride ions [24, 37, 50]. In humans, up to 5 % of the administered dose of sevoflurane undergoes metabolism [48, 75], catalysed by the 2E1 isoform of cytochrome P450 [45, 49]. Studies in animals have demonstrated that this enzyme can be induced by phenobarbitone [11, 54], isoniazid [69] and ethanol [55], leading to increased serum inorganic fluoride concentration and urinary excretion of fluoride ions.

RENAL EFFECTS

Clinical experience with methoxyflurane suggested that renal impairment could occur if a "threshold" serum fluoride concentration of 50 μmol litre^{-1} was exceeded [13], although clinically evident renal dysfunction was rarely observed at concentrations less than 80 μmol litre^{-1} [58]. After administration of sevoflurane anaesthesia for 1 h, Holaday and Smith found a mean serum fluoride concentration of 22 μmol litre^{-1} in six volunteers [37]. Smith, Ding and White measured serum fluoride concentrations in 50 patients receiving sevoflurane anaesthesia for gynaecological surgery of 135 min mean duration [76]. Fluoride concentrations increased rapidly after exposure to sevoflurane (fig 3), and reached a mean concentration of 25 μmol litre^{-1} at the end of operation. Frink and colleagues reported a mean peak plasma fluoride concentration of 29.3 μmol litre^{-1} 2 h after the end of surgical anaesthesia with 1–7 MAC-h of sevoflurane [24]. Similarly, Newman and colleagues found a mean peak fluoride ion concentration of less than 25 μmol litre^{-1} after 50–350 min of sevoflurane anaesthesia (mean exposure 0.8 MAC-h) in 25 patients [66]. The highest individual fluoride concentration recorded in this investigation was 40.4 μmol litre^{-1} [66]. Unlike other fluoride-producing volatile anaesthetics (e.g. methoxyflurane, halothane, enflurane), fluoride concentrations in morbidly obese patients exposed to sevoflurane were no higher than those detected in patients of normal weight [27].

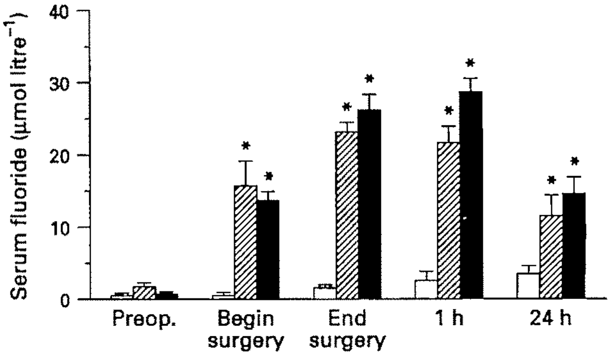

Figure 3 Concentrations of serum fluoride ions (mean, SEM) detected before induction of anaesthesia (Preop.), 30 min after induction (Begin surgery), immediately after the end of anaesthesia (End surgery), and 1 h and 24 h after operation in the propofol–isoflurane (□), propofol–sevoflurane (▨) and sevoflurane–sevoflurane (■) groups. $*P < 0.05$ compared with propofol–isoflurane group. Modified from Smith, Ding and White [76], with permission.

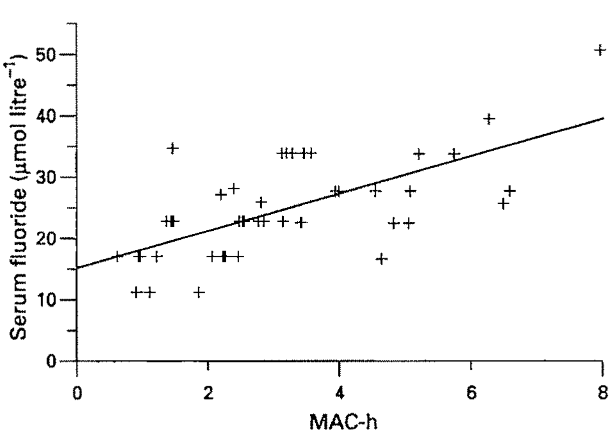

Figure 4 Correlation between serum fluoride ions measured immediately after discontinuation of anaesthesia and anaesthetic exposure in MAC-h for patients receiving sevoflurane for maintenance of anaesthesia ($r^2 = 0.45$). Modified from Smith, Ding and White [76], with permission.

A positive correlation has been demonstrated between peak concentrations of fluoride ions and duration of exposure to sevoflurane (fig. 4). After 1.1 MAC-h of sevoflurane, Shiraishi and Ikeda found that the mean peak serum inorganic fluoride concentration was only 19.3 μmol litre^{-1} [75]. In another study, plasma concentrations of inorganic fluoride were less than 50 μmol litre^{-1} in all patients receiving less than 2 MAC-h of sevoflurane, whereas peak plasma concentrations exceeded 50 μmol litre^{-1} in five patients receiving an average of 4.7 MAC-h [24]. Smith, Ding and White reported a plasma fluoride concentration of 51.4 μmol litre^{-1} after 7.9 MAC-h of sevoflurane [76]. The peak concentration of inorganic fluoride after sevoflurane is similar to that after enflurane anaesthesia [57]. In a volunteer study comparing the effects of prolonged anaesthesia with sevoflurane or enflurane on renal concentration

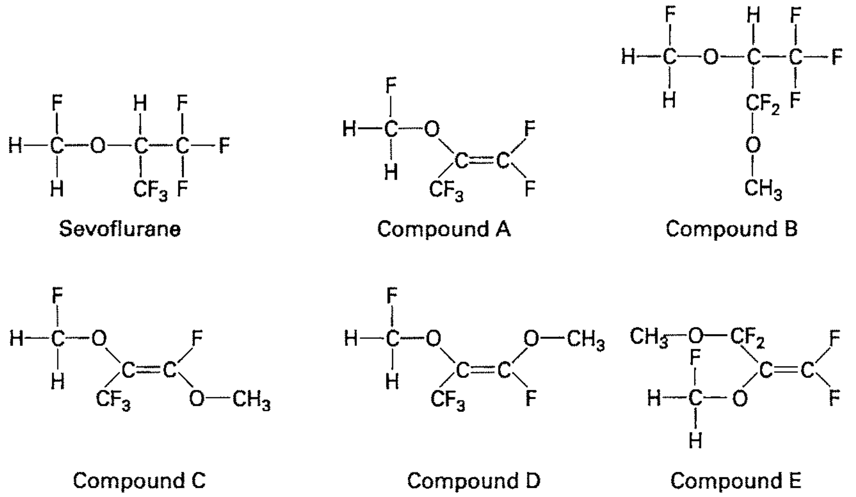

Figure 5 Degradation products of sevoflurane in soda lime under experimental conditions (⩾ 65 °C).

function, the mean peak plasma inorganic fluoride concentration was 47 μmol litre^{-1} after more than 9 MAC-h of sevoflurane anaesthesia [28]. Although three of the seven volunteers had a peak plasma fluoride concentration in excess of 50 μmol litre^{-1}, there was no demonstrable impairment of renal concentrating ability in the sevoflurane group [28]. In contrast, two of the seven volunteers in the enflurane group had reduced maximal urinary osmolality in response to desmopressin (compared with their pre-anaesthesia values) despite a mean peak plasma inorganic fluoride concentration of only 23 μmol litre^{-1} [28]. In another volunteer study involving prolonged anaesthesia, higher peak serum fluoride ions were achieved after 3, 6 and 9 MAC-h of sevoflurane than after similar durations of exposure to enflurane [62]. However, the area under the fluoride concentration–time curves was similar for comparable exposures to either anaesthetic (because of the lower solubility of sevoflurane), and no volunteer demonstrated any impairment of urine concentrating ability [62].

No alterations in urinary enzymes or postoperative renal function were detected after sevoflurane anaesthesia (0.8–2 %) lasting 9–10 h, despite a mean peak serum fluoride concentration in excess of 50 μmol litre^{-1} [56]. In a small ($n = 8$) group of patients exposed to prolonged sevoflurane anaesthesia and in whom peak serum fluoride concentration exceeded 50 μmol litre^{-1}, a slight reduction in urine concentrating ability in response to vasopressin was observed compared with a similar group of patients anaesthetized with isoflurane [34]. However, this difference was not statistically significant and, in addition, patients anaesthetized with sevoflurane had also received more perioperative fluid, which may have affected urine concentrating ability [34]. The nephrotoxic effects of sevoflurane and enflurane have recently been compared in patients with chronically impaired renal function, defined as a serum creatinine concentration of ⩾ 1.5 mg dl^{-1} (130 μmol litre^{-1}) [10]. Sevoflurane and enflurane resulted in peak serum fluoride concentrations of 25 and 13 μmol litre^{-1}, respectively, but neither agent resulted in alterations in postoperative laboratory tests of renal function or in deterioration in renal function [10]. Similar findings were obtained in another preliminary investigation in patients with renal insufficiency (serum creatinine 130–260 μmol litre^{-1}), in whom 0.8–6.5 MAC-h of sevoflurane anaesthesia did not alter serum creatinine or creatinine clearance [53].

It would appear that renal toxicity is not an inevitable consequence of exceeding a "threshold" serum concentration of fluoride ions. Indeed, we must be careful to avoid "applying a fluoride hypothesis developed to explain methoxyflurane nephrotoxicity non-selectively to all anesthetics without supporting data" [47]. The apparent lack of renal toxicity with sevoflurane in humans may be related to its relative insolubility and site of metabolism. Although the rate of *in vitro* hepatic microsomal metabolism of sevoflurane may be similar to that of methoxyflurane, the rapid elimination of sevoflurane reduces the total amount of drug available for *in vivo* metabolism [12], resulting in a rapid decrease in organic fluoride concentration after sevoflurane administration, and probably preventing exposure to fluoride ions for a long enough duration to lead to clinically detectable toxicity [24]. Recent evidence from Kharasch, Hankins and Thummel [46] suggested that intrarenal production of fluoride ions may be more important in the aetiology of methoxyflurane-induced toxicity than peak serum fluoride concentrations [7].

HEPATIC EFFECTS

The other major breakdown product of sevoflurane metabolism is hexafluoroisopropanol, an organic fluoride molecule which is excreted in the urine as a glucuronide conjugate [37, 41, 54]. Although this molecule is potentially hepatotoxic, conjugation of hexafluoroisopropanol occurs so rapidly [48] that clinically significant liver damage seems theoretically impossible [8]. Although the production of both inorganic fluoride ions and hexafluoroisopropanol can be reduced substantially by the selective cytochrome P450 2E1 inhibitor, disulfiram [45], this is unlikely to be a necessary clinical strategy.

INTERACTION WITH CARBON DIOXIDE ABSORBANTS

Another concern with sevoflurane is its interaction with carbon dioxide absorbants. Sevoflurane is absorbed and degraded by both soda lime and Baralyme [2, 29, 52, 79, 84, 87]. When sevoflurane is mixed with soda lime, sealed in a flask and heated, a total of five breakdown products are produced (fig. 5). These have been designated as compounds A, B, C, D and E [8]. However, only compound A (and to a lesser extent compound B) is produced under conditions likely to be encountered clinically. Concern has been raised because these products are toxic in rats. Morio and colleagues determined that the concentration of compound A required to kill 50% of rats (LC_{50}) after 1 h exposure was 1090 ppm and 1050 ppm for males and females, respectively [59]. The LC_{50} for compound A was reduced to approximately 400 ppm after 3 h exposure [31, 59]. The toxicity produced by compound A in rats primarily involves renal, hepatic and cerebral damage.

If it is assumed that compound A produces similarly toxicity in humans, are patients likely to be at significant risk if sevoflurane is delivered from a circle absorber breathing circuit? The evidence suggests that the concentration of compound A achieved in clinical practice is well below the concentration which is toxic to animals. Bito and Ikeda exposed patients to similar concentrations of sevoflurane at various fresh gas flows [3]. Compound A was the only sevoflurane degradation product detected at any of the three fresh gas flow rates examined. The mean maximal concentrations of compound A detected were 19.7 ± 4.3, 8.1 ± 2.7 and 2.1 ± 1.0 ppm at 1, 3 and 6 litre min^{-1}, respectively [3]. The concentration of compound A remained relatively constant between 1 and 3 h of exposure to sevoflurane at all three flow rates [3]. Frink and colleagues examined sevoflurane degradation products during low-flow (770 ml min^{-1}) anaesthesia using either soda lime or Baralyme as the absorbent [29]. All patients received an anaesthetic concentration of sevoflurane for at least 3 h. As in the previous study, compound A was the only breakdown product detected within the circle system. The mean maximal concentration of compound A was 8.2 ± 2.7 ppm when soda lime was used as the absorbant and 20.3 ± 8.7 ppm with Baralyme [29]. The highest concentration of compound A detected in any individual patient was 15.2 ppm with soda lime and 60.8 ppm with Baralyme [29]. Concentrations of compound A increased progressively over the first 4 h of anaesthesia and then declined with continuing exposure to sevoflurane [29]. Similar findings were obtained in another study using even lower gas flows (350 ml min^{-1}) in association with soda lime, in which 17 patients received an average of 2.3 MAC-h of sevoflurane [88]. The mean concentration of compound A was found to be 6 ppm, and the highest recorded value was 22 ppm [88]. After more prolonged exposure, the mean maximum concentration of compound A was 7.6 ± 1.0 ppm, with the highest individual value of 14.1 ppm occurring after 5 h exposure to sevoflurane at a flow of 5 litre min^{-1} [40]. Even after 9 h exposure to 1–1.2 MAC of sevoflurane anaesthesia at 5 litre min^{-1} in volunteers, peak compound A concentrations averaged only 7.6 ± 1.0 ppm, with the maximal concentration occurring after 2 h and remaining constant or declining thereafter [25]. During prolonged exposure (up to 18 h) at low fresh gas flows (1 litre min^{-1}), the mean peak concentrations of compound A achieved were 23.6 ppm and 32.0 ppm using soda lime and Baralyme, respectively [4]. The highest concentration of compound A detected in any patient was 37.4 ppm when soda lime was used as the absorbant, and 41.2 ppm with Baralyme. Compound A concentrations peaked in the first 2–4 h, remained relatively constant from 4–10 h and then declined with continuing anaesthesia [4]. Compound B was detected in small quantities ($\leqslant 0.2$ ppm) in two of the patients in the Baralyme group, but was not found when soda lime was used as the absorbant for prolonged anaesthesia [4].

In a totally closed system, a mean concentration of 19.5 ± 5.4 ppm of compound A was detected after 1 h [2]. The concentration of compound A remained relatively constant over the next 4 h and subsequently decreased slightly with continuing sevoflurane anaesthesia. The highest concentration detected in any patient was 30 ppm [2]. Compound B was also detected in 70% of patients during closed circuit anaesthesia, although the concentration did not exceed 1.5 ppm in any patient [2].

Degradation of sevoflurane appears to be temperature-dependent [59, 79, 87]. The higher concentration of compound A which is produced by interaction with Baralyme probably occurs as a consequence of the higher temperature attained in this absorbant compared with soda lime [29]. Similarly, increased minute ventilation and greater carbon dioxide production both increase absorbant temperature, and hence production of compound A [21]. Chilling soda lime by immersing the carbon dioxide absorbant canister into an ice bath prevented formation of compounds B, C and D and significantly reduced the formation of compound A in a model lung [70]. The production of compound A by interaction with Baralyme is reduced by the presence of water, and also decreases as Baralyme becomes exhausted [87]. These factors may also limit sevoflurane breakdown in clinical practice. Finally, the concentration of compound A is highest during low-flow anaesthesia, and decreased by increasing fresh gas flow [3]. The use of higher flow rates probably increases the washout of breakdown products, while reducing rebreathing and producing lower absorbant temperatures [18].

The amount of compound A produced under a variety of clinically relevant circumstances has always been substantially lower than that which produces acute toxicity in animals. Compound B is somewhat less toxic than compound A [59], and is formed only in a totally closed anaesthetic breathing system or after prolonged anaesthesia at very low flows. However, the concentration recorded is orders of magnitude below the toxic concentration. A further concern has been raised recently because of the finding that exposure of rats to compound A at concentrations of > 50 ppm results in renal corticomedullary tubular necrosis [31]. Clearly, this concentration is much closer to that which has been achieved clinically. However, the natural history and clinical relevance of these histological findings are unknown, as all rats in this study were killed within 4 days of exposure to compound A. Indeed, the renal damage appeared to be less extensive 4 days after exposure to compound A than on the first day, suggesting that the lesions were at least partially reversible [31]. Furthermore, it should also be mentioned that the objectivity of this investigation has been questioned by the editor of the journal in which the article was published [71]. A follow-up study by the same investigative group showed that renal injury in rats required at least 200 ppm when exposure to compound A was limited to 1 h [42]. It is not known whether compound A has a similar pattern of toxicity in humans [17].

Sevoflurane has now been administered to about 1 million patients in Japan without reports of serious adverse reactions or significant hepatic or nephrotoxicity [9, 60]. In addition, no evidence of renal injury or impairment has been detected in any of the published studies of sevoflurane anaesthesia in humans [10, 24, 28, 50, 53, 75, 76]. The effects of multiple exposures to sevoflurane anaesthesia have been evaluated recently in primates [77]. Although subtle increases in hepatic enzymes were detected, these were less marked than the increase caused by multiple exposures to other volatile anaesthetics. No evidence of histopathological toxicity was detected after 24 exposures to 3–5 MAC-h of sevoflurane in cynomolgus monkeys [77]. Thus the toxicity of sevoflurane would appear to be more of a theoretical than a clinical problem. However, with worldwide clinical exposure to this volatile anaesthetic, any significant toxic effects should become apparent in the near future.

Conclusion

Sevoflurane is not the "ideal" volatile anaesthetic. However, its low blood:gas solubility in combination with minimal airway irritation allows for smooth and rapid induction of anaesthesia. Although these properties may be of benefit to adult patients, sevoflurane is likely to become an even more popular choice for paediatric anaesthesia. Rapid recovery compared with halothane, and smooth and calm emergence are also advantageous in children. For adults, the relative insolubility of sevoflurane should facilitate control of anaesthetic depth during the maintenance period, even at low gas flows. Combined with conventional vaporizer technology and a familiar concentration range, anaesthetists should have little difficulty in using sevoflurane as a maintenance anaesthetic. Rapid emergence from anaesthesia with sevoflurane facilitates more efficient patient turnover and may confer additional benefits after more prolonged anaesthesia.

While sevoflurane diverges from the mythical ideal anaesthetic in its degree of metabolism and potentially toxic byproducts, the body of experimental and clinical evidence to date suggests that sevoflurane is safe when administered under the usual clinical conditions. Further investigations may be required before sevoflurane can be declared safe under *all* circumstances (e.g. low-flow or closed circuit anaesthesia, in the presence of chronic renal insufficiency). For the present, it is wise to caution against the use of sevoflurane in patients with significantly impaired renal function [58] and for prolonged anaesthesia at very low total fresh gas flows (< 2 litre min^{-1}). Indeed, the USA product licence for sevoflurane contains just such restrictions, although similar limitations have not been applied in the UK.

The relative cost of sevoflurane is unknown at present. Sevoflurane can be administered safely at low gas flows (2–3 litre min^{-1}), and its low solubility will assist in adjusting its delivery. Further investigations are required to determine the most beneficial and cost effective use of sevoflurane. Nevertheless, the long-awaited arrival of this volatile agent should prove to be a most useful addition to clinical anaesthesia.

SHORT COMMUNICATIONS

Effect of neuromuscular block on depth of anaesthesia as measured by the auditory evoked response

C. E. RICHMOND, A. MATSON, C. THORNTON, C. J. DORÉ AND D. E. F. NEWTON

Summary

In a double-blind, randomized, controlled, prospective study, we have investigated the effects of vecuronium and laryngoscopy on the auditory evoked response (AER) of the electroencephalogram (EEG) in 40 ASA I and II patients under steady state anaesthesia. After stable anaesthesia had been achieved with 1.0 MAC of isoflurane and nitrous oxide in oxygen, patients were allocated randomly to receive two separate doses of vecuronium 0.05 mg kg^{-1} or saline. The AER was recorded before and after each dose and then after 20-s laryngoscopy in each group to determine any changes in the early cortical components of the AER waveform (Pa and Nb). There were no statistically significant changes between the vecuronium and saline groups. However, there was a statistically significant increase in mean Pa amplitude of 36% ($P = 0.008$) and a reduction in mean Nb latency of 6% ($P = 0.05$) after laryngoscopy in both the paralysed and unparalysed groups, and these changes did not differ significantly between groups. There were correspondingly significant haemodynamic responses to laryngoscopy in both groups. We conclude that neuromuscular block with vecuronium does not affect depth of anaesthesia as measured by the AER in either stimulated or unstimulated patients. In addition, we have demonstrated clearly the arousal effect of laryngoscopy on the AER. (*Br. J. Anaesth.* 1996; **76**: 446–448)

Key words

Neuromuscular block. Neuromuscular block, vecuronium. Larynx, laryngoscopy. Monitoring, evoked potentials. Anaesthesia, depth.

Neuromuscular block was thought to decrease anaesthetic requirements in humans [1, 2], but recent investigations have not confirmed this [3, 4]. We have used the auditory evoked response (AER), which reflects the level of anaesthetic depth [5], to investigate this effect. The Pa and Nb waves from the primary auditory cortex show graded changes in amplitude and latency with increasing concentrations for a wide range of anaesthetics [5]. When a stimulus is applied to a patient during steady state anaesthesia, for example skin incision [5], Pa and Nb amplitudes increase suggesting cortical arousal. The AER therefore reflects both the level of anaesthesia and the balance between anaesthesia and stimulation in anaesthetized patients. In this study, we have examined the effect on the AER of neuromuscular block and laryngoscopy during a period after induction of anaesthesia.

Method and results

With the approval of the Harrow Research Ethics Committee, written informed consent was obtained from 40 ASA I or II patients undergoing surgery. We chose patients only if neuromuscular block and ventilation via a laryngeal mask airway were appropriate. Patients were premedicated with temazepam 10 mg orally, 1 h before operation. Before induction, full monitoring was commenced and heart rate, oxygen saturation, arterial pressure and neuromuscular block were recorded continually. The AER was monitored as described previously [6]. Anaesthesia was induced with fentanyl 1 μg kg^{-1} and propofol 2–3 mg kg^{-1}. A laryngeal mask was inserted and the patient's lungs ventilated with 66% nitrous oxide in oxygen and isoflurane to an end-tidal concentration of 0.35–0.4% (MAC 1.0) and an end-tidal carbon dioxide concentration of 4.5–5.0% (Datex Capnomac). Patients were allocated randomly, using sealed envelopes, to receive two doses of either vecuronium 0.05 mg kg^{-1} or a similar volume of saline. The two groups were similar; there were seven females and 13 males with a mean age of 45.6 yr in the vecuronium group and 10 females and 16 males with a mean age of 46.8 yr in the saline group.

After a 10-min stabilization period, the AER was monitored for a period of 1024 sweeps before and after each dose of vecuronium or placebo and before and after stimulation by laryngoscopy for 20 s. Pa and Nb amplitudes and latencies were determined at

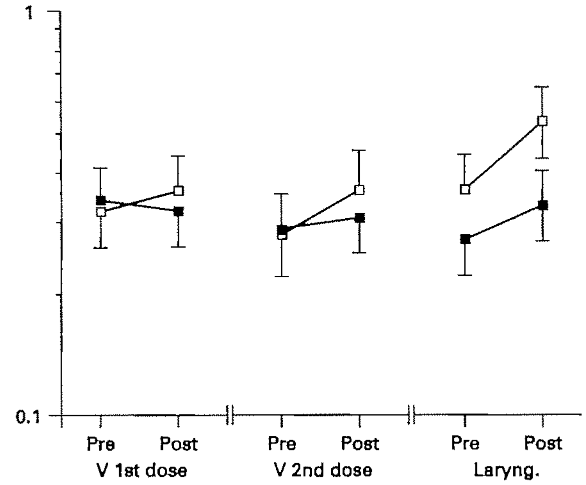

Figure 1 Mean (95 % confidence intervals) Pa amplitudes before and after each dose of vecuronium (V) (■) or saline (□), and before and after laryngoscopy (laryng.).

each time and analysis of variance was performed on $\log_{10}$ transformed data. The effect of drug or placebo was assessed between patients, and the effect of the time when it was given and the interaction between drug and time were assessed within patients. The probability level at which the null hypothesis was rejected was $P < 0.05$.

Overall, laryngoscopy caused a highly significant increase in Pa amplitude of 36 % ($P = 0.008$) and a reduction in Nb latency of 5.7 % ($P = 0.05$). This powerful stimulatory effect was not modified significantly by vecuronium compared with saline (fig. 1 shows the mean and 95 % confidence intervals (CI) for Pa amplitude). In the vecuronium group, mean Pa amplitude (µV) before laryngoscopy was 0.27 (95 % CI 0.22–0.34), increasing to 0.33 (0.27–0.4) after laryngoscopy. In the saline group, equivalent values were 0.36 (0.3–0.44) before and 0.53 (0.43–0.64) after laryngoscopy. Nb latency (mS) equivalent values in the vecuronium group were 62.2 (58.5–66.1) before and 59.0 (55.5–62.6) after laryngoscopy and in the saline group, 54.8 (51.6–58.2) before and 51.3 (48.3–54.5) after laryngoscopy.

In unstimulated patients, before laryngoscopy, there was no significant effect of vecuronium on any AER variable compared with the saline group. With respect to the first dose of vecuronium or saline, mean Pa amplitudes (µV) were: 0.34 (0.28–0.41) before vecuronium, 0.32 (0.26–0.39) after vecuronium, 0.32 (0.26–0.39) before saline, 0.36 (0.29–0.44) after saline. Equivalent values for Nb latency (mS) were: 57.5 (54.1–61.1) before vecuronium, 57.2 (53.9–60.8) after vecuronium, 56.4 (53.1–59.9) before saline, 57.5 (54.1–61.1) after saline. With respect to the second dose of vecuronium or saline, mean values for Pa amplitude were: 0.29 (0.23–0.35) before vecuronium, 0.31 (0.25–0.38) after vecuronium, 0.28 (0.23–0.35) before saline, 0.36 (0.3–0.45) after saline. Equivalent values for Nb latency (mS) were 62.1 (58.4–66.0) before vecuronium, 60.6 (57.0–64.3) after vecuronium, 56.8 (53.5–60.4) before saline, 57.4 (54.1–61.0) after saline.

The haemodynamic changes with laryngoscopy were also highly significant in both groups. Mean changes in heart rate was 6.6 (SEM 1.9) beat min^{-1} for the vecuronium group and 8.2 (1.9) beat min^{-1} for the saline group, from an average baseline of 58 beat min^{-1} ($P < 0.001$). Mean changes in systolic arterial pressure was 16.6 (SD 2.7) mm Hg in the vecuronium group and 18.5 (3.4) mm Hg in the saline group from an average baseline value of 95 mm Hg ($P < 0.001$). There was no statistically significant difference between the vecuronium and saline groups.

Comment

There was no clinically significant effect on the AER when vecuronium was given during steady state anaesthesia in unstimulated patients. Forbes, Cohen and Eger demonstrated a 25 % reduction in halothane requirements in humans after administration of pancuronium 0.1 mg kg^{-1} [1]. They suggested that pancuronium reduced MAC by abolishing muscle spindle afferent input to the reticular activating system, causing cortical depression. All neuromuscular blocking agents should reduce anaesthetic requirements to the same degree at equipotent doses. In this study, we should have seen a measurable change in the AER but we did not. Fahey and colleagues were also unable to find a change in the MAC of halothane in patients given pancuronium 0.1 mg kg^{-1}, vecuronium 0.1 mg kg^{-1} or atracurium 0.5 mg kg^{-1} [3]. Sessler, Olofsson and Chow, using frequency of spontaneous lower oesophageal contractions as a measure of anaesthetic depth, showed that the MAC of halothane in patients paralysed with vecuronium 0.1 mg kg^{-1} did not differ from that in unparalysed patients [4]. Schwartz, Navedo and Berman have shown that pancuronium 0.1 mg kg^{-1} administered to dogs given isoflurane, caused an increase in the percentage of the EEG that was isoelectric [2] compared with burst suppression; this was dose-related and reversible. They also suggested that reduced proprioceptive afferent activity caused the cortical depression.

In contrast with the effect of vecuronium, we have demonstrated that laryngoscopy produced lightening of depth of anaesthesia as measured by the AER. This effect was independent of the presence of neuromuscular block and coincided with the haemodynamic response to laryngoscopy.

Comparison of ondansetron and prochlorperazine for the prevention of nausea and vomiting after adenotonsillectomy†

A. A. VAN DEN BERG

Summary

This study has compared the incidences of nausea, vomiting and headache after ondansetron 0.06 mg kg^{-1} i.v., prochlorperazine 0.2 mg kg^{-1} i.m. and prochlorperazine 0.1 mg kg^{-1} i.v. given during induction of general anaesthesia to 282 patients undergoing adenotonsillectomy. The cardiovascular effects of the drugs were similar. After operation, nausea *per se* and vomiting *per se* occurred with similar frequency, in between 6% and 11% and 11% and 19%, respectively, in each test group. Nausea and vomiting in the same patient was reduced from 29% to 2% by i.v. ondansetron ($P < 0.0005$) and to 3% by i.m. prochlorperazine ($P < 0.0005$), and appeared to be less severe in these groups. Headache was most frequent after i.v. ondansetron (35%: $P < 0.05$), but occurred with similar frequency after i.m. prochlorperazine (32%) and i.v. prochlorperazine (29%). (*Br. J. Anaesth.* 1996; **76**: 449–451)

Key words

Pharmacology, ondansetron. Pharmacology, prochlorperazine. Vomiting, antiemetics. Vomiting, nausea. Surgery, otolaryngological.

Retching and vomiting after tonsillectomy are undesirable as they aggravate pain and may predispose to haemorrhage. The incidence of postoperative vomiting after adenotonsillectomy in this institution, where many patients undergoing tonsillectomy are adults, is about 30% [1]. Studies on the prophylactic use of antiemetics have revealed that prochlorperazine 0.2 mg kg^{-1} i.m. or 0.1 mg kg^{-1} i.v. is more effective than either metoclopramide 0.15 mg kg^{-1} orally or i.v., or droperidol 0.037 mg kg^{-1} i.v. [2]. While ondansetron 0.06 mg kg^{-1} i.v. has proved superior as a prophylactic antiemetic compared with metoclopramide [3] and droperidol [4], the relative efficacies of ondansetron and prochlorperazine have not been investigated.

This study has compared the efficacy of ondansetron 0.06 mg kg^{-1} i.v., prochlorperazine 0.2 mg kg^{-1} i.m. (as per licensing regulations in Europe) and prochlorperazine 0.1 mg kg^{-1} i.v. (as per licensing regulations in North America) [5]. Prochlorperazine given i.v. may cause hypotension or hypertension [5] and ondansetron may cause headache, and therefore this study also assessed the effects immediately after administration on heart rate and arterial pressure and, after operation, on headache.

Methods and results

The study was designed with respect to experience gained during studies of antiemetics in this hospital [2]. Here, non-Arabic-speaking British and Filipino nurses care for patients in the postoperative recovery and surgical wards. Language constraints, combined with the problem of eliciting subjective complaints from children, precluded queries regarding nausea in the recovery ward.

With Hospital Ethics Committee approval and parent (or guardian) consent, 282 ASA I–II Saudi nationals of all ages presenting for routine tonsillectomy (with or without adenoidectomy) were allocated randomly on arrival in the operating room to receive saline (as control) or one of the three antiemetic formulations with induction of anaesthesia.

Premedication comprised temazepam 0.5 mg kg^{-1} as elixir or capsules given orally, and EMLA cream applied to the dorsum of the left hand, 1.5 h before surgery. In theatre, routine monitoring devices (electrocardiogram, non-invasive automatic arterial pressure device, oxygen saturation monitor) were applied, an i.v. cannula inserted and preoxygenation commenced. Anaesthesia was induced with thiopentone 4.0 mg kg^{-1}, atracurium 0.6 mg kg^{-1} and nalbuphine 0.2 mg kg^{-1}, after which the appropriate test drug was administered (ondansetron 0.06 mg kg^{-1} i.v., prochlorperazine 0.2 mg kg^{-1} i.m., prochlorperazine 0.1 mg kg^{-1} i.v. or saline 1–2 ml). The larynx was sprayed with aerosolized lignocaine (10%) and a tracheal tube inserted. Heart rate and arterial pressures were recorded 1, 4, 7 and 10 min after tracheal intubation to assess the immediate cardiovascular effects of the test drugs.

Anaesthesia was maintained with 0.8% isoflurane and 67% nitrous oxide in oxygen. Respiration was controlled using an Ohmeda AV7700 ventilator with standardized respiratory variables and the Bain circuit to maintain an end-tidal carbon dioxide concentration of 4.5–5.0 kPa (Hewlett Packard 47210A Capnometer). Ringer's lactate or glucose–saline was infused during operation at a rate of 8 ml kg^{-1} h^{-1} and continued after operation at a rate of 2.0 ml kg^{-1} h^{-1} until oral fluids were tolerated. Dur-

ing surgery, after the initial 1,-, 4-, 7- and 10-min recordings of heart rate and arterial pressure, any increases in heart rate or increases in systolic arterial pressure $> 20\%$ of pre-induction values were treated with esmolol 2.0–3.0 mg kg^{-1} i.v. At the end of anaesthesia, residual neuromuscular block was antagonized with neostigmine 0.035 mg kg^{-1} and atropine 0.017 mg kg^{-1}. Nalbuphine 0.1 mg i.v. or 0.2 mg kg^{-1} i.m., paracetamol 10 mg kg^{-1} and prochlorperazine 0.2 mg kg^{-1} i.m. were prescribed to treat postoperative pain and sickness at the discretion of nursing staff.

The test drugs were coded and, to ensure blindness, all documentation was appropriately endorsed. Before induction of anaesthesia, note was made of patient details, antiemetic group, heart rate (HR), and systolic (SAP), diastolic (DAP) and mean (MAP) arterial pressures. At termination of surgery and anaesthesia, duration of surgery was noted and any vomiting or retching immediately after extubation. Nurses in the recovery ward recorded details of vomiting, retching, extrapyramidal movements, antiemetic and analgesic requirements. During the first 24-h postoperative period, note was made by ward nurses of nausea, retching, vomiting or extrapyramidal reactions, and of antiemetic and analgesic drugs given. On the morning after surgery the author, also blinded to the test drug, visited the ward to review drug, temperature, fluid balance and nursing records. In addition, each patient or, in the case of younger children, their relative or guardian, was interviewed with respect to nausea, retching, vomiting and headache.

Data were analysed using analysis of variance, Student's t and chi-square tests with Yates' correction, where appropriate. To compare the effects on HR and arterial pressures, the areas under the time curves for HR, SAP, DAP and MAP were computed for each patient using the trapezoidal rule, and differences between drugs tested using two-way analysis of variance and the technique of Scheffé [6]. Chi-square tests were used to compare nausea, vomiting and postoperative drug requirements. The effects of the antiemetics in modifying the severity of vomiting were assessed by comparing the numbers of single and multiple vomiters in each group and the times when nausea, vomiting and retching occurred. Retching and vomiting were analysed collectively.

Of the 282 patients studied, 33 were aged 3 yr or less, 129 were aged 4–12 yr and 120 were older children or adults. One child refused premedication, but was included in the study and received i.v. ondansetron. The study groups were comparable in characteristics and need for analgesia and antiemetics in the recovery and surgical wards. No extrapyramidal reactions were reported and one patient in each group vomited in the recovery ward (table 1).

Analysis of HR and arterial pressures did not reveal any differences associated with the use of the test drugs.

In approximately 20 children in each group, communication difficulties prevented elucidation of nausea and headache in the postoperative ward. Where communication was possible, nausea *per se* occurred with similar frequency, in between 6% and 11% of patients, in each test drug group. Vomiting *per se*, without an accompanying complaint of nausea, also occurred with similar frequency, in between 11% and 19% of patients, in each test group. The incidences of the dual complaint of nausea and vomiting were also similar in those given placebo and i.v. prochlorperazine (29% and 21%, respectively), but greatly reduced (to 3% and 2%, respectively) in those given i.m. prochlorperazine and i.v. ondansetron ($P < 0.0005$, chi-square, both comparisons). The latter treatments also significantly modified the severity of vomiting by reducing the number of patients experiencing multiple vomits. However, the time to onset of nausea or vomiting was similar in all groups.

Those patients receiving saline (control) had the lowest incidences of postoperative headache (16 %), while those receiving i.m. prochlorperazine, i.v. prochloraperazine and i.v. ondansetron had higher, but similar, incidences (32 %, 29 % and 35 %, respectively). However, only the ondansetron–placebo difference was significant ($P < 0.05$).

Comment

This double-blind, controlled study was conducted to compare: the antiemetic efficacies of ondansetron 0.06 mg kg^{-1} i.v., prochlorperazine 0.2 mg kg^{-1} i.m. and prochlorperazine 0.1 mg kg^{-1} i.v., given during induction of anaesthesia for in-patient adenotonsillectomy; the immediate effects of these drugs on HR and arterial pressure; and the effects on the incidence of headache in the postoperative period.

Neither prochlorperazine nor ondansetron reduced the incidence of postoperative nausea *per se* or vomiting *pe se*. I.m. prochlorperazine and i.v. ondansetron markedly reduced the number of patients experiencing nausea associated with vomiting, and also reduced the severity of vomiting in those who did vomit. Absence of PONV occurred most frequently in those given i.v. ondansetron.

The test drugs produced no adverse cardiovascular effects within 10 min of administration, but ondansetron was associated with the highest incidence of postoperative headache.

A problem in paediatric anaesthesia is the propensity of children to develop extrapyramidal reactions if given an antiemetic drug (such as metoclopramide, a phenothiazine or droperidol) which has an anti-dopaminergic mode of action. Allied to the risk of inducing changes in arterial pressure that may follow i.v. injection of a phenothiazine [5], this rationalized the testing of the smaller dose of i.v. prochlorperazine (0.1 mg kg^{-1}, equal to 50 % of the recommended i.m. dose [5]). While no adverse cardiovascular or extrapyramidal events occurred after either prochlorperazine treatments, the smaller dose of prochlorperazine given i.v. was conspicuous in not alleviating sickness.

Ondansetron exerts its effect via inhibition of 5-hydroxytryptamine, but may thereby cause headache. Although headache occurred most commonly in those given ondansetron (35 %), surprisingly similar incidences were reported in those given i.m. prochlorperazine (32 %) and i.v. prochlorperazine (29 %). Headache is, however, a less debilitating and hazardous morbidity after adenotonsillectomy than nausea and vomiting and should not inhibit the use of ondansetron in these patients.

Smaller children have greater bupivacaine plasma concentrations after ilioinguinal block

T. SMITH, P. MORATIN AND H. WULF

Summary

We have measured plasma concentrations of bupivacaine after ilioinguinal block in children of different sizes. We studied 14 children with weights 10–15 kg and 17 children with weights 15–30 kg. Each child received 0.5% bupivacaine 0.25 ml kg^{-1} (1.25 mg kg^{-1}) (Carbostesin, Astra, Germany). Venous blood was obtained before the block (control) and at 5, 10, 15, 20, 30 and 60 min after block. Mean maximal concentration in the 10–15-kg group (1.5 (SD 0.9)mg litre^{-1}, range 0.43–4.0 mg litre^{-1}, at 18 (5) min) was significantly higher ($P < 0.05$) than that in the 15–30-kg group (0.9 (0.3)mg litre^{-1} range 0.35–1.34 mg litre^{-1}, at 16 (5) min). In the 10–15-kg group, unexpectedly high (up to 4 mg litre^{-1}) bupivacaine concentrations were observed and often concentrations remained high (> 2 mg litre^{-1}) at 60 min. We conclude that smaller children appear to differ in the pharmacokinetic handling of bupivacaine. The maximum safe plasma concentration of bupivacaine in small children, although not clearly established, is likely to be approximately 4 mg litre^{-1}. We recommend, therefore, that a dose of bupivacaine 1.25 mg kg^{-1} should not be exceeded in the perioperative period when performing ilioinguinal block in children < 15 kg in weight. (*Br. J. Anaesth.* 1996; **76**: 452–455)

Ilioinguinal block with bupivacaine is used widely in children undergoing inguinal hernia or orchidopexy surgery. Some blocks are ineffective and often children require bilateral surgery; in these children repeated or bilateral blocks may be indicated. The question of how safely additional ilioinguinal blocks can be performed in small children requires knowledge of bupivacaine plasma concentrations after a single block. Stow and colleagues [1] and Epstein and colleagues [2] reported reassuringly low concentrations in children. However, their studies were small and failed to consider the possible differences related to child size. In this study, we have compared plasma concentrations of bupivacaine after ilioinguinal block in two groups of children: 10–15 kg and 15–30 kg in weight.

Methods and results

After obtaining Ethics Committee approval and written informed consent from the parents, we studied 14 children weighing 10–15 kg and 17 children weighing 15–30 kg. All children were ASA I and not receiving any medications before hospital admission. All were undergoing elective surgery for inguinal hernia, hydrocele or orchidopexy.

Premedication comprised EMLA cream over a prominent vein and midazolam 0.3 mg kg^{-1} rectally. An upper limb vein was cannulated, atropine 0.01 mg kg^{-1} given and anaesthesia induced with methohexitone 1–2 mg kg^{-1}. Neuromuscular block for intubation was produced with suxamethonium 1.5 mg kg^{-1}. After intubation, anaesthesia was maintained with 0.5–2 % isoflurane and 50–70 % nitrous oxide in oxygen. Another vein was cannulated in the opposite upper limb to the first for blood sampling. An ilioinguinal block with 0.5 % bupivacaine 0.25 ml kg^{-1} (Carbostesin, Astra, Germany) was then performed. Using a 0.55-mm diameter Sprotte needle (Pajunk, Germany), 80 % of bupivacaine was injected (after negative aspiration for blood) two finger breadths of the child medial to the anterior superior iliac spine at the depth where loss of resistance occurred as the needle pierced the external oblique fascia (here the ilioinguinal and iliohypogastric nerves run between the external oblique and internal oblique muscles). The remaining 20 % was injected s.c. in lines radiating inferiorly and medially from the injection point (to block cutaneous nerve fibres missed by ilioinguinal nerve block).

The child then underwent surgery and blood samples were obtained at 5, 10, 15, 20, 30, 45 and 60 min after the block. K-EDTA tubes were used and blood was centrifuged, plasma extracted and frozen at −20 °C until analysis.

Plasma concentrations of bupivacaine were measured by high pressure liquid phase chromatography, as described previously [3].

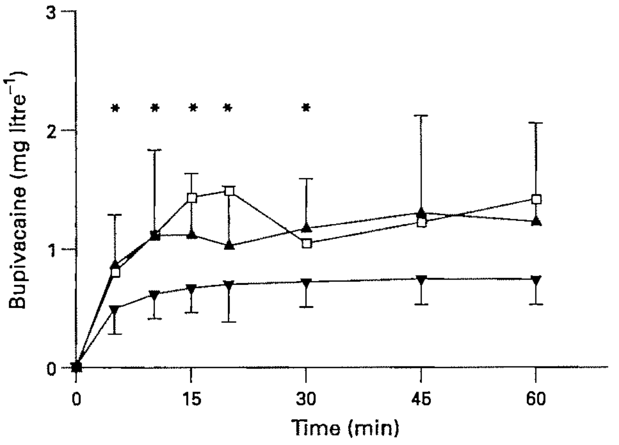

Figure 1 Bupivacaine plasma concentrations after ilioinguinal block with 0.5 % bupivacaine 0.25 ml kg^{-1} (1.25 mg kg^{-1}) in the 10–15 kg ($n = 14$) (▲) and 15–30 kg ($n = 17$) (▼) groups. □ = Values of an individual 12-kg child, showing a second increase in plasma bupivacaine concentration coinciding with emergence from anaesthesia (extubation at 47 min). *$P < 0.05$ between the two groups.

With GraphPad Prism 1.03 software and an IBM compatible PC, ANOVA, linear regression analysis and the Mann–Whitney *U* test were used to evaluate the data. $P < 0.05$ was considered significant. Data are expressed as mean (SD).

In the 10–15-kg group, mean maximum plasma bupivacaine concentration was 1.5 (SD 0.9) mg litre^{-1} (range 0.43–4.0 mg litre^{-1}) at a mean time of 18 (5) min after the block (fig. 1). The corresponding values for the 15–30-kg group were 0.9 (0.3) (0.35–1.34) mg litre^{-1} at 16 (5) min. The difference in maximum plasma concentration observed between the two weight groups was significant ($P < 0.05$), as were the differences at 5, 10, 15, and 30 min ($P < 0.05$). Four of the 10–15-kg children had maximum concentrations exceeding 2 mg litre^{-1} whereas none of the larger children exceeded this value.

There were no complications and, in particular, no side effects attributable to systemic toxicity of bupivacaine.

Comment

Our bupivacaine dose of 1.25 mg kg^{-1} was considerably less than the maximum recommended dose for peripheral nerve blocks in children of 2 mg kg^{-1} [4, 5]. Despite this, the 10–15-kg group had unexpectedly high plasma bupivacaine concentrations, the highest bordering on the generally accepted toxic range for adults of > 4 mg litre^{-1} [6, 7]. In contrast, concentrations in the 15–30-kg group were low, consistent with the results of previous studies by Stow and colleagues [1] and Epstein and colleagues [2]. Stow and colleagues, using 1.25 mg kg^{-1}, reported a mean peak concentration of 0.79 mg litre^{-1} at 22.3 min in children with a mean weight of 20 kg; the highest individual concentration observed was not reported. Epstein and colleagues, using 2 mg kg^{-1}, reported a mean concentration of 1.35 mg litre^{-1} at 26 min in 14 children with a mean weight of 18.6 kg; the highest observed concentration was 2.23 mg litre^{-1}.

Our study, and those of Stow and Epstein, showed that plasma concentrations may be near their maximum even 1 h after the block. This is different from the rapid decrease in bupivacaine plasma concentrations observed in adult studies [8–11]. Interestingly, in some cases we observed a second peak of plasma bupivacaine concentration coinciding with the end of anaesthesia (see fig. 1); this was probably the result of increased local anaesthetic absorption resulting from the hyperdynamic circulation associated with emergence from anaesthesia and awake extubation.

There are three important questions arising from this study. First, what are the possible causes for the observed differences between the two sizes of children? There are three possibilities: (i) more rapid absorption because of increased cardiac output in relation to body mass; (ii) decreased tissue uptake—Mather, Long and Thomas [12] observed that during the first 30 min, tissue uptake is much more important than metabolism in determining bupivacaine venous concentration; (iii) decreased drug metabolism—bupivacaine, in common with other amide local anaesthetics, is metabolized almost completely in the liver before excretion [13]. Infants have reduced microsomal enzyme metabolism [14, 15] and elimination half-life is prolonged. These differences are greatest in neonates, and therefore the likelihood of high bupivacaine plasma concentrations after ilioinguinal block is probably even higher in this group than in our 10–15-kg group.

It is possible that administration of methohexitone could have decreased bupivacaine metabolism in the smaller children. Both drugs are metabolized in the liver but detailed knowledge of their metabolism is lacking [13, 16–18] and there are no data on possible interactions.

We believe that the probability of error in dose causing high plasma bupivacaine concentrations in our 10–15-kg group is very small, as all doses were checked by an observer. The wide range of maximum concentrations in the 15–30-kg group is consistent with other studies of plasma concentration of bupivacaine after local block [1, 2, 9–11]. The range in the 10–15-kg group was even greater; this could reflect differences in maturation of the children in terms of bupivacaine pharmacokinetics, and also the variable haemodynamics in such small children could be important.

Second, what concentration of plasma bupivacaine is safe in small children? The generally accepted toxic range for adults is an arterial plasma concentration exceeding 4 mg litre^{-1}. This implies that the acceptable venous plasma concentration is less than 4 mg litre^{-1}, as arterial bupivacaine concentrations are consistently higher than corresponding venous concentrations [9]. The value of 4 mg litre^{-1} was proposed by Jordfeldt and colleagues [6] in 1968 and was based on toxicity studies in dogs. Subsequently, Moore, Balfour and Fitzgibbons [7] reported a case history in which an arterial bupivacaine plasma concentration of 5.1 mg litre^{-1} caused convulsions which ceased when the concentration approached 3.5 mg litre^{-1}.

However, Denson and colleagues [19] have shown that patients may be asymptomatic with venous plasma bupivacaine concentrations exceeding 6 mg $litre^{-1}$, but symptomatic with concentrations as low as 2.1 mg $litre^{-1}$. In the study of Denson and colleagues, differences may have been caused by variations in bupivacaine-binding plasma proteins. Normally, approximately 92 % of plasma bupivacaine is protein bound, mainly to α_1 acid glycoprotein and albumin [20]. It is free bupivacaine that causes toxicity, a venous concentration of 0.24 mg $litre^{-1}$ probably represents the threshold in adults [19]. Competition for plasma protein binding sites by other drugs may increase the free plasma bupivacaine concentration and thus risk of toxicity. Atropine [21] and diazepam [22] (and therefore probably other benzodiazepine drugs) have no effect on bupivacaine plasma protein binding. However, diphenylhydantoin, quinidine, pethidine, and desipramine have all been shown to increase the free fraction of plasma bupivacaine [21].

The rate of increase in local anaesthetic plasma concentration may be more important than the actual concentration [23]. Sedative medications (and general anaesthetics) may increase considerably the threshold for CNS toxicity for local anaesthetic agents [6].

Children and adults may differ in sensitivity to bupivacaine. In animal studies, immature pigs [24] and sheep [25] have been found to be more resistant to bupivacaine toxicity, but young mice are more prone to CNS toxicity than adult mice [26]. The only data related to human children originate from the case reports of McClosky, Huan and Deshpande [28] of systemic toxicity after continuous caudal bupivacaine infusions. A 3.9-kg neonate experienced cardiovascular toxicity with a plasma bupivacaine concentration of 5.6 mg $litre^{-1}$. An 8-yr-old, 45-kg child developed fits with a concentration of 6.6 mg $litre^{-1}$. These reports suggest that it is wise not to exceed a venous concentration of 4 mg $litre^{-1}$ in children. Our findings suggest that while bilateral or repeat blocks are probably safe in children exceeding 15 kg, they could lead to plasma bupivacaine concentrations in the toxic range in smaller children. Neonates have been shown to have reduced protein binding of bupivacaine with the free fraction accordingly increased [28], and therefore the risk of toxicity may be even higher in this group.

There are no reports of toxic adverse reactions after ilioinguinal block in children. However, it must be remembered that the block is almost always performed during general anaesthesia.

Third, could the ilioinguinal block technique be altered to give lower plasma bupivacaine concentrations? There are two possible changes to our ilioinguinal block technique which may result in lower plasma bupivacaine concentrations. The first is the use of adrenaline to reduce the rate of absorption. Hayse-Gregson, Achola and Smith [29] studied the changes in haemodynamics and plasma catecholamine concentrations in adults after field block for inguinal herniorrhaphy using lignocaine and adrenaline 1 in 200000. They found a significant increase in heart rate and potentiation of arrhythmias. The other major possibility is the use of 0.25 % bupivacaine instead of 0.5 %. It is our experience that 0.25 % bupivacaine gives a less rapid and less reliable block, but a controlled trial is needed to assess this. Finally, we are aware that most anaesthetists do not use our technique of injecting 20 % of bupivacaine inferiorly and medially s.c. We have found this modification provides very reliable analgesia for skin incision. All children received the same block technique so this modification could not have caused the differences observed between the two groups.

We suggest that, although the toxic venous plasma bupivacaine concentration in small children has not been defined, it would seem unwise to exceed 4 mg $litre^{-1}$. We conclude that very small children differ from larger ones in their pharmacokinetic handling of bupivacaine and are likely to have higher plasma concentrations when bupivacaine is administered according to body weight. We recommend that a total dose of bupivacaine 1.25 mg kg^{-1} should not be exceeded in the perioperative period when performing ilioinguinal blocks in children less than 15 kg in weight.

Laryngeal mask airway performance: effect of cuff deflation during anaesthesia

G. N. MORRIS AND R. MARJOT

Summary

We studied the effect of deflating the laryngeal mask airway (LMA) cuff *in situ* on recorded respiratory tidal ventilation in 30 spontaneously breathing anaesthetized patients. Another 26 patients were studied in whom the LMA cuff was undisturbed. Deflation of the cuff to a pressure of 22 mm Hg (below an estimated arteriolar perfusion pressure of the pharyngeal mucosa), by removing approximately 50% of the recommended cuff injection volume, had a minimal effect on tidal ventilation ($P = 0.9$). This manoeuvre may have a role in minimizing transmitted cuff pressure on the adjacent pharyngeal mucosa. Complete cuff deflation, however, resulted in a 17% decrease in mean tidal ventilation ($P < 0.05$), with two patients (6%) demonstrating a substantial leak around the cuff and airway obstruction. The practice of complete cuff deflation during the recovery period from anaesthesia cannot be recommended. (*Br. J. Anaesth.* 1996; **76**: 456–458)

Key words

Complications, mucosal pressure. Equipment, masks anaesthesia.

The two principal functions of the cuff of the laryngeal mask airway (LMA) are to orientate the mask on inflation and to subsequently generate a low pressure seal around the laryngeal inlet. However, it has been shown to exert substantial pressures on the adjacent pharyngeal mucosa. This occurs even before full inflation with the manufacturer's recommended injection volumes and despite apparent accommodation by the pharynx [1].

The morbidity resulting from such pressures exceeding mucosal capillary perfusion pressure remains undetermined. Intra-cuff pressure monitoring is currently recommended by the manufacturer to avoid postoperative throat discomfort [2]. Several methods of limiting intra-cuff pressure have been suggested, including submaximal cuff inflation or partial deflation of the cuff during anaesthesia. These manoeuvres have recently been endorsed by the inventor of the device, Dr A. I. J. Brain [3].

This study was undertaken to determine the effect of LMA cuff deflation during anaesthesia on LMA performance.

Methods and results

After obtaining Hospital Ethics Committee approval and informed consent, we studied 56 adult ASA I or II unpremedicated patients (29 males) presenting for elective minor surgery. Anaesthesia incorporating spontaneous ventilation via an LMA was appropriate and not contraindicated for any patient.

An appropriately sized LMA (3 for females, 4 for males) was checked [2] and the pilot tube connected via a three-way tap to a 50-ml Plastipak syringe and a Spectramed pressure transducer (PIOEZ) with a recorder. The same transducer was calibrated against a mercury column and the zero point determined before each study (non-linear error < 2%). Each LMA cuff was evacuated to a pressure of −20 mm Hg. The syringe volume was then adjusted to the manufacturer's recommended injection volume (20 ml for size 3, 30 ml for size 4 LMA). This sealed system was not disrupted until the end of each study.

All patients were fasted and unpremedicated. Anaesthesia was induced with propofol 2–3 mg kg^{-1} and fentanyl 1 μg kg^{-1}. The LMA was inserted as described by the manufacturer [2] by one of the two investigators and the cuff inflated fully with the preset volume. Adequacy of placement was judged by the absence of any clinical or audible evidence of upper airway obstruction, examination of the capnography trace and the ease of positive pressure ventilation applied while the patients were apnoeic. The head and neck were then placed in a neutral position resting on one pillow. Anaesthesia was maintained with 1–2.5% isoflurane, and 60% nitrous oxide in oxygen; patients breathed spontaneously from a circle system. Each tidal volume was recorded during the study period using a Narkomed 4 (North American Drager) Spiromed positive displacement rotating lobe impeller (error < ±10 ml).

The patients were allocated to one of two groups (30 patients in group 1, 26 patients in group 2) and were studied 15 min after induction of anaesthesia. During this period, tidal volume recordings were

G. N. MORRIS*, MB, BS, MRCGP, FRCA, R. MARJOT, MB, BS, FRCA, Anaesthetic Department, Royal United Hospital, Combe Park, Bath BA1 3NG, Avon. Accepted for publication: October 17, 1996.

*Present address: Department of Anaesthesiology, University of Virginia, PO Box 238, Charlottesville, Virginia 22908, USA.

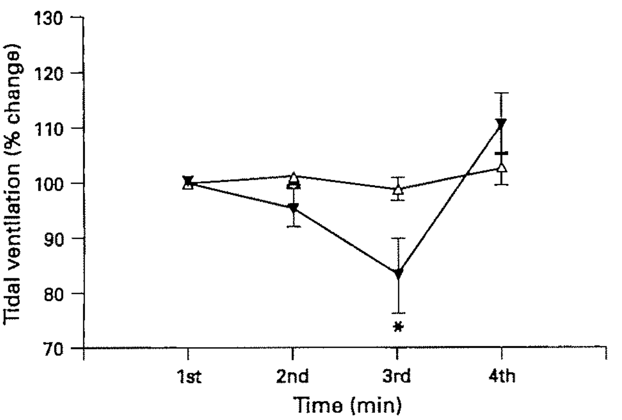

Figure 1 Mean (SEM) tidal ventilation plotted as a percentage of baseline recordings made during the first minute (1st). For group 1 (▼), recordings were made during the second (2nd), third (3rd) and fourth (4th) consecutive minutes with the LMA cuff deflated to 22 mm Hg intra-cuff pressure (2nd), fully deflated (3rd) and fully re-inflated (4th). For group 2 (△), all recordings were made with the LMA cuff unaltered over the same time period (2nd, 3rd, 4th). $*P = 0.05$ compared with baseline recordings in group 1.

made over 4 consecutive minutes. In group 1, for the first minute the LMA was undisturbed, for the second minute the cuff was deflated to a pressure of 22 mm Hg, for the third minute the cuff was fully deflated to −20 mm Hg, and for the fourth minute the cuff was re-inflated fully with the gas stored in the closed syringe system. Tidal volumes were recorded with the fresh gas flow turned off and the expiratory valve closed to make a closed circle system. Inspired and expired isoflurane and nitrous oxide concentrations remained constant throughout the readings. In group 2, patients were treated identically but tidal volumes were recorded over four consecutive 1-min periods without the cuff being altered in any way.

Within-group data were analysed using two-way analysis of variance (ANOVA) for repeated measures (Micosoft Excel). A probability value of less than 0.05 was considered to be significant. Data are presented as mean (SEM).

There was no difference between the groups in terms of age (group 1, 37 (range 21–80) yr; group 2, 37 (19–75) yr), sex ratio (group 1, 18 males, 12 females; group 2, 11 males, 15 females) or body mass index (group 1, 27.5 (0.6) kg m^{-2}; group 2, 25.4 (0.4) kg m^{-2}).

Intra-cuff pressures after initial inflation were substantial and increased during anaesthesia as cuff volume increased with diffusion of nitrous oxide into the cuff. Reduction in intra-cuff pressure to 22 mm Hg required removal of approximately 50 % of the initial cuff volume (size 4 LMA 16.3 (1) ml; size 3 LMA 10.7 (0.6) ml).

The mean respiratory tidal volume recorded during the first minute of the study period, before cuff deflation, was taken as baseline and plotted as 100 %. Subsequently recorded mean tidal volumes were plotted as a percentage of these values (fig. 1). Mean tidal volume in patients in group 1 decreased to 95 % of the baseline value when the cuff was deflated to 22 mm Hg ($P = 0.9$). The response to this degree of deflation was variable, and in eight patients (26 %) tidal ventilation increased slightly.

When the cuff was deflated fully, mean tidal volume decreased significantly to 83 % of baseline ($P = 0.035$). At this time, two patients (6 %) had no recordable tidal ventilation with noisy and partially obstructed breathing. When the cuff was re-inflated fully, mean tidal ventilation increased to 110 % of the original baseline value, and any obstruction was relieved. This increase was not significant compared with the baseline mean tidal ventilation ($P = 0.18$).

There was no significant change in the recorded mean tidal volumes of patients in group 2 throughout the study period (fig. 1).

Comment

Inflating the LMA cuff to the volume recommended by the manufacturer [2] results in transmitted pressures on the pharynx in excess of mucosal capillary perfusion pressure [1]. The morbidity resulting from these high transmitted pressures on the pharyngeal mucosa is unknown. There have been isolated reports of trauma to the posterior pharyngeal wall, uvula and large tonsils, and compression of the hypoglossal nerve [4], lingual artery [5] and recurrent laryngeal nerve [6]. Intra-cuff pressure monitoring is recommended but no acceptable level is stipulated [2]. Several methods of limiting intra-cuff pressure have been suggested, including submaximal cuff inflation or partial cuff deflation during anaesthesia [3].

We have studied, in spontaneously breathing anaesthetized patients, the effect of deflating the LMA cuff *in situ* on recorded respiratory tidal volumes. Mean respiratory tidal ventilation decreased as LMA cuff volumes (and pressures) were reduced. This effect was minimal when the cuff was deflated to a pressure of 22 mm Hg with the withdrawal of approximately 50 % of the initial inflation volume. Complete cuff deflation resulted in a significant decrease in recorded tidal ventilation. This may have resulted from tidal ventilation escaping around the sides of the partially and fully deflated LMA cuff or a degree of upper airway obstruction, or both. Two patients (6 %) demonstrated a substantial leak around the LMA cuff with clinical evidence of upper airway obstruction. The practice of some anaesthetists and recovery nursing staff to fully deflate the LMA cuff during the period of recovery from anaesthesia cannot be supported. This practice is contrary to the manufacturer's instructions [2] which states that deflation should only be performed when "the patient can open their mouth on command". There was a return to baseline mean tidal ventilation when the cuff was re-inflated fully (with the same gas), to the original cuff volume.

There was no change in the tidal volumes recorded in group 2 throughout the study, which would exclude any chance alteration in the level of surgical stimulus or depth of anaesthesia as being responsible for the changes observed in group 1.

We have demonstrated that the cuff of the LMA may be deflated to a pressure of 22 mm Hg (i.e. below the arteriolar perfusion pressure of the pharyngeal mucosa) with minimal effect on the recorded tidal ventilation, in spontaneously ventilating patients. The effect of this manoeuvre should, however, be assessed for each individual patient. Full deflation of the cuff results in a significant decrease in recorded tidal ventilation. The practice of complete cuff deflation during recovery from anaesthesia cannot be recommended.

Delayed forced air warming prevents hypothermia during abdominal aortic surgery

J. Karayan, D. Thomas, L. Lacoste, K. Dhoste, J. B. Ricco and J. Fusciardi

Summary

We have evaluated the efficacy of the delayed forced air warming during abdominal aortic surgery in 18 patients. Patients were allocated randomly to one of two groups: the control group ($n = 9$) received no intraoperative warming device; the Bair-Hugger group ($n = 9$) had active skin surface warming with an upper body cover. The device was activated when core temperature decreased to less than 36 °C. The reduction in core temperature was 0.6 °C during the first hour after induction and 0.4 °C during the second hour in both groups. In the control group, core temperature continued to decrease until the end of surgery, whereas in the Bair-Hugger group, the reduction in core temperature stopped after 1 h of warming, and then rewarming began. At the end of surgery, core temperature in the Bair-Hugger group was similar to core temperature before induction, and was higher than core temperature in the control group ($P < 0.003$).(*Br. J. Anaesth.* 1996; **76**: 459–460)

Intraoperative hypothermia is common during abdominal aortic surgery [1]. Forced air warming has been shown to be an efficient preventive method against hypothermia in a wide variety of surgical procedures [2–5]. In these studies, skin warming was started at the beginning of anaesthesia. After induction of anaesthesia for abdominal aortic surgery, insertion of i.v. cannulae, haemodynamic monitoring and subsequent surgical preparation delay warming for 1 h, while initial hypothermia induced by internal heat redistribution continues. The aims of this study were to evaluate the efficacy of forced air warming during abdominal aortic surgery when initial hypothermia had began.

Methods and results

In a prospective design, we studied 18 adult ASA II or III patients undergoing elective abdominal aortic surgery (aortic aneurysm repair or aortobifemoral bypass). None was obese, febrile or had a history of endocrine disease. Two hours before surgery, patients received preoperative cardiovascular treatment orally and morphine 0.1 mg kg^{-1} i.m. Anaesthesia was induced with flunitrazepam 0.03 mg kg^{-1} and fentanyl 5 μg kg^{-1} i.v.; pancuronium 0.1 mg kg^{-1} was then administered and the trachea intubated. The lungs were ventilated via a semi-closed circle system, at a fresh gas flow of 1.5 litre min^{-1} to maintain end-tidal $P\text{CO}_2$ at 4.8–5.3 kPa. Anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen, fentanyl 5 μg kg^{-1} h^{-1} and pancuronium. Core temperature (Tc) and haemodynamic state were monitored using a pulmonary artery catheter inserted before induction of anaesthesia. The operating room temperature was kept at 20–21 °C throughout surgery. All infused i.v. fluids were warmed (Fenwal). Patients were then allocated randomly to one of two groups. In nine patients a warm cotton sheet was placed over the upper chest and arms (control group (CG)). In the other nine patients the upper chest and arms (i.e. 24% of body surface area) were covered by an upper body forced air blower cover (model 520) attached to a Bair-Hugger model 500 (Augustine Medical, Eden Prairie, MN, USA) which was set on high (Bair-Hugger group (BHG)). The forced air blanket was covered by two cotton sheets. The warming system was activated as soon as Tc decreased to less than 36 °C. At the end of surgery, patients were transferred to the intensive care unit for continuous ventilation until complete recovery. Data were analysed with ANOVA and the Mann–Whitney U test. Differences were considered statistically significant when $P < 0.05$.

The two groups did not differ in age (mean 59 (range 42–79) yr in group CG *vs* 59 (43–79) yr in group BHG), mean duration of anaesthesia (366 (SD 53) min in group CG *vs* 400 (50) min in group BHG), duration of surgery (278 (54) min in group CG *vs* 312 (47) min in group BHG), end-tidal isoflurane concentration (0.6 (0.3)% in group CG *vs* 0.8 (0.2)% in group BHG), blood loss (0.4 (0.2) litre in group CG *vs* 0.8 (0.4) litre in group BHG), infused volume of solutions (3.1 (0.6) litre in group CG *vs* 3.8 (0.8) litre in group BHG) and operating room temperature (21 (0.5) °C in group CG *vs* 21 (0.7) °C in group BHG).

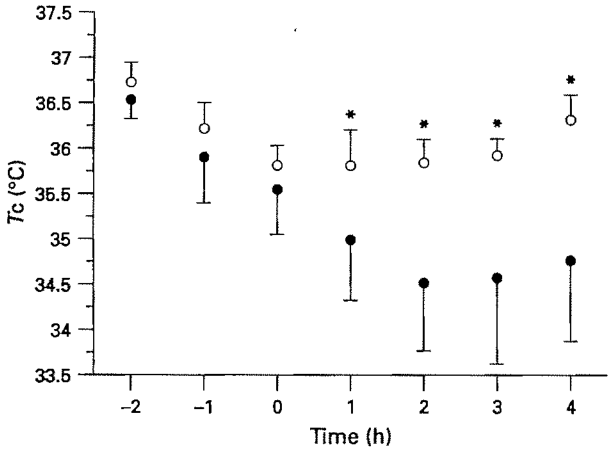

Figure 1 Intraoperative changes in core temperature (*T*c) (mean, SD) in the control (●) and Bair-Hugger (○) groups. Elapsed time zero (*T*0) identifies the beginning of rewarming in the Bair-Hugger group. *$P < 0.05$ *vs* control group.

Variations in *T*c for the patients are shown in figure 1. Before induction of anaesthesia there was no difference in mean *T*c between the groups (36.5 (SD 0.2) °C in group CG *vs* 36.7 (0.2) °C in group BHG). During the first hour after induction of anaesthesia, *T*c in both groups decreased (0.6 °C), and by the second hour a subsequent reduction of 0.4 °C had occurred. In group CG, *T*c continued to decrease until the end of the intervention (34.7 (1.0) °C). In group BHG, *T*c decreased to less than 36 °C (35.8 (0.2) °C) 2 h after induction. At this time the warming system was activated. One hour after the onset of active warming the reduction in temperature was stopped, and then the patients began to rewarm. During the subsequent course of the procedure, *T*c remained significantly higher in group BHG than in group CG ($P < 0.003$). *T*c in group BHG at the end of surgery was 36.5 (0.3) °C, that is similar to *T*c before induction.

Comment

All unwarmed patients were hypothermic at the end of surgery. In contrast, delayed forced air warming prevented intraoperative hypothermia.

Several authors have shown that the use of a limited skin surface is sufficient to prevent postoperative hypothermia [2–5], a finding confirmed by our study. However, in these studies skin warming was started just after induction of anaesthesia. The main purpose of our study was to show that delayed skin warming may be efficient during abdominal aortic surgery lasting more than 5 h.

A decrease in *T*c was observed during the first hour of anaesthesia in all patients. This initial hypothermia cannot be prevented, even if warming is started as soon as the patient is placed on the operating table [2]. In our study warming was started later, when *T*c decreased to less than 36 °C. There were several reasons for this delay in activating the warming system: first, the use of a warming system before induction would have required a cover on the lower limbs. In our opinion this seemed hazardous in patients with aortoiliac occlusive disease because of the risk of burning. Moreover, Beebe and colleagues showed that in pigs, warming of the hind legs during abdominal aortic surgery worsened the haemodynamic consequences of aortic declamping [6]. Second, putting the cover over the upper limbs would have avoided this risk, but insertion of invasive monitoring in the upper part of the body would have been precluded. Third, because of these two imperatives and in order to standardize the BHG group, we arbitrarily activated cutaneous warming at 36 °C.

Our study demonstrated that limited warming of the upper chest and arms was effective after the initial hypothermia by redistribution had started; it stopped the cooling and provided a normal *T*c at the end of the intervention. However, a minimum duration of 2 h is mandatory to start core warming, and 4 h of warming are needed to normalize *T*c.

Fentanyl increases intracellular Ca^{2+} concentrations in SH-SY5Y cells

A. L. WANDLESS, D. SMART AND D. G. LAMBERT

Summary

Classically, opioids inhibit Ca^{2+} influx, but recent reports suggest opioids may also stimulate Ca^{2+} entry. Therefore, we have measured the effect of opioids on intracellular Ca^{2+} ($[Ca^{2+}]_i$), fluorimetrically, in Fura-2-loaded SH-SY5Y cells. Fentanyl 0.3 μmol litre^{-1} caused a mean increase in $[Ca^{2+}]_i$ of 18.8 (SEM 2.1) nmol litre^{-1} in some (30.3%) batches of SH-SY5Y cells. In responding cells, the fentanyl-induced increase in $[Ca^{2+}]_i$ was dose-dependent, with an EC_{50} of 0.73 μmol litre^{-1}. This response was naloxone-reversible, and the δ opioid agonist [D-Pen^{2,5}]enkephalin had no effect on $[Ca^{2+}]_i$, suggesting the fentanyl-induced Ca^{2+} response was entirely mediated by the μ opioid receptor. Fentanyl 0.3 μmol litre^{-1} increased $[Ca^{2+}]_i$ without preactivation of phospholipase C by another agonist, and this was markedly reduced by Ni^{2+} 2.5 mmol litre^{-1}. These data suggest that μ opioids directly increase $[Ca^{2+}]_i$ by stimulating Ca^{2+} influx in SH-SY5Y cells. (*Br. J. Anaesth.* 1996; **76**: 461–463)

Key words

Analgesics opioid, fentanyl. Receptors, opioid. Model, neuroblastoma cells. Ions, calcium.

Classically, opioids inhibit Ca^{2+} entry via voltage-sensitive Ca^{2+} channels (VSCC), and this is generally accepted as part of the cellular basis for analgesia [1]. However, several recent reports have shown that opioids also stimulate Ca^{2+} influx [2]. Indeed, it has been proposed that opioid-induced increases in intracellular Ca^{2+} concentrations ($[Ca^{2+}]_i$) may be involved in the biochemical events underlying analgesia [3].

We have reported recently that μ, but not δ, opioids activate phospholipase C (PLC) in SH-SY5Y human neuroblastoma cells via a pertussis toxin-sensitive G-protein [1]. The subsequent increase in inositol(1,4,5)triphosphate ($Ins(1,4,5)P_3$) formation was abolished by removal of extracellular Ca^{2+} or by preincubation with nifedipine or (*R*+)Bay K8644 [1, 2], suggesting that μ opioids open L-type VSCC, thus allowing Ca^{2+} influx to activate PLC [2]. However, previous studies using SH-SY5Y cells failed to detect any opioid-induced increase in $[Ca^{2+}]_i$ unless PLC had been pre-activated by another agonist [4, 5]. Therefore, in the current investigation we have examined the effects of μ and δ opioids on $[Ca^{2+}]_i$, measured fluorimetrically in Fura-2-loaded cells, and report that μ opioids directly stimulate Ca^{2+} influx in SH-SY5Y cells.

Methods and results

SH-SY5Y (from Dr J. L. Biedler, passages 75–100) cells were maintained in minimum essential medium with Earle's salts and L-glutamine 2 mmol litre^{-1} supplemented with penicillin 100 u.ml^{-1}, streptomycin 100 μg ml^{-1}, fungizone 2.5 μg ml^{-1} and 10% fetal calf serum (Gibco, UK). Cells were harvested with HEPES-buffered saline 10 mmol litre^{-1}–0.02% EDTA, pH 7.4, washed twice with and resuspended in Krebs–HEPES buffer, pH 7.4, of the following composition (mmol litre^{-1}): Na^+ 143.3; K^+ 4.7; Ca^{2+} 2.5; Mg^{2+} 1.2; Cl^- 125.6; $H_2PO_4^-$ 1.2; SO_4^{2-} 1.2; glucose 11.7; and HEPES 10.

Each batch of cells was divided into 5–7 cuvettes and $[Ca^{2+}]_i$ was measured fluorimetrically in Fura-2-loaded whole cell populations in these cuvettes, as described previously [6]. Briefly, cells were incubated at 37 °C with Fura-2/AM 3 μmol litre^{-1} (Sigma, UK) for 30 min, washed and incubated at 20 °C for 20 min to allow complete ester hydrolysis. Some cells were preincubated with naloxone 1 μmol litre^{-1} at 20 °C for 5 min immediately before use. $[Ca^{2+}]_i$ was measured in 2-ml suspensions at 37 °C in a Perkin–Elmer LS50B spectrofluorimeter, using 340/380-nm excitation wavelengths, with emission at 510 nm. $[Ca^{2+}]_i$ was calculated from the 340/380 ratio as described previously [6], where Rmax and Rmin were determined with Triton-X (0.01%) and EGTA (4.5 mmol litre^{-1}, pH > 8.0), respectively. Changes of less than 5 nmol litre^{-1} were treated as 0.

Data are given as mean (SEM) or, where appropriate, as a representative trace of at least $n = 5$. EC_{50} values were obtained by computer-assisted curve fitting using Graphpad. Statistical comparisons were made where appropriate by ANOVA or Student's *t*-test, or both.

Fentanyl 0.3 μmol litre^{-1}, a μ-preferring opioid agonist [1], caused a naloxone-reversible increase (18.6 (2.2) nmol litre^{-1}) in $[Ca^{2+}]_i$ (fig. 1A) in some (30.3% from $n = 33$) batches of SH-SY5Y cells. It is

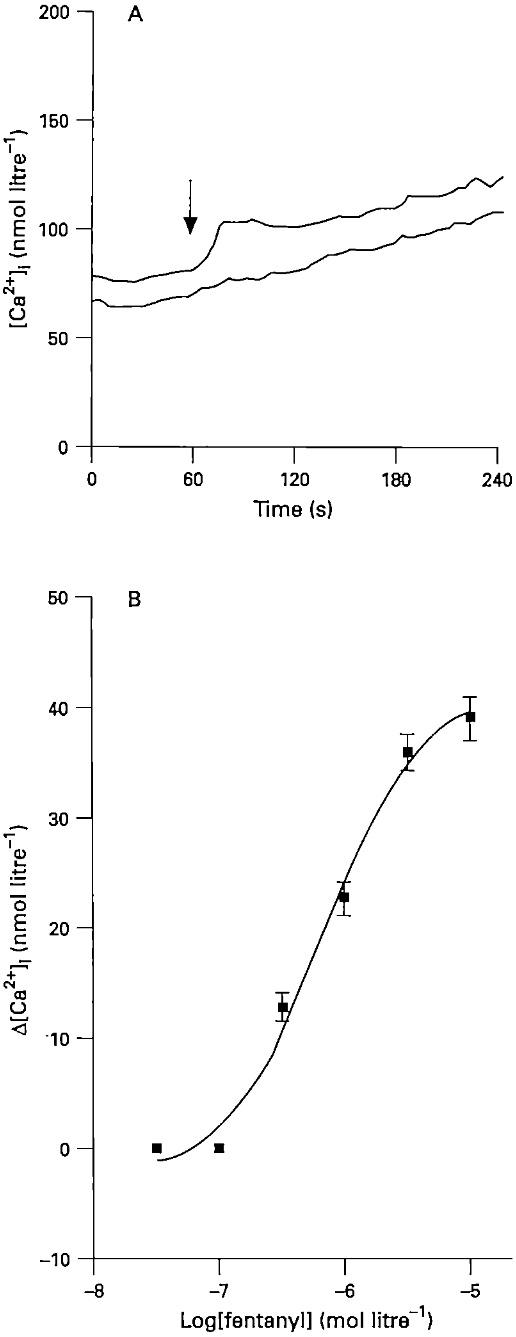

Figure 1 Time course (A) and dose-dependency (B) of the effect of fentanyl on $[Ca^{2+}]_i$ in SH-SY5Y cells. Cells were loaded with the Ca^{2+}-indicator dye Fura-2, and $[Ca^{2+}]_i$ measured by fluorimetry before and after the addition (indicated by arrow) of fentanyl 30 nmol litre^{-1}–10 μmol litre^{-1}. A: Lower trace is in the presence of naloxone 1 μmol litre^{-1} (data are representative of $n = 5$). (B) Data are mean, SEM (n = 5–8). SH-SY5Y dose–response curve was $P < 0.05$ by ANOVA.

worth noting that all samples (i.e. cuvettes) from the same batch of cells responded in the same way, and that the non-responders had normal Ca^{2+} responses to carbachol (data not shown). In responding cells, the response was dose-dependent (fig. 1B), with an EC_{50} of 0.73 μmol litre^{-1}. Preincubation with Ni^{2+} 2.5 mmol litre^{-1} markedly reduced the fentanyl (0.3 μmol litre^{-1})-induced increase in $[Ca^{2+}]_i$ (from 18.8 (2.1) to 7.0 (2.8) nmol litre^{-1}), indicating that the response was caused by Ca^{2+} influx. The δ opioid agonist DPDPE (1 μmol litre^{-1}) had no effect on $[Ca^{2+}]_i$ in SH-SY5Y cells (data not shown), even if PLC had been pre-activated with carbachol 50 μmol litre^{-1}, contrary to previous reports [4, 5]. This suggests that the opioid-induced Ca^{2+} response in SH-SY5Y cells could be μ-specific, and is in agreement with the evidence that μ, but not δ, opioids stimulate Ins(1,4,5)P_3 formation in these cells [1]. However, full pharmacological characterization of the Ca^{2+} response to fentanyl was not possible because of the small size and variability of occurrence of the response.

Comment

We have shown that μ opioids cause a dose-dependent increase in $[Ca^{2+}]_i$ in SH-SY5Y cells, and that this response does not require pre-activation of PLC with another agonist. Earlier studies using SH-SY5Y cells failed to detect any such changes [4, 5]. However, there is indirect evidence that μ opioids stimulate Ca^{2+} influx in SH-SY5Y cells, as block of Ca^{2+} entry with Ni^{2+} or nifedipine abolished μ opioid-induced Ins(1,4,5)P_3 formation in these cells [1, 2]. Opioid-induced increases in $[Ca^{2+}]_i$, and the subsequent stimulation of K^+ channel activity, has been suggested as one of the cellular mechanisms underlying analgesia [3]. Indeed, we have previously reported data suggesting that μ opioids increase Ca^{2+}-activated K^+ channel activity in SH-SY5Y cells [2]. Alternatively, there is evidence linking opioid-induced increases in $[Ca^{2+}]_i$ to the development of tolerance [2].

It has been proposed that opioids can only increase $[Ca^{2+}]_i$ in SH-SY5Y cells if the cell has been "primed" by prior activation of PLC [4, 5]. However, we have clearly demonstrated that opioids can increase $[Ca^{2+}]_i$ without pre-activation of PLC in this cell type. Moreover, even when we pre-activated PLC in SH-SY5Y cells with carbachol, DPDPE did not increase $[Ca^{2+}]_i$, contrary to previous reports [4, 5]. This suggests that this clonal cell-line may not be as homogeneous as previously thought, particularly as in the present study only 30.3% of the batches of cells responded. Alternatively, these discrepancies may reflect the effects of different cell culture regimens.

We have proposed previously that μ, but not δ, opioids stimulate Ins(1,4,5)P_3 formation in SH-SY5Y cells by opening L-type VSCC and so allowing Ca^{2+} influx to activate PLC [2]. In the current investigation we found that μ, but not δ opioids stimulated Ca^{2+} influx in SH-SY5Y cells, which supports this hypothesis. However, comparison of the dose–response curves for these two responses, with EC_{50} values of 16 and 730 nmol litre^{-1} for opioid-induced Ins(1,4,5)P_3 formation [1] and increased $[Ca^{2+}]_i$, respectively, indicates that the two phenomena may not be causally related. However, large, localized increases in $[Ca^{2+}]_i$ in the vicinity of the plasma membrane could still activate membrane-bound PLC, yet would be underestimated, or even missed entirely, using measurements of $[Ca^{2+}]_i$ in whole cell populations. Therefore, further studies using subcellular fluorescence imaging are necessary to test our hypothesis.

In conclusion, we report here for the first time that μ opioids increase [Ca^{2+}]$_i$ by stimulating Ca^{2+} influx in SH-SY5Y cells, and that this response does not require "priming" of the cell by prior activation of PLC with another agonist.

CASE REPORTS

Myocardial ischaemia associated with Ehlers–Danlos syndrome

C. M. PRICE, S. FORD, L. ST JOHN JONES AND V. MURDAY

Summary

A 38-yr-old man with an unusual type of Ehlers–Danlos syndrome presented for elective abdominal aortic aneurysm repair. During surgery he developed acute myocardial ischaemia, resulting in abandonment of the procedure. He was shown subsequently to have severe triple vessel coronary artery disease. Silent ischaemia associated with severe coronary artery disease, although rare, may be associated with the syndrome and is difficult to recognize as other cardiac abnormalities are frequently present. (*Br. J. Anaesth.* 1996; **76**: 464–466)

Key words

Ehlers–Danlos syndrome. Surgery, aneurysm. Heart, ischaemia. Complications, Ehlers–Danlos syndrome.

Ehlers–Danlos syndrome is a heterogeneous group of connective tissue disorders. It was described by Ehlers in 1899 and by Danlos in 1908. Its main features are articular hyperlaxicity, cutaneous hyperelasticity, vascular fragility and cutaneous fragility [1]. These features present the anaesthetist with potential problems and hazards. Many different types are classified on clinical criteria. However, the majority of patients do not fit neatly into any of the types. Recent developments in understanding the molecular structure of collagen have further confused the issue with the finding that similar abnormalities of the same type of collagen can produce varying phenotypes of Ehlers–Danlos syndrome or osteogenesis imperfecta. Although all Ehlers–Danlos syndrome types may present problems for the anaesthetist, it is type IV which poses the greatest problems and has been the subject of previous case reports [2–4]. Type IV is usually associated with abnormalities of type III collagen. Sufferers may have friable arteries which can rupture spontaneously causing sudden death.

We report a case of a young, apparently healthy man, who had an unspecified type of Ehlers–Danlos syndrome, with type 1 collagen abnormality. He developed acute, severe myocardial ischaemia during operation for elective aortic aneurysm repair. Emergency coronary artery bypass grafting was subsequently performed. To our knowledge this is the first case report of myocardial ischaemia occurring during anaesthesia that is specifically associated with Ehlers–Danlos syndrome.

Case report

A 38-yr-old man presented for elective abdominal aortic aneurysm repair. The aneurysm, measuring 7 cm, was discovered after x-ray of his lumbar spine. In the past he had undergone repair of a patent ductus arteriosus at 3 yr of age and was routinely followed-up by various cardiologists. When aged 13 yr he was found to have mild supravalvular pulmonary stenosis and was investigated for chest discomfort after cycling when aged 28 yr. An echocardiogram at that time revealed aortic regurgitation and mild left ventricular hypertrophy. He remained well and continued to have a yearly cardiology review, including an echocardiogram. Mild deterioration in left ventricular function was noted on echocardiogram 2 yr before this procedure for which he was commenced on enalapril. His exercise tolerance was good and he continued to cycle 5–10 miles a day until his aneurysm was discovered.

He was seen before operation by a cardiologist. On examination, he was noted to be of short stature with some dysmorphic features. His skin was velvety soft and he had absent earlobes. He had moderate kyphoscoliosis, flat feet and hypermobile joints, but no scarring. Para-umbilical and inguinal herniae were noted. Cardiovascular examination revealed murmur of aortic regurgitation, pulse in sinus rhythm with an arterial pressure of 120/60 mm Hg. Haematological and biochemical investigations, including clotting studies, were all normal. Chest x-ray was unremarkable. The electrocardiogram (ECG) showed prolonged QRS complexes, left ventricular hypertrophy and Q-waves in the inferolateral leads. These changes had all been present for the past decade and were thought to relate to his congenital heart defects and cardiac surgery. Echocardiographic findings were of moderate aortic regurgitation with an aortic root measurement of 4 cm, normal end-diastolic volume and mild impairment of systolic function. Ultrasound scan of his abdomen revealed a 7.2-cm infrarenal aneurysm extending to the bifurcation. The cardiologist also felt that he had

C. M. PRICE*, DCH, FRCA, S. FORD†, FRCA, L. ST JOHN JONES, FRCA, Crawley Hospital, Crawley, West Sussex. V. MURDAY, MRCP, St George's Hospital, London. Accepted for publication: October 27, 1995.

Present addresses:
*Queen Alexandra Hospital, Cosham, Portsmouth.
†St George's Hospital, London.

dysmorphic features suggestive of Ehlers–Danlos syndrome and so referred him for a genetic examination. Although there was no family history of Ehlers–Danlos syndrome, his parents were noted to be first cousins. In the absence of any history of excessive bleeding, bruising or scarring, the provisional genetic opinion was that he had type VI Ehlers–Danlos syndrome, as opposed to the more common types I or IV.

Before operation it was felt that, in view of his congenital heart disease, he would benefit from pulmonary artery (PA) catheterization. He was therefore admitted to the intensive care unit. A PA catheter was inserted without difficulty. Measurements revealed cardiac output of a 4.7 litre min^{-1} with a pulmonary capillary wedge pressure of 12 mm Hg. In theatre a radial artery cannula was inserted, also without difficulty. Monitoring was then started and included an ECG in the CM5 configuration, pulse oximetry, direct arterial pressure and pulmonary artery pressure. His lungs were then preoxygenated and anaesthesia was induced with propofol 140 mg, fentanyl 150 μg and vecuronium 10 mg. Laryngoscopy revealed a grade 3 larynx necessitating intubation with the aid of a gum elastic bougie. An extradural catheter was inserted at L1–2. Sensation during insertion was found to be strange because of the abnormal feel of the ligaments. He was given Gelofusine 500 ml and a test dose of 0.5 % bupivacaine 3 ml without incident. This was followed by 0.5 % bupivacaine 7 ml and diamorphine 2.5 mg, given in incremental doses. His arterial pressure remained stable. The operation proceeded uneventfully until, during mobilization of the aneurysm, he developed marked ST segment elevation on the ECG which rapidly progressed to a supraventricular tachycardia, followed by ventricular tachycardia. His arterial pressure then decreased to 55/40 mm Hg. He required DC cardioversion of 50, 100 and then 200 J to restore sinus rhythm. Before this there was no episode of hypotension. However, after restoration of sinus rhythm he had an intermittent sinus tachycardia of 130 beat min^{-1} accompanied by hypotension and the procedure was therefore abandoned. These episodes were short-lived, not requiring further treatment. During the next 30 min, cardiovascular stability improved, ST segment on the ECG returned to normal and he did not require further treatment. He was transferred to the intensive care unit where a 12-lead ECG was performed. This showed no change from his previous ECG and an echocardiogram showed no deterioration from preoperative function.

He was sedated and his lungs ventilated overnight in intensive care and he remained stable. The following day attempts were therefore made to wean him, but this resulted in the return of marked tachycardia with accompanying ST segment elevation. Weaning was stopped and transfer to the regional cardiothoracic unit was arranged.

Cardiac catheterization revealed the presence of severe generalized triple vessel disease. He underwent coronary artery bypass grafting the following day without any further attempts to wean him. The aorta was noted to be extremely friable. He was stable throughout the procedure. He underwent an uneventful abdominal aneurysm repair 1 week later. Skin biopsy was taken for fibroblast culture and collagen studies.

Discussion

Ehlers–Danlos syndrome has a complicated, multifaceted presentation. Our patient was felt to have type VI Ehlers–Danlos syndrome, caused by lysyl oxidase deficiency on the basis of a likely recessive inheritance, the presence of scoliosis, scarring and the absence of bruising [5]. However, collagen studies did not confirm this and were more consistent with a type I collagen abnormality. This is associated more commonly with osteogenesis imperfecta although it has been reported in association with type VII Ehlers–Danlos syndrome [6]. Our patient did not fit neatly into any category. Indeed, the immense heterogeneity of the collagen diseases and improved detection of the genetic defects involved are likely to lead to re-classification of collagen disorders on the basis of the actual defective gene in the future.

Anaesthetic problems in Ehlers–Danlos syndrome were reviewed extensively by Dolan, Sisko and Riley [2]. Problems may occur in all types because of lax, unstable joints, abnormal skin elasticity and friable vessels. These lead to difficulty with tracheal intubation and insertion of cannulae or catheters. Abnormal vessel walls and platelet defects may lead to uncontrollable haemorrhage [7]. There may also be lung cysts present, increasing the risk of pneumothorax [9]. Dolan, Sisko and Riley did not recommend the use of extradural analgesia because of the risk of haematoma, but since then two authors have described its successful use in obstetric anaesthesia [3, 4]. We felt that extradural anaesthesia was appropriate in our patient. Extradural block is used routinely in many centres for aortic aneurysm repair as it provides excellent analgesia, reducing anaesthetic requirements during operation. After operation, pain may lead to increased oxygen requirement thus increasing the risk of myocardial ischaemia. Extradural analgesia reduces this risk compared with systemic opioids [9]. In aortic insufficiency an increase in afterload caused by pain may worsen regurgitation, with the risk of acute left ventricular volume overload [10]. Extradural analgesia may prevent this or actually decrease afterload. The extradural catheter was inserted under controlled conditions by an experienced operator with incremental doses of local anaesthetic accompanied by monitoring of pulmonary artery wedge pressure. Tachycardia, arrhythmia and hypotension occurred 1 h after the last dose of bupivacaine and we felt therefore that his problems were unrelated to the effects of the extradural.

Cardiac complications are a recognized feature of Ehlers–Danlos syndrome [11]. The main problems are: (a) valvular diseases—regurgitation or prolapse caused by abnormal valve structure; (b) congenital heart disease—atrioventricular septal defects, tetralogy of Fallot and dextrocardia; (c) conduction defects—atrioventricular block, incomplete right bundle branch block and extrasystoles.

Coronary artery disease occurring in association with Ehlers–Danlos syndrome has been reported [11]. Both cases were in type IV disease and led to myocardial infarction. All cases, including our own, had age ranges in their thirties. Neither of the cases reported had symptoms of angina pectoris before their myocardial infarction. It seems likely that fragility and friability of the coronary arteries leading to plaque formation may be implicated. In our patient ischaemia was related to handling of the aneurysm and later attempts to wean him. He did not develop myocardial infarction.

Because of the many cardiac defects seen in Ehlers–Danlos syndrome, ECG recordings are likely to be abnormal, making the detection of ischaemia more difficult. Cardiac catheterization has been described as hazardous in Ehlers–Danlos syndrome as the friable arteries make haemorrhage from the entry site likely [9]. Exercise or dipyridamole thallium scanning has been recommended for certain at risk candidates undergoing aortic aneurysm repair. It would perhaps be a suitable screening measure in Ehlers–Danlos syndrome sufferers before undertaking a major procedure.

In summary, the anaesthetic implications of Ehlers–Danlos syndrome are multiple. Before surgery, the help of a geneticist is useful to characterize the type of Ehlers–Danlos syndrome presenting so that a more accurate prediction can be made of the problems likely to occur. Myocardial ischaemia, although rare, can occur in young sufferers of Ehlers–Danlos syndrome without prior symptoms. This makes diagnosis difficult, especially if associated with other congenital abnormalities. This possibility should, however, be borne in mind and the appropriate investigations, such as thallium scanning, performed.

Reducing the potential morbidity of an unintentional spinal anaesthetic by aspirating cerebrospinal fluid

P. SOUTHORN, G. M. S. VASDEV, R. C. CHANTIGIAN AND G. M. LAWSON

Summary

We describe two cases where we attempted to reduce the adverse effects of inadvertent spinal anaesthesia by aspirating local anaesthetic-contaminated cerebrospinal fluid (CSF). Analysis of this CSF for its local anaesthetic concentration revealed that we were able to recover 51 % and 39 % of the administered lignocaine. It is suggested that such aspiration may be a helpful additional measure to the supportive management of this complication. (*Br. J. Anaesth.* 1996; **76**: 467–469)

Key words

Anaesthetic techniques, extradural. Cerebrospinal fluid. Complications, morbidity.

Injection of an appropriate dose of local anaesthetic for extradural anaesthesia into an extradural catheter which has perforated the dura mater may result in total spinal anaesthesia. On the last two occasions when this complication occurred in our institution, we immediately aspirated contaminated cerebrospinal fluid (CSF), in an attempt to reduce the height of the block. Because our patients did not develop total spinal anaesthesia and analysis of the aspirated CSF showed that significant amounts of injected local anaesthetic could be recovered by this means, we suggest that such aspiration may be a helpful adjunct to the conventional supportive management of patients in this situation.

Case report

PATIENT NO. 1

An extradural anaesthetic was planned for a repeat elective Caesarean section in a 28-yr-old healthy woman with a contracted pelvis and unstable fetal lie. With the patient in the left lateral position, the extradural space at L3–4 was identified with an extradural needle using the loss of resistance to saline technique. An extradural catheter was advanced 4 cm through this needle and aspiration was negative for CSF or blood. After the patient had been placed in the supine position with left uterine displacement and the i.v. fluid bolus had been completed, a test dose of 2 % lignocaine 3 ml with adrenaline 1:200000 was injected into the extradural catheter. This produced no sensory or motor block and no change in the patient's heart rate, as monitored by an electrocardiogram and pulse oximeter, over the course of the next 4 min. Subsequently, 2 % lignocaine 7 ml with adrenaline 1:200000 and fentanyl 10 $\mu g\ ml^{-1}$ were injected through the catheter. Within 4–5 min, the patient stated that her legs had become completely numb and simultaneously her arterial pressure decreased from 120/80 to 70/50 mm Hg. Aspiration now revealed free-flowing CSF. A total of 20 ml of CSF was withdrawn over 40 s and sent in a glass bottle to the laboratory for analysis of lignocaine and fentanyl content.

Simultaneously, the patient's hypotension was managed by exaggerating left uterine displacement, placing the patient in the Trendelenburg position, giving an additional i.v. fluid bolus and repeated i.v. injections of ephedrine 5 mg (35 mg in total). Oxygen had been administered continuously via a face mask since insertion of the extradural catheter. The patient's arterial pressure stabilized at 110/70 mm Hg, she did not lose consciousness, her ventilatory frequency and laryngeal reflexes were normal and the fetal heart rate monitor revealed no evidence of fetal distress. On questioning, the patient complained that her arms felt heavier than usual but she had no demonstrable muscle weakness in either arm. By temperature discrimination, the spinal anaesthetic had extended to the C3–4 level.

Thirty-six minutes after the initial test dose of local anaesthetic, a 3650-g male infant was delivered, with Apgar scores of 7 and 8 at 1 and 5 min, respectively. After operation the catheter was removed intact and 3.75 h after receiving the local anaesthetic, the block had completely worn off. The patient had an uneventful postoperative course and did not develop a post-dural puncture headache.

PATIENT NO. 2

Extradural anaesthesia was planned for a 68-yr-old woman who was to undergo right total hip arthroplasty. With the patient lying on her side, the extradural space between L2–3 was identified with an extradural needle using the loss of resistance to saline technique. An extradural catheter was passed

LAWSON, PHD (Department of Laboratory Medicine); Mayo Clinic and Foundation, 200 First Street SW, Rochester, MN 55905, USA. Accepted for publication: October 17, 1995.

Correspondence to P. S.

easily through this needle and aspiration of the latter was negative for CSF and blood. A test dose of 2% lignocaine 3 ml with adrenaline 1:200000 injected through the catheter produced no sensory or motor block and no change in heart rate, as monitored by an electrocardiogram and pulse oximeter after 3 min. In the subsequent 3 min, 2% lignocaine, 17 ml with adrenaline 1:200000 was injected incrementally through the catheter. Eleven minutes later, arterial pressure decreased from 150/80 to 94/40 mm Hg. This was treated promptly with ephedrine 10 mg i.v., an i.v. fluid bolus of 500 ml and her arterial pressure stabilized at 120/70 mm Hg.

Eighteen minutes after local anaesthetic administration, the patient could not move her hands and by sensory discrimination the level of block was at C5–6. Aspiration of the extradural catheter at this time revealed free flowing CSF and 30 ml was removed, placed in a glass bottle and sent to the laboratory for lignocaine assay. Ten minutes later she started recovering the use of her hands. Shortly afterwards, surgery commenced. Eighty-six minutes after the initial administration of lignocaine, the patient complained of some minor discomfort at the site of surgery. To treat this, 0.5% bupivacaine 1 ml was injected intrathecally through the catheter. A second 1 ml of 0.5% isobaric bupivacaine was administered 31 min later. This allowed surgery to be completed without discomfort. At the end of surgery, the extradural catheter was removed intact. The patient had an uneventful postoperative course and did not develop a post-dural puncture headache.

LIGNOCAINE AND FENTANYL ASSAY

Lignocaine concentration in CSF was measured by an enzyme multiplied immunoassay technique (EMIT) using calibrators and reagents obtained from Syva Company (San Jose, CA, USA) adapted to a Monarch automated chemistry analyser (Instrumentation Laboratory, Lexington, MA, USA). The assay, used routinely to measure lignocaine concentration in serum, was validated for use on CSF by assaying lignocaine standards of known concentration prepared by dissolving pure lignocaine in a solution designed to mimic the electrolyte composition, osmolality and pH of normal CSF. Percentage recovery (mean (SD)) at three concentrations spanning the assay linear range was 97.6 (7.1)%. Fentanyl was extracted from CSF with chloroform:ethylacetate (80:20, v:v), and the organic phase was dried down under nitrogen. The residue was resuspended in methanol 100 μl and assayed for fentanyl by gas chromatography–mass spectrometry using a Hewlett-Packard (Palo Alto, CA, USA) 5980/5987 instrument. Deuterated fentanyl was added to CSF as an internal standard to correct for losses incurred during extraction and chromatography.

Discussion

The results are summarized in table 1. In the two patients, we recovered 51% and 39% of lignocaine administered intrathecally. Although definite conclusions cannot be drawn based on findings in two patients, the success in retrieving lignocaine combined with the lack of signs and symptoms of total spinal anaesthesia suggest that such CSF aspiration may be beneficial.

Table 1 Lignocaine and fentanyl recovery by CSF aspiration

	Patient No. 1	Patient No. 2
Total dose lignocaine injected (mg)	200	400
Volume of CSF removed (ml)	20	30
Concentration of lignocaine in CSF recovered (mg ml^{-1})	5.1	5.2
Total amount of lignocaine recovered		
mg	102	156
Percentage as injected	51	39
Total dose fentanyl injected (μg)	70	—
Concentration of fentanyl in CSF recovered (μg ml^{-1})	0.16	—
Percentage fentanyl recovered	4.7	—

Withdrawal of CSF to control the level of continuous spinal anaesthesia was described in 1948 [1]. Contaminated CSF removal as part of the management of an inadvertent spinal anaesthetic was suggested originally in a 1980 editorial [2]. We believe this report is the first to support this suggestion. Such CSF aspiration has been used routinely to attempt to overcome the potentially fatal consequences resulting from inadvertent excess intrathecal methotrexate [3–5]. It has also been used to treat intrathecal morphine overdose [6].

In addition to the need for more patient-based data, several other questions need to be addressed before CSF aspiration is incorporated routinely in the treatment of inadvertent spinal anaesthesia. Pharmacokinetic principles have been used to predict the percentage of intrathecally injected methotrexate removed by different volumes of CSF aspiration when performed at various time intervals after drug administration [3]. We aspirated 20 ml of CSF in our first patient and 30 ml in the second.The ideal volume of CSF to be recovered in this clinical situation remains to be resolved. Presumably removal of larger volumes than we used is more likely to result in post-dural puncture headache. The immediacy of such aspirations to maximize recovery of drug may also be important. This report does not suggest how much time may elapse from injection of local anaesthetic before this manoeuvre loses its clinical benefit. Drug recovery also depends on drugs diffusibility and lipid solubility [7]. This is illustrated by patient No. 1 in whom we recovered 51% of the administered lignocaine, but were only able to retrieve 4.7% of the concomitantly administered fentanyl.

COMMENTARY

Consensus statement on autologous transfusion

PROCEEDINGS OF A CONSENSUS CONFERENCE HELD BY THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, OCTOBER 4–6, 1995

People of the UK have been and continue to be well served by their National Blood Transfusion Services. The panel emphasized the need to utilize good surgical techniques which minimize blood loss and recognized the importance of efforts to limit the use of blood to clinical necessity.

Notwithstanding the safety of allogeneic blood transfusion, several questions have been raised internationally, particularly in North America and the European Union, suggesting that the supply of blood can be supplemented by autologous transfusion techniques. It is recognized that all blood transfusions carry risks. Screening of donated blood, however, has greatly reduced the potential risks of transfusion-transmitted diseases. There remains a degree of uncertainty on the immunological effects of allogeneic transfusion. When used as the sole source of transfused blood, the principal advantage of autologous blood transfusion is the avoidance of the risks of transmitting infectious agents and the potential immunological side effects of allogeneic transfused blood.

The panel noted the paucity of controlled, randomized trials in the evaluation of these procedures and recognized the need to develop appropriate methodology and outcome measures to determine risk benefit and cost effectiveness. Provision of services, present and future, should take account of the rights, interests and requirements of patients. Good medical practice requires disclosure of alternatives in addition to risks and benefits.

Preoperative autologous donation (PAD)

At the present time, in the UK, there is a low degree of public interest, although the facility of PAD is potentially widely available. In centres which offer this facility, the present take-up is low compared with a take-up rate in America of up to 10%, accounting for 5% of total blood usage. Not all patients are suitable and patients must be selected carefully on medical grounds. Eligible patients who undergo elective orthopaedic surgery are the primary targets of PAD and it is possible to achieve exclusive use of autologous blood in at least 75% of cases.

A current disadvantage is the difficulty of guaranteeing non-cancellation of routine surgery within the NHS. Other disadvantages include the possibility of cardiovascular accidents after donation. A further concern is that the operation has to be scheduled to allow for usually 1–4 donations at approximately weekly intervals. In some patients this could be a disadvantage. Although there are practical difficulties associated with the general introduction of PAD in the UK, we foresee that this practice may become more widespread provided that appropriate resources are made available.

Acute normovolaemic haemodilution (ANH)

The evidence presented suggests that when used alone, ANH has a limited capability for preventing the need for allogeneic blood. We acknowledge that there are potential benefits and hazards, and that careful evaluation of this technique is essential before it can be recommended for widespread use.

Intraoperative salvage (IS)

The clinical benefits of IS become more apparent in surgical procedures with acute blood loss of more than 1000 ml. Blood loss levels below this volume would not support the use of IS, particularly with respect to cost benefit. Provided that a rigid standard operating procedure is in place and the equipment is easily available with appropriate staff training, the side effects of IS are fewer than those associated with allogeneic transfusion. An increasing body of evidence indicates that this procedure can substantially reduce the need for allogeneic blood.

Future directions

Further work in the development of appropriate blood substitutes and agents to enhance haemostasis will help to reduce the need for allogeneic transfusion. We would also favour the establishment of a national register of adverse events relating to all autologous transfusion procedures.

CORRESPONDENCE

Histamine release by neuromuscular blocking agents

Sir,—The design of the study by Naguib and colleagues [1] on the histamine releasing potencies of various neuromuscular blocking drugs resulted in cardiovascular changes which were profound, adverse and predictable. For example, the data sheet for mivacurium suggests administration over 5–15 s. The authors chose 5 s, despite quoting references which showed potential adverse haemodynamic changes caused by rapid administration of some benzylisoquinolinium neuromuscular blockers. Three minutes after administration of mivacurium, the control mean arterial pressure (MAP) of 76.0 mm Hg had decreased to a mean of 58.1 mm Hg, 2 SD below which gives an MAP of 43.7 mm Hg. Hypotension and tachycardia represents the worst possible combination of cardiovascular variables for myocardial perfusion, already compromised by covert coronary atherosclerosis at 60 yr of age, the maximum age in the study sample.

Sir,—The design of our study [1] was not different from that of similar studies. For example, Basta and colleagues [2] and Moss and colleagues [3] administered atracurium and dimethyltubocurarine and tubocurarine, respectively, as a single rapid (5 s) bolus. Administration of mivacurium over 5 s is still within the recommendations of the manufacturer. However, slower administration of larger doses of benzylisoquinolinium compounds such as mivacurium 0.25 mg kg^{-1}, for example over 60 s, results in no significant changes in histamine concentrations or haemodynamic variables [4]. Therefore, with slower administration, the inherent differences between the neuromuscular blocking drugs studied could not have been elicited.

The dramatic scenario created by Dr Todd in his letter does not match our data. The patients in the mivacurium group were aged 20–41 (mean 28.4) yr. The ranges of mean arterial pressure and heart rate observed in this group were, respectively, 47–70 mm Hg and 76–93 beat min^{-1}. For those patients who may be compromised cardiovascularly, it is clear that selecting a drug with less histamine release may be an appropriate choice.

Preoperative fasting for paediatric anaesthesia

Sir,—I was surprised to find that reference No. 46 in the article by Phillips, Daborn and Hatch [1] concerning the osmolality of feeding mixtures during experimental injections of milk into tracheas was a reference more than 40 yr old. I would have hoped that the authors would be aware that feeding mixtures, their contents and specifically their osmolality have changed a little during nearly half a century in order to modify those mixtures to resemble human milk as closely as possible. Surely this modification should be considered before one could conclude that formula feeds "cause a greater degree of pulmonary oedema than human or cow's milk when aspirated...".

M. Hopp
Paediatric Endocrine and Growth Clinic
Johannesburg Hospital
University of the Witwatersrand
South Africa

1. Phillips S, Daborn AK, Hatch DJ. Preoperative fasting for paediatric anaesthesia. *British Journal of Anaesthesia* 1994; 73: 529–536.

Sir,—The issue of the relative safety of breast milk and formula feeds remains contentious. It is confused by the variety of types of formula available. Whey based feeds are generally thought to leave the stomach more quickly than feeds with a casein base, but mothers find them less satisfying for their babies. The reference referred to by Dr Hopp was the most recent we could find relating to the pathological changes produced by aspiration of milk. We do not dispute that formula milks have indeed changed but we do not have experimental evidence for what occurs when they are aspirated.

Use of i.m. temperature probes during cardiopulmonary bypass in humans

Sir,—Benson and colleagues might be forgiven when they write that they could not find reports of i.m. temperature measurements during and after cardiopulmonary bypass (CPB) and that differences between nasopharyngeal and muscle temperatures have not been reported previously [1].

It is probable that recently retired cardiac anaesthetists from the Queen Elizabeth Hospital, Birmingham, would have assured him that i.m. temperature probes have certainly been used for this purpose in the rather distant past. Even my memory, confirmed by my own limited database [2, 3], tells me that such measurements at leg and buttock sites were reported from the Westminster Hospital some years ago and it was common practice in other cardiac units at that time and later. Books published a mere 15 yr ago mentioned placing muscle probes for temperature measurement during cardiac operations [4, 5]. I would expect a more protracted search than my own would reveal many more references to muscle temperature and hypothermic CPB.

Regarding the restoration of muscle temperature to normal body temperature, there is one current view that a degree of hypothermia in the immediate postoperative period after CPB may be advantageous [6] (provided the patient is not allowed to increase muscle tone or shiver). This relates to the fact that subclinical CNS injury is common after CPB [7] and that hypothermia has a protective effect on the brain after any ischaemic event [8]. Striving to restore muscle temperature to normal results in the brain temperature being normal or even above normal towards termination of CPB and this could aggravate any injury [9]. Thus in these days of cost-effectiveness, the trend for rapid rewarming and rapid progress through the cardiac intensive care unit may not be in the best interest of the patient's brain.

Sir,—We are grateful for the opportunity to reply to Dr Manners' letter, some of which we suspect was written rather tongue in cheek. We were unaware of the article by Burton in 1964 and were very interested to read it. Although the other references cited by Dr Manners refer to temperature probes, they in no way invalidate our study or its contribution to the literature. It seems that little, if any, research post-dates that of Burton until the publication of our article and the abstract of Johnson, Desai and Ponte [1]. A repeat detailed search back to 1980 failed to reveal any other relevant research. If any nearly retired anaesthetists have more references, data or unpublished research we would be delighted to hear from them!

With respect to the concept of mild hypothermia and cerebral protection, what evidence there is seems questionable and on the basis of current research the jury is most definitely still out. The prevention of shivering, which is known to jeopardize cerebral oxygenation, is amenable to treatment by conventional, accepted means. It was not our practice to overwarm any patient studied. Our observations which compared deep muscle temperatures with those in the nasopharynx were intended to allow a more rational future therapeutic attack on the problem of afterdrop.

EEG arousal during laryngoscopy and intubation

Sir,—We read with interest the recent article by Wilder-Smith, Hagon and Tassonyi [1]. The authors observed arousal effects on the EEG after tracheal intubation in patients anaesthetized with either propofol or thiopentone. They stated that the effect site concentrations of both propofol and thiopentone were not in equilibrium, but argued that this was unlikely to have influenced EEG arousal, as it changed abruptly at the time of tracheal intubation. Without control groups, where patients are anaesthetized but the trachea is not intubated, the cause of the arousal cannot be attributed to intubation.

Furthermore, they concluded that propofol depressed nociception more than thiopentone. Without demonstrating the EEG effects with time after boluses of each drug without intubation, it is impossible to draw this conclusion; again a control group is necessary.

1. Wilder-Smith OHG, Hagon O, Tassonyi E. EEG arousal during laryngoscopy and intubation: comparison of thiopentone or propofol supplemented with nitrous oxide. *British Journal of Anaesthesia* 1995; 75: 441–446.

Sir,—We thank Drs Shannon, McGreggor and Brunner for their interest in our study. While we would agree that the concept of a control group not undergoing laryngoscopy and intubation is theoretically attractive, we submit that in practice the absence of such a group does not affect the conclusions drawn from the study. Briefly, these were that the nociception of laryngoscopy and intubation is associated with EEG arousal, and that this arousal is attenuated more by *hypnotically* equipotent doses of propofol than thiopentone, thus suggesting better antinociception by propofol than thiopentone.

The only alternative origin for the EEG "arousal reaction" described is a pharmacological one. While not explicitly stating that the effect site and plasma concentrations of propofol or thiopentone are not in equilibrium, our discussion addressed the issues resulting from that lack of equilibrium, and how unlikely they were to explain the EEG arousal observed. The pharmacological explanation is unsatisfactory for the following reasons:

(1) The EEG is accepted as a good reflection of hypnotic effect site concentrations in the unstimulated subject [1]. In both groups, the EEG time course, and hence the effect site concentration, was similar up to the time of laryngoscopy and intubation. Only in close temporal association with laryngoscopy and intubation does the EEG diverge and change direction abruptly, and this in the context of a previously stable or very slowly changing EEG. This abrupt discontinuity is even clearer in the unprocessed EEG. Such behaviour, distant from the time of injection, is difficult to explain in pharmacokinetic (or pharmacodynamic) terms.

(2) The EEG excitation of the arousal reaction associated with laryngoscopy and intubation is qualitatively and quantitatively different from the EEG excitation known to be of pharmacokinetic origin (i.e. as a result of the presence of excitatory biophase concentrations of anaesthetic agent) and seen earlier in the study. For example, in the thiopentone group, the excitatory EEG arousal reaction with laryngoscopy and intubation was 3–4 times larger and lasted at least three times longer than the earlier EEG excitation of pharmacological origin associated with induction.

(3) The time course of the EEG (and effect site concentrations) during bolus injection of anaesthetic agents in the absence of stimulation such as laryngoscopy and intubation is now well described [1–4] and accessible in the form of modelling programs [5, 6]. An arousal reaction of the type seen in our study, or other types of EEG excitation, did not occur in these models 3–5 min after injection in the absence of stimulation. These models also suggest that effect site concentrations *start* to decrease from their peak 5 min after injection at the earliest, with excitatory effect site concentrations being reached even later.

Venous thromboembolism and cardiovascular surgery

Sir,—While reading the excellent review article "Prevention of postoperative venous thromboembolism" by Bullingham and Strunin [1], I noticed they stated that patients undergoing bypass or valve surgery are "usually fully anticoagulated" in the "preoperative" period. In the cardiothoracic unit where I am presently working this is not the case. Many patients present having recently taken aspirin (which is normally stopped) and approximately 10 % have received heparin infusions for unstable angina but the majority are not fully anticoagulated. In the peroperative period they are anticoagulated with heparin for bypass and although antagonized with protamine, presumably have a degree of anticoagulation after operation, related mainly to platelet dysfunction. I suggest therefore that the lack of deaths arising from pulmonary embolism in patients undergoing coronary bypass surgery in the NCEPOD study is related to *peroperative* anticoagulation and not to their *preoperative* state.

Sir,—Dr McDonald has drawn attention to a misprint in our review article [1]. We intended to refer to the effect that *peroperative* and not *preoperative* anticoagulation might have on the incidence of venous thromboembolism after cardiac surgery. As Dr McDonald has pointed out, peroperative anticoagulation is routine for most cardiac operations, while preoperative anticoagulation is uncommon. We thank Dr Mcdonald for drawing our attention to this error.

Prevention of vomiting after paediatric strabismus surgery

Sir,—While I was very interested in the systematic review of prevention of vomiting after paediatric strabismus surgery [1], I suspect that this methodology has fundamental flaws, particularly if the reviewers are not active practitioners in the field they are reviewing. For example, no mention is made in this analysis of the influence of analgesic technique and tracheal intubation on the occurrence of emesis. As paediatric anaesthetists we know that opioids and tracheal intubation are commonly used for this type of surgery in many countries and that if these two aspects of the technique are avoided where possible, the incidence of postoperative vomiting is very infrequent (< 10 %).

The pain of squint surgery is mostly conjunctival in origin and topical analgesia with drops of amethocaine, oxybuprocaine or NSAID can be used in place of parenteral opioids. It is no longer necessary to intubate the trachea in the majority of children for strabismus surgery with the advent of the laryngeal mask airway.

The conclusion that propofol should not be used in this group is drawn but it is not made clear that this refers to a "propofol infusion for maintenance" technique as opposed to a "propofol for induction, nitrous oxide–oxygen–volatile agent for maintenance" technique.

Therefore, the emetogenic anaesthetic techniques used in the published series which the authors reviewed are in my view obsolete and a move forward to the non-intubation, non-opioid era will have a much greater effect than any antiemetic drug on the prevention of vomiting after paediatric strabismus surgery. Systematic reviews can give a false impression and practising anaesthetists are often "well ahead of the game". In this regard, I think the ethical window for conducting such studies in paediatric strabismus surgery will soon be closed if enough paediatric and children's anaesthetists adopt a more modern approach to these cases.

I strongly commend a propofol–laryngeal mask–topical anaesthesia technique with spontaneous respiration of nitrous oxide–oxygen–volatile agent as day-case anaesthesia for the majority of paediatric squint surgery in terms of its efficacy and lack of emesis. We are currently auditing this assertion but will it be eligible for inclusion in the next systematic review?

Department of Paediatric Anaesthesia and Intensive Care
Royal Hospital for Sick Children
Glasgow

1. Tramèr M, Moore A, McQuay H. Prevention of vomiting after paediatric strabismus surgery: a systematic review using the numbers-needed-to-treat method. *British Journal of Anaesthesia* 1995; 75: 556–561.

Sir,—We thank Dr Morton for his interest in our systematic review [1]. However, some of his comments show that we have failed to convey the methodological rules for performing clinical trials and systematic reviews. He advocates his own clinical approach to postoperative vomiting (POV) in paediatric strabismus surgery. We wish to comment on these two issues.

The aim of our study was to compare both efficacy and potential harm of currently used prophylactic antiemetic treatments in a well defined subgroup of patients at particular risk of POV. There were three main results of the combined analysis of all relevant published randomized controlled trials (RCT). First, the mean incidence of POV in controls without antiemetic prophylaxis was more than 50 % (with a wide range). Second, the overall efficacy of prophylaxis compared with placebo or with no treatment or, in the case of propofol, with another anaesthetic technique, was disappointing. Third, the potential of propofol for harm was alarming. As stated in the text and table, propofol as a maintenance regimen was compared with halogenated inhalation anaesthetics.

Evaluating the benefit of any treatment involves making comparisons. The statement that a particular anaesthetic technique decreases the incidence of POV in paediatric strabismus surgery to < 10 % sounds good but is, in the absence of any comparison, no more than a personal view. Before a new therapy is introduced into clinical practice it should have proved to be at least as effective and to induce less harm than old treatments. The widely accepted gold standard to define efficacy and to exclude harm with the least possible bias is the RCT. Clinicians have known for a long time that ignoring this rule may lead to overestimation of treatment effect [2, 3].

All 2044 children in the analysed 27 RCT underwent tracheal intubation. In ophthalmic surgery, as in other situations with more difficult access to the upper airways, many active practitioners, paediatric anaesthetists included, prefer to have the upper airway of the patient secured (i.e. to have the trachea intubated). A laryngeal mask may eventually prove to be less emetogenic than a tracheal tube, but is this technique as safe in paediatric strabismus surgery? Being "well ahead of the game" may have a dark side.

Increasing patient comfort is an attractive target. Decreasing the incidence of POV implies relieving an unpleasant but time limited condition. POV never becomes chronic and almost never kills. Therefore, the level of acceptance of any treatment-induced risk may be low for most clinicians (and patients). Well designed RCT (not audits reflecting personal views) will perhaps show in the near future if the laryngeal mask in paediatric strabismus surgery is advantageous, not only new but also beneficial.

Unfortunately, even paediatric anaesthetists do not know why a particular patient vomits after surgery and another does not. Life would be much easier if we could avoid opioids and tracheal intubation in all children in order to decrease the incidence of POV to less than 10%. One of the most striking results was the extraordinarily wide range of incidences of vomiting in these studies. However, only six studies reported the use of intra-operative opioids [4–9] and in one the incidence of vomiting was very low [7]. Indeed, the highest incidences of vomiting were reported in studies where opioids were avoided [10–12]. While it is widely believed that opioids increase significantly the risk of POV, there is little evidence to support this. The suggested approach with topical analgesia appears original but is not new; recently published experiences from an RCT were not enthusiastic [13].

Clinicians have to balance treatment efficacy and potential for harm. Systematic reviews of relevant RCT with quantitative analysis of extracted data on both efficacy and adverse effects are powerful tools to make this judgement. However, systematic reviews depend on the quality of reports delivering analysable data. Innovative approaches should be subject to trials of appropriate quality. Good practitioners need to understand some methodology, just as systematic reviewers need to have a grasp of clinical realities.

Maternal sequelae of childbirth

Sir,—Professor Reynolds has drawn attention to the serious neurological complications consequent upon spinal anaesthesia which were described by Ferguson and Watkins in 1938, and by Kennedy, Effron and Perry in 1950 [1–3]. Professor Reynolds attributes these complications solely to the neurotoxicity of the spinal anaesthetic solutions used, which is a satisfactory explanation for most of the cases in Ferguson and Watkins' case series. However, medical opinion has held that the more persistent and serious neurological disabilities such as were described by Kennedy's team could not all be ascribed to local anaesthetic neurotoxicity and that the problem has yet to be understood fully [4].

The Woolley and Roe case [4] has since demonstrated that spinal anaesthetic solutions can be contaminated with acid from spinal needles and syringes if descaling solutions are not washed out of water boiler sterilizers. As these water boilers would have been used when Kennedy's patients were given their spinal anaesthetics, acid contamination is a plausible explanation for these tragedies also. Confirmation at laminectomy of adhesive arachnoiditis (one of the consequences of damage by acid) in four of Kennedy's patients supports this explanation.

These water boilers remain in use today in parts of the world where medical facilities are less well developed, and the potential risk which they pose would not have become clear without this re-evaluation of an apparently unrelated historical problem. Yet again we see that an awareness of history protects us from repeating earlier mistakes.

4. Hutter CDD. The Woolley and Roe case. A reassessment. *Anaesthesia* 1990; **45**: 859–864.

Sir,—I thank Dr Hutter for his interest in my editorial. I did not, however, intend to leave readers with the impression that I attributed neurological sequelae of spinal anaesthesia in the 1930s and 1950s to local anaesthetic neurotoxicity. What I actually referred to were neurotoxic *formulations* and *techniques*. Readers might be interested to hear that the formulation of procaine that was used for spinal anaesthesia in 14 cases of cauda equina syndrome reported from Manchester contained 10% procaine, glycerine and either gliadin or gum acacia, in 15% alcohol [1]. The idea of this formulation, termed heavy duracaine, was to prolong the action of procaine, an odd choice since cinchocaine, a very long-acting drug, was available then. The *technique* I referred to was the light spinal technique which involved displacement of a large volume of cerebrospinal fluid by a foreign solution. I acknowledge that this solution itself may have been contaminated, although like Dr Hutter I would not subscribe to the phenol-entering-invisible-cracks theory. However, it was not, as Dr Hutter suggests, the Woolley and Roe cases that demonstrated that spinal injections may have been contaminated with acid from sterilizers, but Dr Hutter himself [2]. His article gives a fascinating account of his investigation of these cases and the development of his hypothesis.

The western world may congratulate itself on having left behind the amazing concoctions of the 1930s, the light spinal technique using 10 ml of hypobaric cinchocaine, boiling water sterilizers, soaking ampoules in phenol, etc. Nevertheless, recent accounts of neurotoxicity after accidental total spinal anaesthesia [3, 4] and puddling in the subarachnoid space of apparently respectable 2–5 % lignocaine solutions [5–7] must remind us how easily injections into the subarachnoid space may cause radicular irritation and even cauda equina syndrome. Perhaps we have reason to be thankful that in the UK bupivacaine rather than lignocaine is used for spinal anaesthesia.

Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide?

Sir,—We read with interest the article by Kyttä and colleagues [1] on monitoring lung compliance and end-tidal oxygen content for the detection of venous air embolism and wish to make some comments.

The authors used 100 % oxygen with 0.5–0.7 % isoflurane for maintenance of anaesthesia during posterior fossa surgery. The use of less than 1 MAC of isoflurane in oxygen during maintenance of anaesthesia is likely to be associated with awareness. Although many neuroanaesthetists have abandoned nitrous oxide during intracranial surgery, it is still being used in various centres worldwide and would have decreased the likelihood of awareness. We presume that the authors considered that the use of nitrous oxide would increase the incidence of air embolism, but it has been demonstrated that this is not the case in neurosurgical patients undergoing surgery in the sitting position [2]. Alternatively, a mixture of oxygen in air with an FI_{O_2} of 0.3–0.4 and a concentration of isoflurane in excess of 1 MAC or an infusion of i.v. anaesthetic agents can be used for maintenance of anaesthesia during neurosurgical operations.

PEEP was used for the prevention of air embolism in the sitting position, despite the associated reduction in venous return and cardiovascular instability. As a result of an increase in right atrial pressure, PEEP should reduce the pressure gradient between the cerebral venous sinuses and the right atrium. However, it has been demonstrated that PEEP has little value in the prevention of venous air embolism [3]. Moreover, the authors used hyperventilation with PEEP in their anaesthetic technique. Hyperventilation has been shown to reduce the transverse sinus pressure to within the atmospheric to subatmospheric range which could increase the risk of air embolism. Moderate hypoventilation has been recommended during the most critical period of exposing the posterior fossa followed by normoventilation when surgery of the lesion has begun [4].

In this study, the decrease in the difference between inspired and end-tidal oxygen content was 2–2.5 % during induced air embolism in animals breathing 100 % oxygen. This may be consequent on alteration in composition of alveolar gases as a result of a sudden reduction in end-tidal carbon dioxide concentration. This decrease in the difference in inspired and end-tidal oxygen concentration may not be as great when maintaining anaesthesia with oxygen–air or oxygen–nitrous oxide with an FI_{O_2} of 0.3–0.4. As air embolism is being reported increasingly after operations other than neurosurgery, the results would have been more applicable to clinical practice if an inspired oxygen concentration of 30–40 % had been used. In this study, the increase in end-tidal oxygen content occurred after the changes in end-tidal carbon dioxide concentration. In clinical practice, when air embolism is suspected because of a reduction in end-tidal carbon dioxide concentration, the oxygen in the inspired mixture is increased immediately to 100 %. Therefore, at that time the end-tidal and inspired oxygen content difference may not be of value in monitoring for detection of air embolism.

The increase in peak airway pressure reflects a decrease in dynamic pulmonary compliance if tidal volume is constant. The authors recorded an average increase in peak airway pressure of less than 1 cm H_2O subsequent to induced air embolism in animals. This is a small increase and it is doubtful if it would be sufficiently reliable to be a useful monitor in clinical practice. Changes in airway pressure of this magnitude are not uncommon during uneventful anaesthesia and surgery. The results of this study confirm that dynamic pulmonary compliance is a less sensitive monitor than end-tidal carbon dioxide concentration in the early detection of air embolism. It has been demonstrated previously that the increase in airway pressure should not be relied upon as a monitoring aid for detection of venous air embolism [5]. The large variability of the change in airway pressure (SEM 2.0–3.0 cm H_2O) in the animal study supports this argument.

5. Dash HH, Bithal PK, Joshi S, Saini SS. Airway pressure monitoring as an aid in the diagnosis of air embolism. *Journal of Neurosurgical Anesthesiology* 1993; **5**: 159–163.

Sir,—Thank you for the opportunity to reply to the correspondence on our recent study on the detection of venous air embolism [1].

Our standard regimen in maintaining anaesthesia during posterior fossa surgery includes high-dose fentanyl and pancuronium as needed, in addition to an end-tidal concentration of 0.5–0.7 % of isoflurane in oxygen. Awareness has not been reported by any of our patients. Higher concentrations of isoflurane may cause haemodynamic lability in patients undergoing surgery in the sitting position.

The use of nitrous oxide in neuroanaesthesia is controversial. In patients at risk of venous air embolism (VAE) it is not recommended as it may increase the size of the air bubbles resulting in more pronounced consequences of air embolism [2]. The incidence of VAE cannot be expected to decrease on abandoning nitrous oxide, the occurrence of VAE being dependent mainly on the surgical technique and positioning of the patient.

There is no evidence of possible detrimental effects of low PEEP in neurosurgical patients. In our experimental study, no PEEP was applied. In the study of Zentner, Albrecht and Hassler [3], hypoventilation was recommended for the prevention of VAE during posterior fossa surgery. However, in the editorial comment by Roy F. Cucchiara, it was pointed out that hypoventilation compromises surgical exposure. We agree with the latter, and do not hypoventilate the lungs of our patients.

Changes in the differences between inspired and expired oxygen content were significant in this particular experimental setting. We agree with the correspondent that the changes do not follow a similar pattern if oxygen in air or oxygen in nitrous oxide are used as inspiratory gases during maintenance of anaesthesia [Kyttä, Randell, Tanskanen, unpublished observation, manuscript in preparation].

We did not recommend the use of changes in peak airway pressure for the detection of VAE. However, the decreases observed in dynamic lung compliance were more pronounced and followed VAE consistently. For calculation of dynamic lung compliance, changes in airway pressures during the respiratory cycle and changes in tidal volume are used. We still hold to our conclusion that monitoring of inspiratory to expiratory oxygen concentration, and dynamic lung compliance are valuable *supplements to other monitoring techniques* for the detection of pulmonary VAE [1].

Spinal anaesthesia for Caesarean section in women with incomplete extradural analgesia

Sir,—The requirement for operative delivery in the event of inadequate extradural block is not an uncommon problem in obstetric anaesthesia, requiring an alternative anaesthetic technique. Spinal anaesthesia would appear to offer many benefits in this situation and has been recommended [1]. However, six recent case reports describing unacceptably high spinal block in 10 parturients have called into question the safety of spinal anaesthesia where there is existing extradural block [2–7].

Several theories have been proposed to account for these unexpected high block levels including: compression of the dural sac by fluid in the extradural space [8]; leakage of extradural local anaesthetic through the dural hole [9]; the existence of subclinical analgesia at a higher spinal level [10]; or continuing spread of the spinal independent of the extradural.

However, in these cited case reports, seven of the 10 women had the spinal inserted in the sitting position, while nine of 10 were placed in the wedged supine position after spinal anaesthesia. It is our contention that the key to the eventual height of the spinal block in such circumstances is the position of the patient during and after insertion of the spinal and that spinal anaesthesia may be used safely in the presence of extradural block provided there is meticulous attention to patient positioning.

To study this, we have performed spinal anaesthesia in 12 women (mean age 29 yr, mean weight 80 (SD 13) kg, mean height 163 (6) cm) presenting for emergency Caesarean section who had inadequate extradural block for a variety of reasons such as: unblocked segment; unilateral block; maternal dissatisfaction with the extradural; or because we considered that the urgency of the situation did not allow time for the extradural to be extended.

Six of the women had received extradural infusions and six bolus doses of bupivacaine extradurally. Block height before spinal anaesthesia varied from L2 to T8 (median T12). Doses of drugs given extradurally before spinal anaesthesia was commenced varied considerably. The median dose of bupivacaine was 102 (range 25–225) mg, the median dose of fentanyl 10 (0–200) µg. A crystalloid preload of 1000 ml was given and the extradural catheter removed. The patient was positioned in the left lateral position with two pillows under the head and shoulders such that the spine was maintained with the cervical spine higher than the lumbar spine. Spinal anaesthesia was produced using 0.5% hyperbaric bupivacaine 2.5 ml with fentanyl 10 µg via a 25-gauge Whitacre needle. The patient was then turned immediately to the right lateral position, maintaining the position of the spine as before.

Block height was assessed 5 min after spinal injection and every 5 min thereafter. Reverse Trendelenburg tilt was used to prevent the block spreading in a cephalad direction and Trendelenburg tilt used where necessary to develop the height of the block, aiming at a final block height of T4. After 20 min, the patient was turned to the supine position with a left lumbar wedge and prepared for surgery. Median final block height was T3 (range T3–6). Median systolic pressure was 96 (range 85–126) mm Hg, maintained with i.v. ephedrine where necessary (maximum dose 15 mg).

While we have not attempted to define the cause(s) of the reported high blocks, we have shown in this small series that unacceptably high spinal block may be prevented by careful positioning during and after subarachnoid injection.

BOOK REVIEWS

Primer of Intraoperative Neurophysiologic Monitoring. G. B. Russell and L. D. Rodichock (editors). Published by Butterworth-Heinemann, Oxford. Pp. 331; indexed; illustrated. Price £50.00.

This book of 331 pages comprises 25 referenced chapters written by 26 contributing authors from Pennsylvania, Utah, North Carolina and Canada. The book can be divided broadly into two sections; the larger first section covers electrical monitoring, the first two chapters being devoted to the history and functional neuroanatomy, and the next 17 chapters cover various aspects of EEG and evoked potential monitoring. The subsequent smaller section comprises a series of chapters dealing with intraoperative monitoring using intracranial pressure, transcranial Doppler and cerebral oximetry.

Although this book is packed with useful information on neurophysiological monitoring, I found it difficult to read, because chapters vary in their style of writing and there is considerable repetition. Some of the chapters contain largely technical information on EEG or evoked potential monitoring, while others are styled more towards the practical use of these techniques and the problems encountered during anaesthesia for neurosurgical procedures.

Overall this book would be easier to read had the editors streamlined it into a smaller number of more comprehensive chapters. Nevertheless, some chapters are sufficiently comprehensive to be useful reading in their own right for the anaesthetist. For example, chapter 5 gives a broad review of the components of an EEG machine, different methods of monitoring EEG and the particular problems encountered in the operating theatre environment. Chapter 12 gives a detailed analysis of evoked potentials with reference to the effects of anaesthetic agents and is particularly valuable as it discusses in detail the interpretation of evoked potentials during operations, as illustrated by case reports. Chapter 18 is of particular interest to the anaesthetist as it covers the pharmacological effects of anaesthesia on neurophysiological monitoring. Chapter 20 gives an interesting insight into the assessment and response that is appropriate to anomalies detected during intraoperative electrophysiological monitoring and discusses in detail the relative sensitivity and specificity of the monitoring techniques for different operative procedures.

The later chapters of the book are written in a different style and provide an overview of monitoring techniques that might be of value in the future in the operating theatre environment, but the chapters are well referenced and would be a good starting source for those interested in these subjects.

In summary, although this book contains excellent information it is rather disjointed with much repetition. I believe editing the book into a smaller number of more comprehensive chapters would have greatly assisted the reader in identifying specific areas of interest when using this book as a reference. Nevertheless, there are several chapters which would be of interest to an anaesthetist involved in neurophysiological intraoperative monitoring.

N. M. Dearden

Wylie & Churchill-Davidson's A Practice of Anaesthesia, 6th Edn. T. E. J. Healy and P. J. Cohen (editors). Published by Edward Arnold, London. Pp. 1536; indexed; illustrated.

Wylie and Churchill-Davidson's A Practice of Anaesthesia was first published in 1960 and soon became established as a standard text. Regular updates culminated in the production of the fifth edition in 1984. However, there were no further editions; that is until now, 11 years later. Consequently, this edition represents a major rewrite orchestrated by the two editors, Thomas Healy and Peter Cohen. They have been successful in producing a fine textbook which contains considerably more chapters compared with previous editions. They have managed also to keep the contents in one large volume and endeavoured to cover all aspects of modern day international anaesthetic practice.

The book comprises 26 chapters, many by well known experts from Europe, USA and Australasia, and is well indexed. In general, the references are useful and recent, with many helpful suggestions for further reading.

The book is set out in four sections. The first section covers history and basic science. Each chapter provides a good summary of the basic principles on which anaesthetic practice is based. Generally, these chapters are well written and supported by many excellent diagrams and tables. Apart from the standard choice of subject matter, several relatively new and topical subjects have been included, for example autologous blood transfusion, computers in anaesthesia, calcium and magnesium in anaesthesia and transmission of infection in the operating theatre. Space has not allowed several of these chapters to be comprehensive and detailed; consequently, some subjects are covered briefly. However, a full treatment of basic principles and science is not the purpose of this book and the chapters provide a useful reminder before moving on to the next section.

Section 2 sets out to describe the principles of clinical practice in general areas such as paediatrics, geriatrics, hepatic failure, renal failure, recovery, nutritional support and postoperative analgesia. Apart from these and other standard topics, particularly good and interesting accounts of patient safety, critical incidents, the difficult airway, hyperbaric medicine, trauma associated with patient transfer and positioning are available.

The third section confines itself to a systematic treatment of anaesthetic practice, as applied to specific specialties. Many of these chapters are particularly good and often supported by excellent photographs. However, probably because of size constraints, a few areas are dealt with rather briefly. Despite the intent to appeal on both sides of the Atlantic, the European reader is not aware of any potential conflict in approach.

The final section of the book is imaginative and covers topics not often discussed in large textbooks, for example medicolegal matters, quality assurance, cost management and ethical considerations. The authors have supplied good accounts of these difficult areas; it is particularly interesting to compare the chapter describing legal matters in the UK with that discussing the situation in the USA.

I found this textbook a delight to read. It would be useful to any practising anaesthetist, particularly those studying for the final FRCA examination. The decision to confine the subject matter to one volume has led inevitably to brevity in some areas but the editors are to be congratulated in producing an excellent new textbook following the distinguished tradition of Wylie and Churchill-Davidson.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 76, No. 4 APRIL 1996

EDITORIAL I

The 11th World Congress of Anaesthesiology

This issue of the journal marks the occasion of the 11th World Congress of Anaesthesiology which is being held in Sydney, Australia. The over-printing on the front cover of this issue does not signify a special issue or a particularly special selection of manuscripts for publication; it is intended to commemorate the occasion of the World Congress and signifies that *British Journal of Anaesthesia*, being a truly international journal of anaesthesia, will be represented during the congress, both by an exhibition stand staffed by our publishers and also active participation by several members of the Editorial Board in a session on anaesthesia publications.

The international nature of *British Journal of Anaesthesia* is exemplified by our readership, with more than 50% of our subscribers based outside the UK, and by the origin of the material published in each issue of the journal. In this present unselected issue, we have articles from Australia, Denmark, France, Japan, New Zealand, Switzerland and the USA, with only 50% of manuscripts originating from within the UK. In many issues of the journal, articles from outside the UK greatly exceed the number of those from the UK. The gradual policy which the Board of the *BJA* has pursued in making the journal more international is also reflected in the fact that since the last World Congress of Anaesthesiology, held in the Hague in 1992, new members of the Board of the journal have been recruited from the USA, Germany and Australia, and the Board is still actively seeking additional members from outside the UK. It is also perhaps appropriate in this World Congress issue to describe two major innovations in publishing technology for the journal for 1996; namely, printing from disk and publication of a CD-ROM.

Before this year, the process of publishing the journal involved submission of hard copy from authors to the editor, and onward transmission of edited manuscripts to a technical editor who made technical adjustments and marked up the copy for specialist typesetters situated at our printers, Cambridge University Press. The typesetters had the role of keying manuscripts onto computer from hard copy. However, in 1996, this process of typesetting will be eliminated and it will be possible for manuscripts to be handled in disk form, with editing of disks on screen by our technical subeditor and printing directly from that disk, thereby eliminating the tier of typesetters in the printing process. The origination of the pages will be performed at our publishers and at the same time an SGML (standard generalized mark-up language)-encoded neutral form of each article will be locked away in a database. This will enable any material in *BJA* to be re-used for online publishing, collected article publications and perhaps in other technologies which will be developed in future. DTP (desk-top publishing) has been used for many years in other branches of the publishing industry but it is being introduced more slowly in such conservative organizations as monthly scientific journals. For the reader, this should have benefits in reducing the number of potential printing errors, and for authors, it should enable us to reduce the period between acceptance of a manuscript and subsequent publication. Currently, the *BJA* has a good acceptance to publication interval which averaged 4½ months for the period December 1995 to March 1996; our technological innovation should enable us to achieve a potential reduction of 20 days in this process. There will be other additional benefits which will not be as obvious to the reader, such as automated computerized indexing and facilities for electronic transmission of the journal.

The second major exciting technological innovation with which the journal is associated in 1996 is the production of a CD-ROM which has been termed TEAL (the electronic anaesthesiology library). Not only does this represent a major advance in anaesthesia publishing technology but it also allows an exciting collaboration between four major international journals: *Anesthesiology*, *Anesthesia and Analgesia*, *British Journal of Anaesthesia* and *Canadian Journal of Anaesthesia*. In the past year, these four journals have been collaborating in this venture and agreement was reached in producing a single CD-ROM which will incorporate 5 yr of contents (1991–1995) inclusive of all issues of these journals. All of the contents will be featured, including review articles, but abstracts of proceedings of scientific meetings and symposia that are not regular issues will be excluded. In addition, Medline abstracts to all cited references in the four journals within this 5-yr period will also be included on the same disk. This will enable the reader, during perusal of a manuscript, to access instantly on screen an abstract of any article published in this era in any other biomedical journal incorporated on Medline.

The first demonstration of TEAL took place at the 1995 American Society of Anesthesiology Meeting. The demonstration CD contained the contents of the two US journals for 2 yr. At the World Congress in Sydney, there will be a demonstration of a disk containing 3 yr of contents of all four journals. The scheduled publication date for the final version of TEAL is July 1996 and it is now possible to place advance orders. The disk will contain the full 5-yr contents from all four journals with the Medline abstracts on a single CD-ROM. The Boards of the four journals have agreed that, in future, TEAL will be produced in a 5-yr rolling updated format, that is the annual update disk will contain a rolling 5-yr disk set, 1992–1996, 1993–1997, 1994–1998 and so on. It is important to note that the copyright of material on TEAL will remain vested in each of the four respective journals.

The proposed search engine for TEAL will be based on fuzzy logic. This will enable material to be brought up within seconds of typing in a search word. The fuzzy logic component also allows considerable latitude in accuracy of the search word, that is it will respond to either US or British spelling, or even misspelling!

TEAL will allow extremely rapid access to articles with appearance of material on screen as in the printed page of the original journal. It will be possible to print out in the same format as the articles appeared in the printed journal. Other extremely useful features include the ability to reproduce images in as good or better quality than the original printed version and also magnification of some images. It is notable that the cost of TEAL will be considerably cheaper than the cost of binding the journals described on the disk.

TEAL will be demonstrated in the exhibition area at the World Congress and we hope that delegates will take the opportunity to assess the power of this innovation. The editors of the four journals involved in TEAL were extremely enthusiastic and unanimous in their support for the project which has been brought to fruition in an amazingly short time since this concept was first discussed—a superb example of international co-operation. We hope that our enthusiasm is shared by our subscribers and that TEAL proves to be of great value to all anaesthetists, enabling more rapid access to the important and recent international anaesthetic literature.

British Journal of Anaesthesia 1996; **76**: 481–483

EDITORIAL II

Rocuronium: the newest aminosteroid neuromuscular blocking drug

Yet another non-depolarizing neuromuscular blocking drug may seem, especially to the older generation of anaesthetists, unnecessary. This is not so. We require a non-depolarizing agent with a rapid onset of action, in common with suxamethonium, but with a clinical duration of 10–12 min. Such an agent would not have the side effects associated with depolarizing drugs (e.g. hyperkalaemia, increased intraocular pressure, muscle pains) and ideally, its disposal would be independent of organ function.

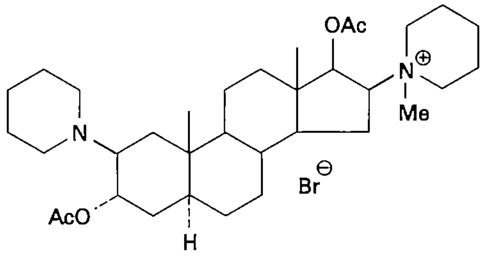
It has perhaps been forgotten that when atracurium and vecuronium became available in 1982, both agents were found to have a shorter onset of action than the pre-existing non-depolarizing drugs. Maximum block after atracurium 0.5 mg kg^{-1} was achieved within 2.0 min, and after vecuronium 0.1 mg kg^{-1}, within 3 min [1]. These onset times were shorter than after tubocurarine 0.6 mg kg^{-1} at nearly 4.0 min [1], but were still longer than after suxamethonium 1.0 mg kg^{-1}. The depolarizing agent could be relied upon to produce maximum block within 1 min and, of the utmost importance, there was little variation in effect between individuals: the SD of that response was only 12 s [2].

In 1994, a new drug became available which narrowed this gap between the onset of action of suxamethonium and the non-depolarizing neuromuscular blocking drugs. Rocuronium has a similar structure to those of pancuronium and vecuronium (fig. 1). In common with vecuronium, rocuronium is a monoquaternary aminosteroid, but it is much less potent, with an ED_{95} (the dose required to produce 95% depression of the twitch response) of 0.3 mg kg^{-1} [3]. This lack of potency is thought to be an important factor in determining onset of neuromuscular block [4]. Whichever neuromuscular blocking drug is used, nearly all of the molecules at the neuromuscular junction are bound to the postsynaptic nicotinic receptor. The majority of these receptors must be occupied to produce neuromuscular block [5]; thus the number of molecules of a neuromuscular blocking drug which must enter the neuromuscular junction to produce a given degree of block is constant. But within a series of compounds, a less potent drug is given in a higher dose; a larger number of molecules are available to diffuse into the neuromuscular junction than the smaller number of molecules of a potent drug. A rapid onset of action is more likely to be achieved with a less potent agent.

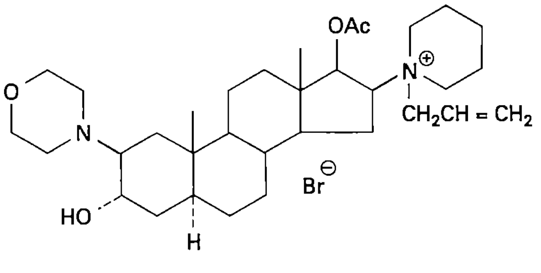
Onset of block

Vecuronium has an ED_{95} of 0.056 mg kg^{-1} [6] and pancuronium an ED_{95} of 0.064 mg kg^{-1} [6]. It would therefore be expected that rocuronium, with an ED_{95} of 0.3 mg kg^{-1}, should have a more rapid onset of action than the older aminosteroids. Early clinical reports confirmed this. Rocuronium 0.6 mg kg^{-1} ($2 \times ED_{95}$) was found to have an onset of action of 60–90 s at the adductor pollicis muscle [7, 8]. The rate of onset is affected by anaesthetic technique: if the neuromuscular blocker is given immediately after the induction agent, then the onset time is a few seconds longer than in a research study, when steady-state anaesthesia has already been achieved with a volatile agent. At this dose, the block produced by rocuronium was not quite as predictable as suxamethonium: the range of effect was greater [9]. If the dose is doubled to 1.2 mg kg^{-1}, intubating conditions very similar to those produced by suxamethonium 1.0 mg kg^{-1} can be achieved reliably [9], but this dose of rocuronium ($4 \times ED_{95}$) has a duration comparable with that of pancuronium 0.1 mg kg^{-1}. Even with a small dose of rocuronium (0.45 mg kg^{-1}), a mean time to maximum effect of 72 s during halothane anaesthesia has been reported, although with an SD of almost 20 s [10].

As with other non-depolarizing neuromuscular blocking drugs, the laryngeal adductor muscles are more resistant to rocuronium than the adductor pollicis muscle (where neuromuscular block is often mentioned). After rocuronium 0.8 mg kg^{-1}, the peak effect in the laryngeal muscles is later, more variable and less profound than after suxamethonium 1.0 mg kg^{-1} [11]. The diaphragm is also more resistant to rocuronium than the adductor pollicis: an intubating dose of rocuronium 0.6 mg kg^{-1} has an effect at the diaphragm comparable with 0.5 mg kg^{-1} in the adductor pollicis [12]. Complete neuromuscu-



Vecuronium



Rocuronium

Figure 1 The monoquaternary aminosteroid, vecuronium, has an acetyl (AcO) group at the 3-carbon position. Deacetylation of vecuronium in the liver produces a 3-hydroxy metabolite which has approximately 50% of the neuromuscular blocking potency of vecuronium [23]. Rocuronium has a hydroxyl group at the 3-carbon position; unlike vecuronium, it will not undergo de-acetylation to produce a 3-OH metabolite with neuromuscular blocking activity.

lar block of the adductor pollicis does not imply that the laryngeal muscles and diaphragm are also completely paralysed.

If it is desirable to achieve a rapid onset of neuromuscular block and suxamethonium is contraindicated, for example in an emergency procedure in a patient with hyperkalaemia, or a patient with a penetrating eye injury, then rocuronium, in a dose of at least $2 \times ED_{95}$ (0.6 mg kg^{-1}), has a distinct advantage over other non-depolarizing neuromuscular blocking drugs. It is also preferable to a small "priming" dose of any other non-depolarizing neuromuscular blocking drug, before a paralysing dose, in an attempt to shorten the time to onset of maximum block [13]; there is no risk of curarization in a conscious patient.

If difficult intubation is anticipated, speed of onset of action is not of the utmost importance: profound block is required, from which rapid recovery can be obtained, if all attempts at intubation fail. In such cases, suxamethonium is still the ideal agent to use, because rocuronium is not a short-acting drug.

Recovery from block

Ten percent recovery of the first twitch of the train-of-four response (T1/T0) after rocuronium 0.45 mg kg^{-1} occurs in a mean time of 27 min during halothane anaesthesia [10]. During isoflurane anaesthesia, 10% recovery of T1/T0 after rocuronium 0.6 mg kg^{-1} occurs in 34 min and 25% recovery in 42 min [14]. After vecuronium 0.1 mg kg^{-1} in patients receiving neuroleptanaesthesia, 10% recovery also occurs in a mean time of 27 min [1], and 25% recovery in 44 min [15]. As with other aminosteroid neuromuscular blocking drugs, potentiation of rocuronium is greater during enflurane or isoflurane anaesthesia than during neuroleptanaesthesia [16], and neostigmine is more effective than edrophonium in antagonizing fade of the train-of-four response at the end of surgery [17].

Thus rocuronium does not have a short duration of action. Moreover, recovery from neuromuscular block occurs during drug redistribution, but the elimination half-life of rocuronium of 86 min [10] is longer than that for vecuronium (53 min) [18].

Renal failure patients

Animal studies have suggested that rocuronium is metabolized in the liver and excreted in bile; in cats, less than 10% of a bolus dose was detected in urine in 24 h [19]. In humans, there is evidence that renal excretion may be greater: 30% in 24 h in one study [20]. The use of rocuronium in patients with renal dysfunction has been reported; the results are conflicting. In a study of rocuronium 0.6 mg kg^{-1} in patients undergoing renal transplantation, onset and recovery times were similar to those of healthy patients [21]. Plasma clearance was similar in both groups, but volume of distribution at steady state was larger in renal patients (264 *vs* 207 ml kg^{-1} in healthy patients). This was thought to explain the longer elimination half-life of rocuronium in renal patients: 97 min compared with 71 min in healthy patients. Cooper and colleagues found longer mean recovery times after rocuronium 0.6 mg kg^{-1} in renal patients undergoing creation of an arteriovenous fistula, than in healthy patients, but this difference was not significant [22]. It is unlikely that rocuronium would produce such a reliable and predictable effect as atracurium in renal failure patients. For example, 25% of T1/T0 after rocuronium 0.6 mg kg^{-1} in renal patients varies from 35 to 115 min; in healthy patients the range is 32–60 min [22].

Unlike vecuronium [23], the metabolites of rocuronium do not have neuromuscular blocking activity [24] (fig. 1). Rocuronium may not have the unpredictable effects of vecuronium if used for prolonged infusion in critically ill patients undergoing intensive therapy: pharmacokinetic studies of rocuronium and its metabolites in such patients are needed.

Cirrhotic patients

The limited evidence on the effect of rocuronium in patients with hepatic cirrhosis is also conflicting [25, 26]. Rocuronium 0.6 mg kg^{-1} has been shown to have a more variable and prolonged effect in this disease state. In one of the two reported studies [25], a reduction in clearance was demonstrated in cirrhotic patients, but this was not statistically significant. In a larger study however, there was more convincing evidence of reduced clearance and prolonged recovery after rocuronium 0.6 mg kg^{-1} in cirrhotic patients [J. M. Hunter, personal communication].

Cardiovascular effects

Atracurium and vecuronium were developed in part to overcome the cardiovascular effects of the older non-depolarizing agents (even though anaesthetists often used these effects to advantage, e.g. hypotension produced by tubocurarine when it was desired to reduce arterial pressure or the sympathomimetic effect of pancuronium in hypovolaemic patients). These drugs are free of such direct cardiovascular effects, but this allows other agents used during anaesthesia to have an unmitigated action, for example the bradycardia produced by opioid analgesics or halothane. In ophthalmic or gynaecological procedures, reflex bradycardia is often detected if atracurium or vecuronium are used. In some, although not all, studies in which rocuronium was given, there was evidence of a slight vagolytic effect [27, 28]. This was not as marked as with pancuronium, but clinicians will realize that they are dealing with a different agent from vecuronium in this respect. Indeed, this feature of rocuronium may be attractive, especially for use in healthy patients during procedures where vagal stimulation commonly occurs, for example cholecystectomy. As with other aminosteroid neuromuscular blocking drugs, there is no evidence of histamine release after the use of rocuronium [28].

Thus rocuronium may be a useful adjunct for clinicians in specific areas of their practice. The onset of block is more rapid than with any other non-depolarizing neuromuscular blocking drug, but rocuronium has a duration of action which is at least as long as vecuronium. It may prove useful during that now rare event—general anaesthesia for Caesarean section [29]. But rocuronium is still not ideal: will Org 9487 one day fulfil the anaesthetist's desire for a rapid onset, rapid offset, non-depolarizing neuromuscular blocking drug [30]? This aminosteroid, which is undergoing clinical trials, is even less potent than rocuronium (ED_{90} 1.15 mg kg^{-1}). In addition to a rapid onset, it may be possible to antagonize the action of Org 9487 within a few minutes of administration. Will Org 9487 therefore become a replacement for suxamethonium? Read this journal for further developments in the field of neuromuscular pharmacology!

CLINICAL INVESTIGATIONS

Dose requirements, efficacy and side effects of morphine and pethidine delivered by patient-controlled analgesia after gynaecological surgery

G. STANLEY, B. APPADU, M. MEAD AND D. J. ROWBOTHAM

Summary

We have compared the dose requirements and side effects of morphine with those of pethidine when administered by patient-controlled analgesia in 40 patients (ASA I–II, 20–65 yr) after elective total abdominal hysterectomy. Patients were allocated randomly, in a double-blind manner, to receive either morphine (bolus dose 2 mg, lockout time 10 min) or pethidine (bolus dose 20 mg, lockout time 10 min) for postoperative pain relief. Mean 24-h morphine and pethidine consumption was 70 (SEM 6.2) mg and 660 (67.8) mg, respectively (ratio 1:9.4). There were no significant differences in postoperative sedation, nausea, pain relief and patient satisfaction (VAS 0–100 mm), and requirements for antiemetics. Four patients receiving pethidine were withdrawn because of postoperative confusion and one receiving morphine because of intractable nausea and vomiting. The 95% confidence interval for this difference between the groups for VAS scores of sedation, nausea and pain were approximately 30 mm. (*Br. J. Anaesth.* 1996; **76**: 484–486)

Key words

Analgesia, postoperative. Analgesia, patient-controlled. Analgesics opioid, morphine. Analgesics opioid, pethidine.

Morphine and pethidine are used commonly for patient-controlled analgesia (PCA). There are some clinical situations where pethidine may be preferred to morphine, for example in asthmatics (anticholinergic action of pethidine) and after bowel anastomoses (dehiscence with morphine [1]) but the choice is often based on other perceived differences in efficacy and side effects such as quality of analgesia and tendency to nausea and vomiting. However, there are few data in the literature to enable proper comparison.

PCA enables comparison of the potency, efficacy and side effects of opioids in the treatment of pain after surgery [2, 3]. Therefore, we have examined, in a prospective, randomized, double-blind study, the relative efficacy and side effects of morphine and pethidine.

Patients and methods

We studied 40 patients, ASA I–II, aged 20–65 yr, undergoing total abdominal hysterectomy. All patients gave written informed consent to the study which was approved by the local Ethics Committee.

Patients were instructed in the use of the PCA machine (Graseby) on the day before surgery. A visual analogue scale (VAS) for assessment of nausea, pain and satisfaction was also explained. Each VAS comprised a 100-mm unmarked line, the ends of which denoted extremes of the variables in question, that is no nausea—extreme nausea; no pain—worst pain imaginable; very unhappy—delighted with everything.

All patients were premedicated with temazepam 10–20 mg orally, 1 h before surgery. Anaesthesia was induced with propofol 2 mg kg^{-1} and tracheal intubation and positive pressure ventilation were facilitated by the use of vecuronium 0.1 mg kg^{-1}. Anaesthesia was maintained with 1% isoflurane and 66% nitrous oxide in oxygen, and fentanyl 2–4 μg kg^{-1}.

Patients were allocated randomly (sealed envelopes) to receive morphine or pethidine by PCA (morphine 2 mg bolus, lockout 10 min; pethidine 20 mg bolus, lockout 10 min). The drug solution was prepared such that 1 ml contained either morphine 2 mg or pethidine 20 mg. The anaesthetist and nurse investigators were blinded to the contents of the PCA syringe. Operation of the PCA device was recorded by a printer (Hewlett–Packard Thermal Printer).

During the immediate recovery period, opioid was administered i.v. in a double-blind fashion in either 1-mg (morphine) or 10-mg (pethidine) increments in the recovery room. Increments were given every 2–4 min by the anaesthetist conducting the study, until pain control was judged to be comfortable and satisfactory by the patient. PCA was then commenced.

VAS scores for pain, nausea and satisfaction were made at 4, 8 and 24 h after commencing PCA. Sedation (wide awake—unable to stay awake) was also assessed at 4, 8 and 24 h by the blinded observers using a VAS scoring system. At the end of the 24-h study period, patients were asked to describe their appreciation of overall pain, nausea and vomiting which was assessed on a three-point verbal scale

(none/slight, moderate, severe). Patient satisfaction was assessed in a similar manner. All measurements were made by a blinded investigator. Prochlorperazine 12.5 mg i.m. was given for nausea on patient request by the nursing staff who were also blinded to the opioid used.

Data were analysed by Student's *t*-test, Mann–Whitney *U* test and chi-square test with Yates' correction, as appropriate. MANOVA for repeated measures was used for visual analogue scores.

Results

There were no significant differences in age, weight, temazepam premedication, duration of surgery and dose of fentanyl administered during surgery (table 1).

Mean 24-hour postoperative opioid consumption by PCA was morphine 70 (SEM 6.2) and pethidine 660 (67.8) mg (ratio 1 : 9.4). There were no significant differences between the groups in the VAS scores for pain, nausea, sedation or satisfaction, and these data, with 95% confidence intervals (CI) for the differences, are shown in table 2. There was no difference also in the number of doses of prochlorperazine administered (table 3).

Table 1 Patient characteristics (mean (SD or range)). No significant differences

	Morphine ($n = 20$)	Pethidine ($n = 20$)
Age (yr)	43 (20–65)	39 (25–49)

Moderately happy	9	9
Happy/delighted	2	6

Overall pain, nausea and vomiting, and satisfaction scores obtained at the end of the study are shown in table 4. These data include those patients (see below) who were withdrawn from the study. There were no significant differences between the two groups.

Four patients in the pethidine group became disorientated and confused, 2–3 h after commencing PCA. They were withdrawn from the study and symptoms disappeared 2–3 h after removing PCA. There were no signs of respiratory depression, the maximum total amount of incremental pethidine received by these patients in the recovery room was 30 mg and overall no patient received more than 50 mg of pethidine in total.

One patient in the morphine group was withdrawn because of intractable nausea and vomiting. This patient became severely nauseated after receiving morphine 3 mg i.v. in the recovery room and was withdrawn from the study 3 h later. Her symptoms remained for several hours despite the use of prochlorperazine and ondansetron.

Discussion

We found no significant differences between morphine and pethidine PCA over a 24-h period in pain, nausea and vomiting, sedation and patient satisfaction. The 95% CI for the differences between the groups for VAS scores of pain, nausea and sedation were approximately 30 mm. The clinical importance of this difference is uncertain but we believe that it is unlikely to be significant. However, one patient was severely nauseated after a small dose of morphine and was withdrawn from study.

Our data are similar to those obtained in patients receiving morphine, pethidine or oxymorphone via PCA after elective Caesarean section during extradural anaesthesia [4]. Also, there were no differences between morphine and pethidine after open cholecystectomy [5]. The comparison in this study was less clear as its primary purpose was to investigate the efficacy and side effects of nalbuphine. However, there may be significant differences between morphine and pethidine when delivered via PCA in children [6]. Morphine was associated with better analgesia and greater sedation, with no other differences in side effects.

Morphine:pethidine potency ratios of between 1:10 and 1:12 have been described in the postoperative period [5,7,8]. Our ratio of 1:9.4 is consistent with these data.

While we did not intend to study postoperative confusion, it was interesting to note that four relatively young, healthy patients in our study became confused and disorientated in the early postoperative period after small doses of pethidine. This was not relieved by administration of oxygen, although there were no signs of respiratory depression, but improved rapidly after cessation of pethidine administration. Postoperative confusion with pethidine has been described previously. For example, in a recent well designed study of 245 postoperative patients, pethidine was associated significantly with postoperative delirium (odds ratio 2.7) [9]. However, these patients tended to be older than those in our study (> 50 yr) and psychological measurements were obtained from day 2 to day 5 after operation.

Confusion may be caused by norpethidine, a metabolite of pethidine [10]. However, in our study, significant plasma concentrations of this metabolite were unlikely as relatively small doses of pethidine were administered before symptoms commenced (maximum 50 mg). Many drugs with a central anticholinergic action are associated with deranged function of the central nervous system [11] and it may be that the anticholinergic action of pethidine was significant in our patients.

In conclusion, we have shown little difference in the pharmacodynamics of pethidine and morphine with respect to analgesia, nausea and vomiting, sedation and patient satisfaction using PCA with the regimen described in relatively healthy patients undergoing elective hysterectomy. However, our work gives further evidence to the view that pethidine may be associated with an increased incidence of postoperative confusion.

Postoperative analgesia by continuous extradural infusion of ropivacaine after upper abdominal surgery†

S. A. Schug, D. A. Scott, J. Payne, P. H. Mooney and B. Hägglöf

Summary

Ropivacaine is a new local anaesthetic with advantages that suggest an important role in the provision of postoperative analgesia. The main aim of this study was to investigate the dose–response relationship of extradural infusion of ropivacaine. We studied 36 ASA I–III patients undergoing upper abdominal surgery during general anaesthesia and extradural block (catheter insertion at T6–9) using 0.5% ropivacaine in a randomized, double-blind study. After surgery nine patients each received an extradural infusion of either ropivacaine 0.1%, 0.2%, 0.3% or saline at a rate of 10 ml h^{-1} for 21 h. All patients had access to i.v. morphine via a PCA device. The ropivacaine groups consumed significantly less morphine over the 21-h infusion period than the saline group (medians: saline 75 mg; 0.1% ropivacaine 32 mg; 0.2% ropivacaine 39 mg; 0.3% ropivacaine 13 mg) ($P < 0.05$). Pain (VAS scores) at rest was significantly lower in all ropivacaine groups than in the saline group after 4 h of infusion (medians: saline 45 mm; 0.1% ropivacaine 15 mm; 0.2% ropivacaine 12 mm; 0.3% ropivacaine 0 mm). Pain on coughing was significantly less in all ropivacaine groups than in the saline group after 4 h infusion (medians: saline 67 mm; 0.1% ropivacaine 44 mm; 0.2% ropivacaine 33 mm; 0.3% ropivacaine 0 mm) and for 0.2% and 0.3% ropivacaine at later times. Motor block was negligible throughout the infusion. Patient satisfaction was higher in the 0.2% and 0.3% ropivacaine groups than in the two other groups. (*Br. J. Anaesth.* 1996; **76**: 487–491)

Key words

Anaesthetics local, ropivacaine. Anaesthetic techniques, extradural. Analgesia, postoperative. Surgery, abdominal.

Ropivacaine is a new, long-acting local anaesthetic, chemically homologous to bupivacaine and mepivacaine. It is the first enantiomerically pure local anaesthetic and exists as the *S*-enantiomer. In preclinical studies, ropivacaine produced less central nervous system and cardiac toxicity than bupivacaine [1]. Furthermore, in healthy volunteers, ropivacaine was less likely than bupivacaine to precipitate central nervous system and cardiovascular changes after i.v. infusion [2]. Data from studies in healthy volunteers and patients suggest that motor block with ropivacaine is less intense and of shorter duration than that with bupivacaine, while onset, duration and extent of sensory block are similar [3–7]. Based on these differences, ropivacaine may be better suited than bupivacaine to postoperative extradural analgesia after major surgery. The aim of the study was to investigate the dose–response relationship of ropivacaine for postoperative analgesia after upper abdominal surgery.

Patients and methods

After obtaining Institutional Ethics Committee approval and written informed consent, we studied patients undergoing abdominal surgery with an incision predominantly above the umbilicus in a double-blind, randomized study. Patients were aged 18–75 yr, ASA I–III, with weights 50–110 kg. Patients were excluded if they had contraindications to extradural anaesthesia or any significant medical history or concomitant disease which would influence postoperative assessments.

Premedication comprising temazepam 10–20 mg was given to most patients. After administration of a crystalloid solution of at least 500 ml, an extradural catheter was inserted 4–5 cm cephalad into the extradural space at T6–9. Five minutes after administration of a 3-ml test dose of 0.5% ropivacaine a 3–7-ml main dose was administered over 5 min. If sensory block to pinprick did not reach T6–4 within 30 min, an additional 5 ml of 0.5% ropivacaine was injected. Anaesthesia was then induced with thiopentone, neuromuscular block (vecuronium or atracurium), isoflurane and nitrous oxide in oxygen, and a maximum dose of fentanyl 200 µg. Additional boluses of 0.5% ropivacaine 5 ml were administered every 2 h during surgery or at signs of inadequate block, with a minimum interval of 30 min between injections. Additional boluses of fentanyl 50 µg were administered during surgery only when there was a

†Presented in part (poster) at the American Society of Anesthesiologists Annual Scientific Meeting, San Francisco, CA, USA, 1994.

need for additional analgesia. Patients who had surgery lasting more than 6 h were excluded from the study.

Within 1 h after the end of surgery, on arrival in the recovery room, an extradural infusion with either saline or 0.1%, 0.2% or 0.3% ropivacaine was commenced at a rate of 10 ml h^{-1} for 21 h (Abbott LifeCare Infuser, Abbott Laboratories, North Chicago, IL, USA). All patients had access to i.v. morphine via a patient-controlled analgesia (PCA) device (Abbott LifeCare PCA Infuser, Abbott Laboratories, North Chicago, IL, USA) with 1-mg bolus doses, 5 min lockout time and no dose limit. Allocation of patients to the study groups was randomized and double-blind.

Wound pain at rest and on coughing was assessed using a visual analogue scale (VAS) (0 mm = no pain; 100 mm = worst pain imaginable) and sensory block to pinprick, and motor block according to a modified Bromage scale (0 = no motor block; 1 = inability to raise extended legs; 2 = inability to flex knees; 3 = inability to flex ankle joints). These assessments were performed every 2 h from the end of surgery until 22:00 and hourly from 08:00 the following morning until return of normal sensation and motor function after discontinuation of the extradural infusion after 21 h; assessments were interrupted from 22:00 to 08:00 to enable patients to sleep overnight. PCA morphine consumption was recorded. Patients rated the overall quality of the treatment on a four-point scale (1 = poor; 2 = fair; 3 = good, 4 = excellent) after 4, 8 and 21 h of infusion. Arterial pressure and heart rate were recorded every hour after operation. Hypotension was defined as a systolic arterial pressure less than 80 mm Hg or more than 30% decrease compared with baseline, hypertension as arterial pressure greater than 180 mm Hg systolic or 110 mm Hg diastolic, bradycardia as heart rate less than 50 beat min^{-1} and tachycardia as heart rate greater than 120 beat min^{-1}. Other spontaneously reported or observed adverse events were recorded throughout the study.

This study was designed as the first dose-finding study of its type. Therefore, SD of relevant variables were not available and thus sample size could not be calculated. Ten patients per group were selected as it was thought that clinically relevant differences could be detected with this sample size. Data were compared in a pairwise manner using the two-tailed Wilcoxon rank sum test adjusted for centre. Differences were considered statistically significant at $P < 0.05$.

Results

We enrolled 50 patients. Eleven patients were withdrawn before commencement of the extradural infusion because of technical failure (three patients), inadequate block (T4–6 was not reached within 45 min after injection of the main dose in two patients), study violation (one patient) or change in surgical approach (five patients). Thirty-nine patients (21 enrolled at Auckland, 18 at Melbourne) were eligible for safety analysis (nine in the saline group and 10 in each of the ropivacaine groups). Three patients were withdrawn from efficacy analysis because of inoperable cancer or PCA or infusion pump failure, leaving nine patients in each of the four groups for efficacy analysis.

The groups were similar in age distribution, height, weight and ASA status, but there was a sex imbalance between groups (table 1). Surgery was mainly nephrectomy, splenectomy or gastrectomy. Catheter insertion, dose of ropivacaine and fentanyl for surgery, duration of surgery and time until commencement of the extradural infusion were also similar in the four groups (table 1).

MORPHINE CONSUMPTION

Figure 1 shows the median values of PCA morphine consumption over the 21 h of extradural infusion. All ropivacaine groups used significantly less morphine than the saline group ($P < 0.05$) and the difference between 0.3% and 0.1% ropivacaine was also significant ($P < 0.05$).

PAIN AT REST AND ON COUGHING

Median values for pain scores (VAS) at rest and on coughing are shown in figures 2 and 3 after 4, 8 and 21 h of infusion. Pain scores at rest were significantly lower in all ropivacaine groups than in the saline group after 4 h of infusion ($P < 0.05$). Pain scores at rest were also lower in the ropivacaine groups than in the saline group after 8 and 21 h of infusion, but this difference was not significant. Pain on coughing was significantly less in all ropivacaine groups than in the saline group after 4 h of infusion and for the 0.2% and 0.3% ropivacaine groups after 8 h ($P < 0.05$). After 21 h of infusion, pain scores on coughing were significantly lower in the 0.3% ropivacaine group than in the saline and 0.1% ropivacaine groups ($P < 0.05$), with no other significant differences between groups.

SENSORY AND MOTOR BLOCK

Sensory block regressed rapidly in the saline group (fig. 4). Upper spread in the ropivacaine groups was dose-dependent and remained stable throughout the infusion. The regression pattern was similar for lower spread in the saline and 0.1% ropivacaine groups. Lower spread remained stable in the 0.2% and 0.3% ropivacaine groups.

Motor block was not observed in the saline and 0.1% ropivacaine groups. One patient each in the 0.2% and 0.3% ropivacaine groups had motor block Bromage degree 1 and 2, respectively, after 4 and 8 h of infusion. After 21 h of infusion, one patient still had motor block degree 1 whereas the patient in the 0.3% ropivacaine group now had motor block degree 3.

QUALITY OF TREATMENT

The proportion of patients rating treatment as excellent at 4, 8 and 21 h of infusion is shown in figure 5. Patient satisfaction was significantly higher in the 0.2% and 0.3% ropivacaine groups compared

	Group			
	S ($n = 9$)	R 0.1 % ($n = 10$)	R 0.2 % ($n = 10$)	R 0.3 % ($n = 10$)
Hypotension	0	1	4	5
Bradycardia	1	0	2	1
Nausea	5	0	6	7
Vomiting	2	0	2	1
Pruritus	1	0	0	0
Confusion/agitation	2	0	0	0

was observed only in the saline group. Other adverse events were equally distributed between the groups during extradural infusion, with the exception of nausea and vomiting (table 2). There was no difference in the incidence of nausea and vomiting in the saline and the two highest dose ropivacaine groups (0.2 % and 0.3 %), but there was no nausea or vomiting in the 0.1 % ropivacaine group. Most side effects were of a mild to moderate nature, except for two patients in the saline group who experienced severe nausea and vomiting and one who experienced severe confusion and agitation.

Discussion

This study was designed as a dose-finding study of ropivacaine for postoperative analgesia by extradural infusion; morphine consumption via PCA was the primary outcome measure. Overall morphine consumption in all ropivacaine groups was significantly lower than that of the saline group. The 0.3 % ropivacaine group showed the lowest morphine consumption. Even though all patients had free access to unrestricted i.v. morphine via a PCA device, initially patients in the saline group were unable to achieve sufficient pain relief at rest. These differences became even more striking for pain relief on coughing, where the 0.3 % ropivacaine group always had the lowest pain scores and the saline and 0.1 % ropivacaine groups never achieved median pain scores less than 30.

Therefore, the study showed that after upper abdominal surgery, extradural infusion of a local anaesthetic produced significantly superior analgesia at rest and on movement compared with systemic opioids alone. It confirms previous retrospective observations [8] and randomized trials [9], but to our knowledge for the first time in the form of a double-blind trial. That the superiority of extradural infusion becomes even more obvious during coughing is in agreement with the description of a "differential analgesic effect" of extradural local anaesthetics, as described by Dahl and colleagues [10]. It is noteworthy that even 0.1 % ropivacaine achieved good analgesia at rest, while only higher concentrations of ropivacaine produced a dense enough block to reduce pain on coughing. This is in accord with the hypothesis of an "extradural sieve" letting through more powerful stimuli at lower local anaesthetic concentrations [11]. From a clinical point of view, pain relief on coughing is most likely of relevance with regard to postoperative outcome. Ability to comply with physiotherapy and to mobilize early could reduce postoperative morbidity [12, 13], particularly after upper abdominal surgery where there may be a high rate of pulmonary complications [14].

In this context it is surprising that patients in the 0.3 % ropivacaine group used some morphine, despite high quality analgesia at all times. From interviews with these patients we conclude that some of this use was an expression of curiosity and boredom. Some patients used morphine for non-surgical aches and pains, such as sore throat from intubation and nasogastric tubes, or for deliberate sedation after hearing about an unexpected diagnosis of cancer. These observations and the inability of all patients to achieve comparable pain scores compromise the often recommended use of PCA as an "objective" pain measurement device [15, 16], but concur with those of other authors [17].

The results for spread of sensory block are in accord with morphine consumption and pain scores. The spread at the end of the infusion period (saline no segments, 0.1 % ropivacaine four segments, 0.2 % ropivacaine eight segments, 0.3 % ropivacaine 10 segments) was clearly dose-dependent and similar to the results obtained by extradural infusion in volunteers [4]. Near stable spreads throughout the infusion period in the 0.2 % and 0.3 % ropivacaine groups and sensory block regression in the 0.1 % ropivacaine group suggest inadequacy of the lower concentration to provide sufficient analgesia.

Motor block was minimal in our patients. We were surprised by one patient in the 0.3 % ropivacaine group who experienced a dense and persistent motor block; he may have suffered an accidental subdural catheter position as he also had the most widely spread sensory block [18], contradicting our own observations of thoracic extradural infusions in more than 1000 patients. The one patient in the 0.2 % ropivacaine group who initially showed a Bromage one block but then recovered, is in accord with our own experiences, that in some patients the initial intraoperative dense block may be maintained by the infusion for some time.

The adverse event which appeared to be attributable to the extradural infusion was hypotension, as its incidence increased in a dose-dependent manner. Nevertheless, the data presented here are in some way an over-representation of this adverse event, as the definition of hypotension in the study was very narrow. Therefore, situations which were often not regarded as hypotension clinically and did not require intervention were described as such. None of the reported hypotensive episodes was severe and those which needed correction were easily treatable by an increase in the i.v. infusion rate. The overall incidence of hypotension in the ropivacaine groups (33 %) was similar to that of 34 % described recently by Leith and colleagues with bupivacaine infusions [19].

All other adverse events occurred rarely or were distributed evenly across all groups. The incidence of nausea and vomiting was high even in the extradural infusion groups. This contradicts other observations of a low incidence of this side effect with extradural analgesia [8, 20], presumably because all of our patients also used some morphine as rescue medication. The absence of this adverse event in the 0.1 % ropivacaine group is probably coincidental. It is interesting that other typical adverse effects of systemic opioids, such as pruritus and confusion, occurred only in the saline group with the highest opioid consumption. Problems with urinary retention could not be assessed as all patients had a urinary catheter *in situ* as part of their surgical management.

Patient satisfaction was also clearly dose-dependent with the lowest scores in the saline group and the highest scores in the 0.3 % ropivacaine group at all times. This confirms our own experience that satisfaction scores are a sensitive tool for assessing postoperative analgesia [21]. The findings contradict the general assumption that patients are most satisfied with PCA as it offers the initial psychological advantage of putting patients in control [22, 23]. Obviously patients value highly significantly better analgesia, which confirms, in a double-blind design, observations published previously [8, 24].

Is there implicit memory after propofol sedation?

R. C. CORK, J. F. HEATON, C. E. CAMPBELL AND J. F. KIHLSTROM

Summary

Recent evidence indicates that implicit memory may be preserved during general anaesthesia. We tested for the presence of explicit and implicit memory in patients undergoing surgical procedures with local or regional anaesthesia and sedation with propofol. Initial i.v. boluses of propofol 0.5 mg kg^{-1} and fentanyl 1 µg kg^{-1} were administered, followed by an infusion of propofol 50 µg kg^{-1} min^{-1}. Administration of one or more doses of propofol 30 mg i.v. during operation was controlled either by the patient or the anaesthetist. At the start of the last skin stitch, patients were presented with a list of 15 stimulus words and the most frequently associated response. The infusion was then discontinued. After 1 h in the recovery area, all patients were tested for free recall, free association, cued recall and recognition on the list presented during surgery (critical list) and a matched list not presented (neutral list). Data of all patients without free recall (explicit memory) were analysed with repeated-measures analysis of variance. Of 36 patients, five demonstrated free recall. For the remaining 31 patients, cued recall and recognition showed no evidence of explicit memory. However, the free association tests demonstrated significant priming. The mean number of critical free associations was 6.6 (SEM 0.4) compared with 5.5 (0.4) neutral free association ($P < 0.05$). In the absence of explicit memory, implicit memory persists after intraoperative sedation with propofol. (*Br. J. Anaesth.* 1996; **76**: 492–498)

Key words

Anaesthetics i.v., propofol. Memory. Anaesthesia, depth.

Memory during anaesthesia has been classified into two different types: explicit and implicit [1]. Explicit memory involves conscious recollection of some previous episode and is what most of us understand as recall during anaesthesia. Implicit memory, however, refers to any effect on a person's experience, thought or action that is attributable to a past event, even if that person does not remember the event. Evidence for implicit memory during general anaesthesia has been controversial [2–4]. Although there is some concern that implicit memory may be spared despite profound impairment in explicit memory, different investigations have yielded different results, even in the same laboratory. For example, we have found that in surgical patients, implicit memory can be preserved during general anaesthesia with a pure oxygen–isoflurane technique [5]. However, using the same programme, we have found that implicit memory is not preserved during nitrous oxide–sufentanil anaesthesia [6]. It is difficult to draw conclusions from other available evidence, however, because of the heterogeneity in the anaesthetic programmes and memory tasks used. The difficulties of research in this area are compounded by the fact that we lack reliable, accurate measures of depth of anaesthesia. Recent investigations of non-patient volunteers found implicit memory preserved only at subanaesthetic concentrations of isoflurane [7] or nitrous oxide [8]. In our study involving anaesthetic concentrations of isoflurane, explicit memory did not occur in any of the patients [5].

Sedative drugs, such as the benzodiazepines, produce profound impairment of explicit memory, but they may spare implicit memory [9–11]. For example, in studies of non-patient volunteers, midazolam impaired recognition memory (a test of explicit memory), but spared priming effects in perceptual identification (a test of implicit memory) [12]. In a study using the same programme, it was found that propofol, a non-benzodiazepine sedative, also dissociated explicit and implicit memory; however, explicit memory was relatively unimpaired compared with midazolam [13]. Because the two drugs produced the same level of sedation, it appears that sedation *per se* does not necessarily impair memory. With the exception of this study, and some anecdotal evidence [14], the amnesic effects of propofol, as distinguished from its sedative effects, are unknown. In this study we tested for the presence of explicit and implicit memory in patients undergoing surgical procedures and sedation with propofol.

Patients and methods

After obtaining approval from the Louisiana State University Institutional Review Board and written informed consent, we studied patients undergoing

ambulatory procedures involving local or regional anaesthesia with sedation. Exclusion criteria were ASA III or greater, allergy to propofol or soybeans, intellectual impairment or hearing difficulty. All patients were trained to "finger tap" as rapidly as possible on a counting device designed specifically for this study (by Joseph M. Moerschbaecher II, PhD, Professor and Head, Department of Pharmacology, LSU Medical Center).

No premedication was administered. Arterial systolic and diastolic pressures, heart rate, pulse oximetry, end-tidal $P\text{CO}_2$ ($P\text{E}'_{\text{CO}_2}$), and temperature were measured throughout the procedure. Before surgery, each patient was given a bolus dose of propofol 0.5 mg kg^{-1} i.v. and fentanyl 1 μg kg^{-1} i.v. The time taken for administration of each bolus was 5 s, and the second drug was given 5 min after the first. The order of administration of the two drugs was determined randomly. A constant infusion of propofol 50 μg kg^{-1} min^{-1} was given via a Bard InfusO.R. (C. R. Bard, Inc., North Reading, MA, USA) for all patients after the initial boluses of fentanyl and propofol. Patients were allocated randomly to receive supplementary boluses of propofol 30 mg during the procedure by one of two techniques: patient-controlled sedation (PCS) or anaesthetist-controlled sedation (ACS). PCS was carried out by the patient pushing a button attached to a demand pump (Bard Ambulatory PCA, C. R. Bard, Inc., North Reading, MA, USA). The patients were told to push the button whenever they wished to be "sleepier". ACS was carried out by the anaesthetist who was given instructions to sedate the patient to a responsiveness score of 4 and a speech score of 3 (see table 1). Clinical variables were recorded at the following events: (1) Baseline, before any drugs were given; (2) 2 min after the initial fentanyl bolus; (3) 2 min after the initial propofol bolus (the order of (2) and (3) were determined randomly); (4) 2 min after surgical incision; (5) at the last skin stitch; (6) on admission to the recovery room; and (7) 1 h after admission to the recovery room. Clinical variables included heart rate, arterial systolic and diastolic pressures, ventilatory frequency, $P\text{E}'_{\text{CO}_2}$ and haemoglobin saturation by pulse oximetry. $P\text{E}'_{\text{CO}_2}$ was not measured in the recovery room. At the same times, ordinal scores of pain reported by the patient, pain perceived by the anaesthetist, and sedation, as measured by scoring responsiveness, speech, facial expression and eye ptosis were allocated from the scale shown in table 1. In addition, the number of finger taps over a 10-s period were recorded. At the end of the procedure, total amounts of propofol, fentanyl and fluids administered were noted.

MEMORY TESTS

Four lists of paired associates developed by Kihlstrom were used for this experiment [15]. Each list consisted of 15 stimulus terms and the most frequent response given to each, as indicated by standard norms. For example, "boy—girl, man—woman, hammer—nail". The word pairs in the four lists were matched in terms of their normal stimulus–response probabilities. The probability of the correct response to a given cue averaged 0.51 for each list. Patients were allocated randomly to listen to one presentation of either lists 1 and 2 (tape A) or lists 3 and 4 (tape B) at the start of the last skin stitch. Both words of each word pair were presented. There was a brief identical introduction to each tape recording: "Please listen to the following word pairs." This introduction was used to adjust volume by the research assistant. Neither the anaesthetist nor other operating room personnel could hear the tape which lasted 90 s. When the word lists had been presented, the infusion of propofol was discontinued and no further administration was permitted.

Postoperative interviews were conducted 1 h after admission to recovery. By this time all patients were awake and responsive. The researcher who conducted the postoperative testing was not the same person who recorded the tape. In addition, this researcher did not know which paired associates had been played to the patient during surgery. The postoperative interviews comprised tests of free recall, cued recall and recognition for explicit memory, and free association for implicit memory. Patients were allocated randomly to receive one of two test sequences during the postoperative interview. Both test sequences included identical questions for free recall and recognition. However, in order to provide for adequate counterbalancing, patients who were given test 1 were tested only on lists 1 and 3 for cued recall and lists 2 and 4 for free association, while those given test 2 were tested on lists 2 and 4 for cued recall and lists 1 and 3 for free association. In each case, the list presented during surgery was the *critical list*, while the list not presented was the *neutral list*. The order of testing was as follows:

Free recall. Patients were asked if they remembered hearing words during surgery. If not they were

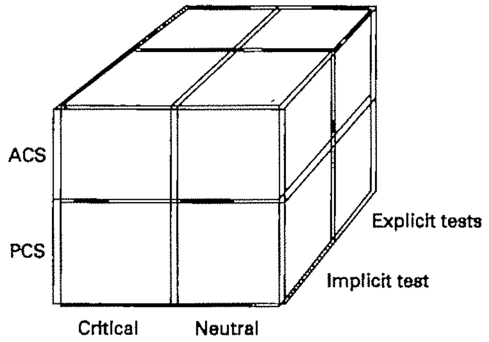

Figure 1 Experimental design. Independent variables are anaesthetist-controlled sedation (ACS) *vs* patient-controlled sedation (PCS), critical *vs* neutral list and implicit *vs* explicit tests. Analysis is with repeated-measures analysis of variance.

reminded that they had been read some words during surgery and were asked to recall any remembered items. A positive response was when patients remembered any of the words presented.

Free association. The cues were read to the patients in random order, and patients were asked to report the first word that came to mind. If no word came to mind, "none" was the accepted response. Patients were not forced to offer a word.

Cued recall. The patients were read the cues in random order and asked if any items reminded them of a word that had been presented during surgery. Again, "no" and/or "none" were acceptable responses. Guessing was discouraged.

Recognition. All 30 word pairs were read in random order and patients were asked to indicate those that had been read during surgery. "None" was an acceptable response and patients were discouraged from guessing.

The experimental design for tape and test is shown in figure 1. Key dependent variables were number of critical and neutral associates as measures of implicit memory (free association) and explicit memory (cued recall and recognition). The critical list of word pairs was played to the patient; the neutral list was not. Data were analysed with repeated measures analysis of variance. Within-subject effects examined were number of correct associations (critical *vs* neutral lists) and measure (free association, cued recall or recognition). The between-subject effect examined was sedation technique (PCS *vs* ACS). In addition, counterbalancing variables tested for potentially confounding effects were tape (A or B), test (1 or 2) and first drug bolus (fentanyl *vs* propofol). Comparison of clinical variables between those patients who demonstrated priming and those who did not was with Student's *t* test for grouped data. We accepted a result as significant if $P < 0.05$. All results for continuous variables are given as mean (SEM).

Results

Of the 36 patients studied, five (14%) demonstrated free recall (explicit memory) of words played on the tape. The analysis that follows focuses on those 31 patients with no free recall of any words on the tape. There were no differences in the results between tapes A and B or between tests 1 and 2. However, these comparisons were only for the complete group of 31 patients. Subgroups were not analysed because of the small number of patients. Table 2 lists the basic descriptive data for the 31 patients without recall, and table 3 the values of different variables collected during operation.

CLINICAL, PAIN AND SEDATION VARIABLES

Clinical variables, including arterial systolic and diastolic pressures, ventilatory frequency, PE'_{CO_2} and haemoglobin saturation by pulse oximetry, are shown in table 4 for the events studied, including baseline, fentanyl bolus, propofol bolus, incision, last stitch, recovery admission and recovery discharge. There was no difference between patients receiving ACS or PCS in clinical variables or in the amount of propofol used (250 (30) mg for ACS *vs* 300 (30) mg for PCS). Heart rate, arterial systolic and diastolic pressures, ventilatory frequency and saturations exhibited significant time effects ($P < 0.05$), but PE'_{CO_2} did not change significantly throughout the procedure. Heart rate was greater, and arterial systolic and diastolic pressures and ventilatory frequency less at the last stitch, when the tape was played, compared with recovery at 1 h, when the interview was conducted ($P < 0.05$). Heart rate, arterial pressures and ventilatory frequency were all less when the tape was played compared with baseline ($P < 0.05$).

Ordinal scores of pain and consciousness are

Table 4 Clinical variables (mean (SEM)). HR = Heart rate, SAP = systolic arterial pressure, DAP = diastolic arterial pressure, f = ventilatory frequency. Order of initial fentanyl and propofol was determined randomly. Fentanyl and propofol results include all patients, irrespective of which drug was given first. *$P < 0.05$ compared with baseline and recovery (1 h)

Ptosis	3.0 (0.0)	2.7 (0.1)	1.8 (0.2)	1.9 (0.2)	2.0 (0.2)	2.8 (0.1)	3.0 (0.0)

summarized in table 5 for the intraoperative and recovery periods. There was no difference between patients receiving ACS and PCS in pain or level of consciousness. Both pain reported by the patient and pain observed by the anaesthetist exhibited a time effect ($P < 0.05$), but neither pain score was significantly different from the other at any time. Finger tapping, responsiveness, speech, facial expression and eye ptosis revealed time effects ($P < 0.05$). As indices of sedation, these variables indicated an awake baseline, sedation after the initial dose of fentanyl and propofol, sedation at the last stitch and return to baseline by admission to the recovery area. These variables were significantly different between the last stitch, when the tape was played, and recovery at 1 h, when the tests for memory were performed ($P < 0.05$).

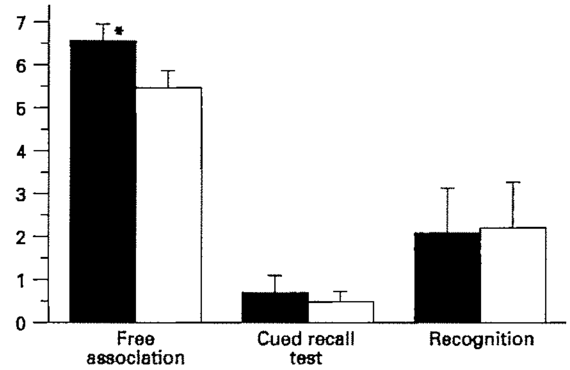

Figure 2 Critical (on tape) (■) and neutral (not on tape) (□) responses provided by the patient at the time of the postoperative interview. Critical responses were greater than neutral responses in the free association test ($P < 0.05$). Numbers of cued recall responses and word pair recognitions were not significantly different between the critical and neutral lists.

MEMORY

The results of five patients who demonstrated free recall were excluded from subsequent analysis, and the cued recall and recognition tests of the remaining 31 revealed no evidence of explicit memory. However, the results from the free association tests performed on the remaining 31 patients suggested implicit memory. Figure 2 shows the number of critical and neutral word pairs provided for each test at the time of the postoperative interview. Cued recall and recognition tests exhibited no difference between the number of critical and neutral word pairs provided as responses during the interview. In contrast, the number of critical free associations was 6.58 (0.36) compared with 5.48 (0.40) neutral free associations ($P < 0.05$). Figure 3 shows the distribution of the number of critical and neutral word pair free associations by number of patients. This shows that the difference detected was attributable to a small consistent difference in a number of patients, rather than extreme differences in a few patients. There were no effects attributable to the counterbalancing variables of tape (A *vs* B) or test (1 *vs* 2). There were also no effects from the initial drug (fentanyl *vs* propofol) or sedation technique (PCS *vs* ACS).

If we define priming as one or more critical responses than neutral responses, 20 of the 31 patients (64.5%) demonstrated priming. A number of clinical and sedation variables, most related to the response of the patient to the initial bolus of propofol,

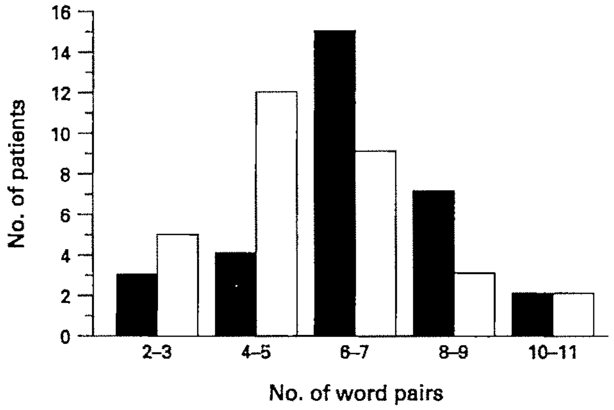

Figure 3 Distribution of the number of critical (■) and neutral (□) word pair free associations by number of patients. This shows that the difference detected was attributable to a small consistent difference between critical and neutral responses in a number of patients, rather than extreme differences in a few patients.

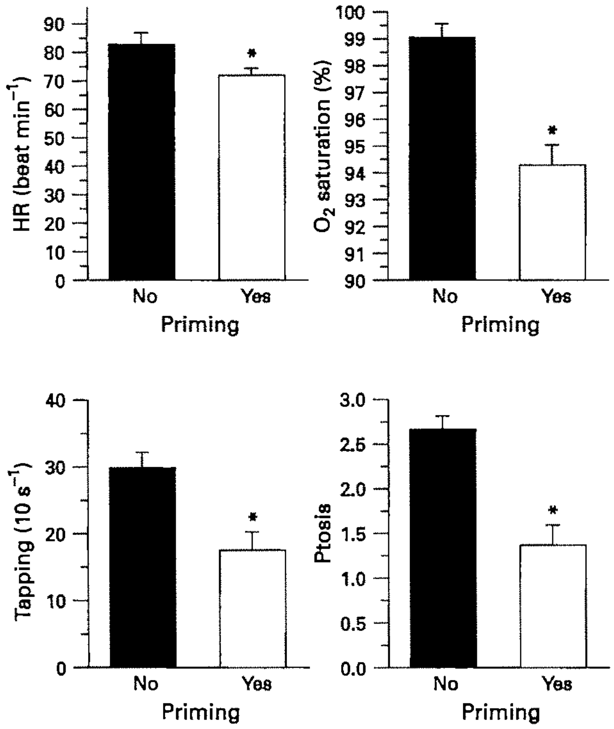

Figure 4 Variables after bolus administration of propofol which were different between those patients who subsequently demonstrated priming and those who did not. Priming was associated with lower heart rate (HR), decreased oxygen (O_2) saturation, slower finger tapping and lower ptosis scores (more ptosis) after the initial bolus of propofol 0.5 mg kg^{-1} ($P < 0.05$).

were associated with priming. Figure 4 shows the four variables which were significantly different between those patients who demonstrated priming and those who did not. Priming was associated with lower heart rate, decreased oxygen saturation, slower finger tapping and lower ptosis scores (more ptosis) after the initial bolus of propofol ($P < 0.05$). In addition to the difference in heart rate after propofol, mean heart rate was 72 (2) beat min^{-1} after the initial bolus of fentanyl for those patients who demonstrated priming, compared with 83 (4) beat min^{-1} for those who did not ($P < 0.05$).

Key variables not associated with priming were total propofol dose, time from the start of infusion and number of propofol boluses. There was no association between the dose of propofol administered and the priming response.

Discussion

This study has shown that patients who received sedation with propofol during surgery showed clear impairments in explicit memory. This was measured by free recall, cued recall and recognition of a list of paired associates presented during surgery. However, these patients also showed a priming effect on free association, which indicates that implicit memory was spared to some degree. This is the first study of ambulatory patients sedated with propofol to show preserved implicit memory, and it corroborates earlier results in non-patient volunteers [14].

For ACS *vs* PCS, our results differed from those of Osborne and colleagues [16] who studied the use of propofol with patient-controlled sedation in subjects undergoing bilateral extraction of third molar teeth during local anaesthesia. They found that patients controlling their own sedation (PCS) were less sedated than those receiving a propofol infusion by an anaesthetist. We found no difference in the level of sedation between ACS and PCS.

Our first two studies of implicit memory during general anaesthesia involved repeatedly playing the word lists to the patients from the first skin incision until the last skin stitch [5, 6]. We reasoned that the more repetitions played, the higher the likelihood of detecting implicit memory. However, a significant problem with this approach is that depth of general anaesthesia during surgery is variable and as yet unmeasurable, varying with both the amount of anaesthetic administered and surgical stimulation. It is possible that depth of anaesthesia during isoflurane–oxygen general anaesthesia (where preservation of implicit memory was demonstrated) varies more with surgical stimulation than depth of anaesthesia during nitrous oxide–sufentanil general anaesthesia (where preservation of implicit memory was not demonstrated).

To overcome this problem, first we used sedation, rather than general anaesthesia, so that we could measure depth by patient response. Second, we provided the patient with only one reading of the critical word pair list at exactly the same point in the procedure for each patient. These steps minimized the effect of varying anaesthetic depths, but neither solves the experimental problem. The solution, of course, is to develop a method of measuring depth of anaesthesia.

Our concerns about repetition enabling us to detect implicit memory are diminished by recent findings showing that repetition and duration of exposure to the stimulus seem to affect explicit but not implicit memory [17, 18]. Our results indicate that a single exposure is sufficient to alter postoperative behaviour. In addition, behaviour is altered in the absence of memory for the source of the suggested alteration in behaviour.

This is the first study of implicit memory that has found significant associations between the way in which patients respond to a drug and the degree of implicit memory. The responses noted, however, seem paradoxical. As shown in figure 3, those patients who later demonstrated implicit memory at the end of the procedure showed increased sensitivity to the initial bolus of propofol at the beginning of the procedure. Ptosis was more evident, and heart rate, oxygen saturation and number of finger taps in 10 s were more depressed by propofol in those patients who exhibited priming. Thus those patients who appeared to be more sedated after the initial bolus of propofol exhibited more implicit memory. There were no differences noted at the last skin stitch when the word pair tapes were played. This observation indicates that patient variability in response to sedation may also play a role in the variability of demonstrated implicit memory. In this case, a more sensitive CNS response to the initial dose of propofol was associated with subsequently increased implicit memory at a later time in the procedure.

Serum concentrations of propofol and dose–response examinations of the effect of different rates of propofol infusion on memory were not performed and EEG was not measured in this study. Our aim was to test for the presence of explicit and implicit memory in patients undergoing surgical procedures and sedation with propofol. Dose–response pharmacodynamic studies of implicit memory in a clinical situation are difficult. Under-sedating and over-sedating patients for a surgical procedure carry unwanted risks and repercussions.

EEG is neither a consistent nor precise measure of depth of anaesthesia. The EEG effects of propofol have been measured with a similar sedation programme by Veselis and colleagues [19]. EEG changes with increased power in the beta and delta frequency ranges were associated with propofol serum concentrations of 0.86 (0.04) $\mu g\ ml^{-1}$. A verbal learning task (Rey auditory–verbal learning task) administered before, during and after infusion demonstrated a marked reduction in short-term memory capacity and dramatically impaired free recall and recognition during infusion. This agrees with our results of inhibition of free recall, cued recall and recognition during infusion of propofol.

Chortkoff, Bennett and Eger observed significant implicit memory at 0.15 minimum alveolar concentration (MAC) of isoflurane in 10 volunteers [7]. At 0.28 MAC, statistical variance in response was greater than at 0.15 MAC, and with 10 observations, the power to detect a difference (if one existed) was compromised. This study and an earlier one by the same group [8] attempted to describe the pharmacodynamics of implicit memory by examining the degree of impairment as a function of drug dose. They found complete suppression of learning (both implicit and explicit) at less than 0.45 MAC of isoflurane in healthy volunteers not undergoing surgery. However, implicit memory may not be "well-behaved" pharmacodynamically because of the number of factors which may contribute to its existence. These include the physiological and psychological state of the patient, timing and degree of surgical stress, and timing and degree of sedation provided by the anaesthetist. Our study revealed no association between the dose of propofol administered and priming evidence of implicit memory.

There is some evidence that the degree of stress may play a role in the preservation of information. Exogenous catecholamines improve learning in anaesthetized rats [20]. Propofol-induced amnesia is impeded by amphetamine administration in mice [21]. Also several studies demonstrating learning during anaesthesia have used nitrous oxide [22–25], which has sympathetic stimulating properties. Our previous study with nitrous oxide also used a large dose of opioid which blunts the stress response. In contrast, our study with isoflurane–oxygen without nitrous oxide was probably a more stressful anaesthetic, because no opioids were given.

Why should propofol spare implicit memory in the absence of explicit memory? In common with the benzodiazepines, propofol interferes with normal hippocampal functioning [26]. Damage to hippocampal structures produces a profound anterograde amnesia affecting explicit memory, while leaving implicit memory intact [27]. Recent neuropsychological studies have provided evidence for a perceptual memory system which stores information about the form and structure, but not the meaning and function, of perceptual objects [28,29]. Hippocampal damage apparently leaves this system intact, permitting priming to occur in the absence of explicit memory. However, not all forms of implicit memory may be spared equally. For example, the literature on implicit memory distinguishes between repetition priming, which can be mediated by a perceptual representation system, and semantic priming, which requires that the meaning and the structure of the stimulus be analysed.

Repetition priming appears to be preserved during sedation for surgery (and, we believe, in certain cases of general anaesthesia for surgery also), but this sparing may not be extended to semantic priming, and other forms of implicit memory. Future studies of implicit memory during both general anaesthesia and sedation should use multiple measures of implicit memory, whose underlying cognitive mechanisms are known.

In theoretical terms, it is possible that propofol, in common with the benzodiazepines, may be used to create a pharmacological model for the study of the role of the hippocampus and other brain structures on memory [10]. But the sparing of implicit memory also has practical implications. Because propofol spares implicit memory, it is possible that surgical patients receiving sedation may be affected after operation by surgical events (such as untoward remarks made by medical personnel), even though they have no conscious recollection of these remarks. Anaesthetists and surgeons should not rely on sedation with propofol to abolish all traces of memory.

Activation of the electrocorticogram by propofol during surgery for epilepsy

M. SMITH, S. J. SMITH, C. A. SCOTT AND W. F. J. HARKNESS

Summary

Propofol is used widely during general anaesthesia but there has been concern that it may be implicated in provoking seizure activity. We have investigated the effects of low-dose propofol on the electrocorticogram of anaesthetized patients undergoing surgery for medically intractable epilepsy. During continuous peroperative recording of the electrocorticogram, propofol was administered in 25 mg increments until burst suppression occurred. Activation of the electrocorticogram occurred in 17 of 20 patients. There was an increase in mean spike frequency in 16, extension of spike distribution in 15 and polyphasia in 13 patients. The mean dose of propofol required to cause burst suppression was 88.2 (range 25–175) mg. We conclude that at low doses, propofol caused activation of the electrocorticogram in epileptic patients but at higher doses burst suppression was induced. (*Br. J. Anaesth.* 1996; **76**: 499–502)

Key words

Anaesthetics i.v., propofol. Epilepsy. Monitoring, electrocorticography.

Propofol is used widely during general anaesthesia and for sedation in the intensive care unit. It is gaining popularity for neurosurgical anaesthesia [1] in part because it causes a dose-dependent decrease in intracranial pressure and cerebral metabolic rate and, at modest doses, cerebral perfusion pressure is maintained [2, 3]. It has a favourable pharmacokinetic profile which allows easy control of depth of sedation and rapid and predictable arousal. However, recently there has been concern that propofol may be implicated in provoking seizure activity and some avoid its use in epileptic patients. In contrast, it has been used successfully in the treatment of status epilepticus and appears to have no adverse effect in neurosurgical patients who are at "high risk" of developing seizure activity.

We have investigated the effect of propofol on the electrocorticogram (ECoG) of anaesthetized patients undergoing surgery for medically intractable epilepsy.

Patients and methods

The study was carried out with the approval of the Joint Medical Ethics Committee of the National Hospital for Neurology and Neurosurgery and Institute of Neurology. We studied 20 patients with medically intractable epilepsy. Premedication was omitted but anticonvulsant medication was continued into the perioperative period and administered on the morning of surgery. Anaesthesia was induced with thiopentone 4–5 mg kg^{-1}, fentanyl 1–3 μg kg^{-1} and vecuronium 0.15 mg kg^{-1}. The trachea was intubated and ventilation controlled to maintain Pa_{CO_2} at 3.8–4.2 kPa. Anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen, and neuromuscular block was continued with infusion of vecuronium. Before recording the ECoG, the inspired isoflurane concentration was maintained at < 1 MAC to minimize anaesthetic-induced changes in the cortical EEG. Arterial pressure was controlled with incremental fentanyl (to a maximum of 8 μg kg^{-1}) and labetolol, and after ECoG recording by deepening anaesthesia with increased inspired isoflurane concentrations.

Heart rate, invasive arterial pressure (radial artery), oxygen saturation and end-tidal carbon dioxide and isoflurane concentrations were monitored continuously. Arterial blood-gas analysis was used to confirm arterial carbon dioxide tensions.

It is a standard part of the epilepsy surgical procedure at the National Hospital to carry out peroperative recording of epileptiform spiking with ECoG to determine the margins of surgical resection. Intraoperative ECoG for temporal lobectomy was recorded using a 25-contact (5 × 5) plate with an inter-contact spacing of 1 cm. The ECoG was recorded as an analogue signal using an 18-channel EEG machine (Nihon-Kohden). Two standard recording positions over the lateral convexity of the temporal lobe are used: anteriorly, with the first row of contacts approximately 1–2 cm behind the pole of the temporal lobe, and posteriorly, with the plate approximately 4 cm from the pole.

After diagnostic corticography, a 3-min period of baseline recording was obtained. Propofol was then administered i.v. in 25-mg increments, at 3-min intervals, until burst suppression occurred.

EEG spike analysis was performed manually before and after administration of propofol by one of the authors (S.J.S.). Activation of the ECoG was

MARTIN SMITH, MB, BS, FRCA (Department of Neuroanaesthesia); SHELAGH J. SMITH, BSC, MB, BS, FRCP, CATHERINE A. SCOTT, BSC, (Department of Neurophysiology); WILLIAM F. J. HARKNESS, FRCS (Department of Neurosurgery); The National Hospital for Neurology and Neurosurgery, Queen Square, London WC1N 3BG. Accepted for publication: December 5, 1995.

defined as: increase in the frequency of spiking; more extensive spike distribution; or polyphasic spikes. The frequency of spiking was taken as the average number of spikes in three randomly selected 20-s periods. The extent of spiking was assessed by counting the number of contacts at which spiking was seen. Extension was deemed to have occurred if spiking was present at two or more additional contacts after propofol. The Wilcoxon test for paired data was used to compare the frequency and extent of spike activity before and after administration of propofol.

Results

We studied seven males and 13 females, mean age 25.6 (range 18–38) yr and mean weight 71.1 (51–97) kg. The pathological diagnosis was hippocampal sclerosis ($n = 16$) or dysembryoplastic neuroepithelial tumour ($n = 4$) and the surgical procedures consisted of tailored temporal lobectomy (including excision of mesial temporal structures) or lesionectomy.

There were no changes in heart rate, arterial pressure, oxygen saturation or end-tidal carbon dioxide tension during the study. The mean dose of propofol required to cause burst suppression was 88.2 (range 25.0–175.0) mg and individual doses are shown in table 1.

Activation of the ECoG by propofol occurred in 17 of 20 patients (table 1). Examples of ECoG recordings with activation are shown in figure 1. Increase in mean spike numbers from 3.6 to 6.7 occurred in 16 patients ($P < 0.005$). There was extension of spike distribution from 3 to 10 contacts in 15 patients ($P < 0.005$) with marked extension

Table 1 ECoG activation after administration of propofol

Patient No.	Weight (kg)	Propofol dose (mg)	Increased in spike numbers	Extension of spike distribution	Development of polyphasia

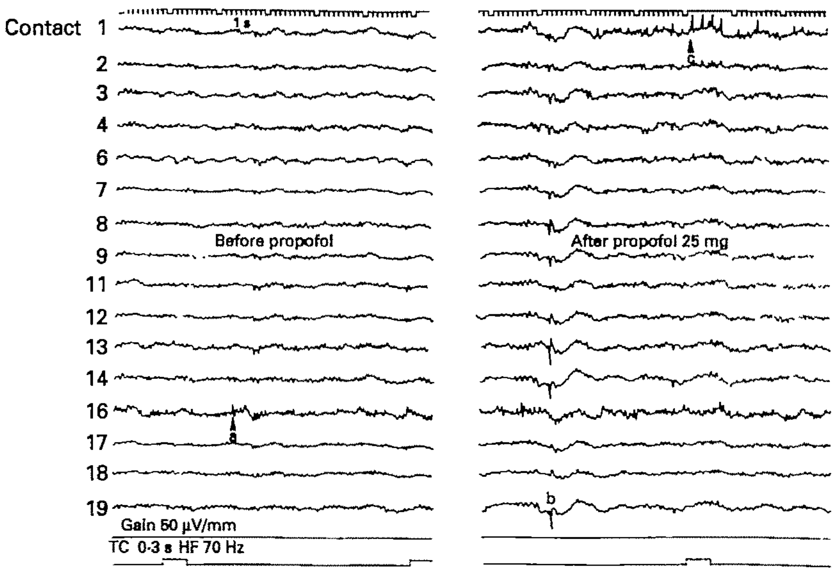

Figure 1 ECoG recording before and after administration of propofol. Before propofol, one epileptiform spike is noted at contact 16 (a). After propofol 25 mg, the epileptiform discharges become more widespread (b) and runs of spikes occur with polyphasia (c). The recording was common referential; same gain and filter settings were used before and after administration of propofol.

(spiking recorded from all contacts) in five. Polyphasia occurred in 13 patients. Ten patients developed a combination of increased spike frequency and distribution, and polyphasia after propofol (table 1).

Activation of the ECoG was not observed in three patients. In one there was continuous spike activity (1 s^{-1}) before and after administration of propofol but there was no change in spike morphology after propofol. In another, burst suppression occurred within 20 s of the initial 25-mg bolus of propofol and in the third there was no spiking before or after propofol administration.

Discussion

Activation of the ECoG by propofol was noted first by Hodkinson, Frith and Mee in 1987 [4]. They described an increase in the frequency of epileptiform spikes and the development of polyspikes, both within and beyond a previously mapped epileptogenic focus, after a bolus of propofol 2 mg kg^{-1}. At the clinical level, generalized seizures and opisthotonos have been attributed to propofol anaesthesia in patients with no previous neurological history and also in those with a history of epilepsy [5–8]. However, several of these case reports did not include EEG conformation of seizure activity and in one with contemporary EEG recording, a subcortical origin of the abnormal movements was postulated [8]. Other causes of seizure activity cannot be excluded in many of the reports. For example, propofol has been implicated as the cause of a grand mal seizure in a patient after termination of propofol sedation 5 days after deep hypothermic circulatory arrest [9]. The validity of implicating propofol as the cause of seizures in a case involving so many other factors has already been questioned [10]. There has however, been sufficient concern to cause the Committee on Safety of Medicine to issue a Safety Action Bulletin in 1992, drawing attention to the possible link between propofol and provocation of seizures [11].

Our results confirmed that, at low doses, propofol caused activation of the ECoG in epileptic patients. The activating effect may be dose related. In a study of propofol in 20 patients with indwelling subdural strip electrodes undergoing chronic monitoring as part of pre-surgical evaluation [12], only five showed induction of epileptiform activity. However, patients in this study received a minimum dose of propofol 50 mg followed by 70- or 140-mg increments, and spike induction occurred most frequently in those patients receiving the lower doses.

Burst suppression in the EEG is generally considered to be the end-point of the treatment of seizures or status epilepticus with anaesthetic agents. All patients in our study developed burst suppression at higher doses of propofol, except for one, in whom burst suppression occurred soon after the initial dose of propofol. Profound burst suppression after bolus administration of propofol (2 mg kg^{-1}) to patients receiving nitrous oxide in oxygen and sufentanil infusion, during anaesthesia for epilepsy surgery, was also noted in a recent study [13]. This study failed to demonstrate an increase in the frequency of interictal spikes, presumably because of the relatively large doses of propofol and the early onset of burst suppression.

Although an activating effect of propofol was observed in our study, it has been shown previously to have anticonvulsant effects in both animals [14–16] and humans. It has been used successfully in the treatment of status epilepticus resistant to other medical therapies [17, 18] and is known to shorten the duration of seizure activity during electroconvulsive therapy [19]. Additionally, many i.v. anaesthetic agents, which are anticonvulsants when given in the usual clinical dose (e.g. thiopentone), show proconsulvant activity at lower doses [20]. It appears likely from our data, and that of other workers [12], that propofol might also have dose-dependent pro- and anticonvulsant properties. In common with other i.v. anaesthetic agents, proconvulsant activity is seen at lower doses and anticonvulsant activity at higher doses.

In our study, the effects of propofol on the ECoG were evaluated during isoflurane anaesthesia and this may have affected the results. However, during the study the inspired concentration of isoflurane was < 1 MAC and it is possible to obtain high quality peroperative ECoG, with little or no apparent anaesthetic interference on the recording, using low-dose isoflurane [21, 22]. However, we are unable to comment on the combined ECoG effects of propofol and isoflurane. Adjuvants, such as opioids and nitrous oxide, cause EEG suppression at lower doses of isoflurane than might otherwise be anticipated [23]. Isoflurane may reduce or suppress background epileptiform activity and has been used successfully in the treatment of status epilepticus [24]. It is possible that isoflurane may in turn suppress the activating effects of propofol and our results may have underestimated the true extent of ECoG activation. The doses of propofol required to produce burst suppression in our patients were lower than normal anaesthetic doses. In one patient, burst suppression occurred within a few seconds of the initial 25-mg bolus of propofol and persisted for almost 15 min. If the presence of isoflurane influences the degree of ECoG change, we believe that its effect would be to reduce rather than enhance the activating effects of propofol.

All patients continued to receive their anticonvulsant medication during and after surgery and drug concentrations were measured before operation to ensure therapeutic concentrations. Although it is possible that the variety of preoperative medication might have altered the effects of propofol on the ECoG, it is again likely that these would minimize the activating effects of propofol. Rapid decreases in plasma concentrations of anticonvulsant medication may result in an increase in epileptiform spiking [25] but it is unlikely that plasma concentrations changed significantly during the study. Furthermore, activation of the ECoG was linked temporally to the administration of propofol. We believe, therefore, that activation of the ECoG observed during our study was related directly to the introduction of propofol.

Whether or not our findings are of clinical significance is a matter for debate. It is also uncertain if similar effects would be noted after administration of propofol to non-epileptic patients. It is conceivable however, that during induction or recovery from propofol anaesthesia or sedation, a stage of activation is passed as blood propofol concentrations increase or decrease through a critical plasma concentration. This may increase the risk of epileptiform activity, particularly in those already predisposed to seizures.

Propofol is often used for intracranial surgery during general anaesthesia and has become the agent of choice for sedation during awake craniotomy [22, 26]. Awake resection of epileptic foci is now commonplace in the USA and gaining popularity in the UK. Cortical mapping of epileptiform activity in awake and anaesthetized patients, and stimulation testing to identify eloquent areas in awake patients, allows careful identification of surgical resection margins. In view of the apparent activation of the ECoG by low doses of propofol, we would not recommend the use of propofol during general anaesthesia for epilepsy when the ECoG is used to guide tailored resection. When propofol is used as an adjunct to sedation during awake procedures, the infusion should be discontinued at least 30 min before cortical mapping with the ECoG.

Periodic cardiovascular and ventilatory activity during midazolam sedation

D. C. GALLETLY, T. B. WILLIAMS AND B. J. ROBINSON

Summary

We have examined the effects of sedation with midazolam 0.1 mg kg^{-1} and reversal with flumazenil 0.5 mg on beat-to-beat heart rate (HR) variability (HRV), systolic arterial pressure (SAP), finger photoplethysmograph amplitude (PLA) and impedence pneumography in eight volunteers. With the onset of sedation there was a small decrease in SAP and increase in HR (ns). Spectral analysis of the HR time series showed reductions in the proportion of power in the high (> 0.15 Hz) frequency "ventilatory" band consistent with midazolam causing vagolysis. During sedation, low frequency (< 0.05 Hz) oscillations of PLA, HR, SAP and ventilation were observed. These were thought to be secondary to activity of coupled cardiorespiratory neurones within the brain stem and the ventilatory periodicity appeared similar to that observed during the early stages of sleep. The diminished high frequency and increased low frequency oscillations induced by midazolam sedation were reversed by administration of flumazenil. (*Br. J. Anaesth.* 1996; **76**: 503–507)

Key words

Hypnotics benzodiazepine, midazolam. Antagonists benzodiazepine, flumazenil. Heart, heart rate. Arterial pressure, drug effects. Measurement techniques, plethysmography.

Analysis of heart rate variability (HRV) is a useful tool for examination of cardiac autonomic tone [1]. Because vagal and sympathetic components of the heart rate (HR) control mechanism are active over different frequency ranges, breakdown of a HR time series using Fourier methods of spectral analysis allows the shifting balance of autonomic control to be examined non-invasively. Similar analysis of systolic arterial pressure (SAP) variability allows extension of these observations to involvement of peripheral cardiovascular mechanisms [2]. Spectral methods of HR [3], SAP [2] and photoplethysmograph pulse amplitude [4] variability analysis have been used to examine the cardiovascular effects of i.v., volatile and inhalation anaesthesia.

Using statistical or time domain methods, the benzodiazepines were one of the first groups of drugs to be studied with regard to HRV; they were observed to cause a decrease in respiratory sinus arrhythmia [5]. Midazolam has modest but clinically important cardiovascular effects and its ability to obtund sympathetic and baroreflex function has been examined in detail [6]. In this study we have examined the effects of midazolam sedation on HRV, arterial pressure and plethysmograph amplitude.

Subjects and methods

After obtaining Ethics Committee approval and informed consent, we studied eight healthy male volunteers, mean age 32 (26–38) yr, mean weight 74 (64–82) kg. Studies were conducted between 08:00 and 11:00 with subjects fasted and refraining from caffeine-containing beverages for at least 12 h. Each subject lay supine and breathed oxygen 5 litre min^{-1} from a Hudson mask. A 22-gauge cannula was inserted into the right antecubital fossa. The following monitoring was commenced: HR (ECG lead CM_5, Corometrics Neo-Trak 502), SAP (continuous non-invasive arterial tonometry, Nellcor N-CAT 500), ventilation (impedance pneumograph, Corometrics Neo-Trak 502) and infra-red finger plethysmography (Hewlett–Packard 78330A). The ECG signal was interfaced with a purpose-built R wave detector generating a 50-ms pulse synchronous with each R wave peak. This pulse triggered a Macintosh IIcx computer with 16-bit ADC board (National Instruments) to record the R–R interval, respiratory amplitude and to determine the trough (diastole) and peak (systole) of each subsequent photoplethysmograph and arterial pressure wave. For graphical display purposes, the output from the impedence pneumograph is shown as the unsigned value through which a five-point moving averager has been passed.

In order to ensure that the ventilatory peak of HRV would not interfere with those frequencies less than 0.15 Hz, subjects were instructed to breathe in time with a 0.24-Hz microcomputer-generated auditory pulse throughout the study. After a 15-min stabilization period, the N-Cat 500 tonometer was calibrated and beat-to-beat recording of cardiorespiratory data commenced. After 5 min the tonometer was recalibrated and subjects received midazolam 0.1 mg kg^{-1} i.v. Twelve to fifteen minutes later the tonometer was recalibrated and flumazenil

---

0.5 mg was administered i.v. Recordings were continued for a further 5-min period after administration of flumazenil.

A 5-min epoch of data was obtained towards the end of the control, midazolam and post-flumazenil periods. Fast Fourier analysis on 256-s segments of HR, respiration, SAP and plethysmograph amplitude (PLA) were performed as described previously [7]. Spectral power (area under the power spectrum curve) was calculated for each variable, for each period, in each subject. This was done for total power and for the power in four frequency bands: very low frequency 0.01–0.02 Hz; low frequency ("vasomotor") 0.02–0.08 Hz; mid frequency ("baroreflex") 0.08–0.15 Hz; and high frequency ("ventilatory") 0.15–0.45 Hz. The power in each band was then expressed as a percentage of the total for the corresponding subject and condition. In the time domain we calculated, for each subject and condition, the mean (SD) of each variable and for the R–R time series, the mean of the consecutive differences of the R–R interval time series.

Changes in the time domain measures and the proportion of power in each spectral range were analysed using ANOVA followed by paired *t* tests (Statview). Total spectral power in each frequency range were compared using the non-parametric Mann–Whitney *U* test.

Results

Table 1 shows the changes in time domain and spectral measures during the study period. The representative raw data are shown in figures 1 and 2.

After midazolam, there was a trend towards increasing HR ($P = 0.08$), decreasing SAP ($P = 0.08$) and increasing PLA. These changes differed between subjects and a clear, sustained, increase in HR, reversed by flumazenil, is apparent in figures 1 and 2. Sustained increases in PLA are shown in figure 2, but these changes appeared not to be reversed by flumazenil.

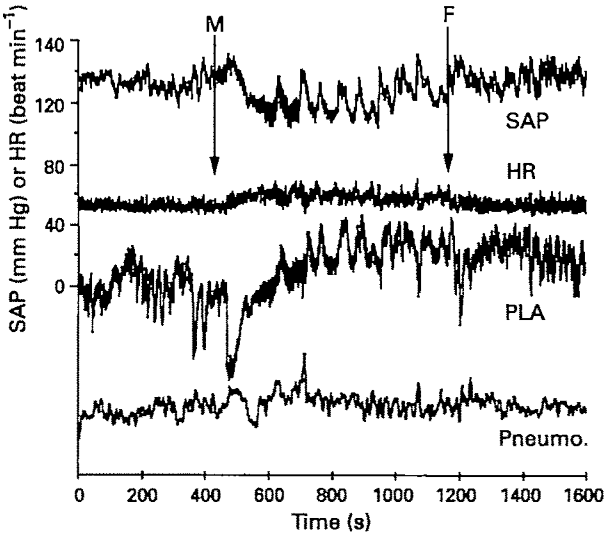

Figure 1 Effect of midazolam (M) and flumazenil (F) reversal of heart rate (HR), systolic arterial pressure (SAP), plethysmograph amplitude (PLA) and pneumogram amplitude (Pneumo.). PLA and pneumogram amplitude are shown on arbitrary scales.

Pneumogram amplitude during midazolam sedation was similar to the control, although during sedation the frequency of ventilation was observed to

increase slightly from the control value of 0.24 Hz to 0.26 (0.02) Hz. Time domain measures (SD, mean consecutive differences) of HR and SAP variability did not differ significantly from control values.

Spectral analysis revealed significant shifts in the HR and PLA power spectra. HR high frequency absolute power and the proportion of power in the high frequency band were reduced while the proportion of power in the band 0.01–0.02 Hz increased from 6 to 22%.

Examination of individual cardiorespiratory time series showed remarkable variability and complexity of effect. Consistent with the changes observed on spectral analysis, figures 1 and 2 show that with administration of midazolam, the appearance of very low and low frequency oscillations is evident in one or more of the cardiovascular measures (SAP, PLA, HR). These waves were most apparent in PLA and to the smallest extent in HR. The period of these oscillations was generally in the region of 40–75 s (0.013–0.025 Hz). The SAP waves appeared as transient elevations above a baseline level, rather than sinusoidal (figs 1, 2). The elevations were of two types: where SAP and PLA oscillations were out of phase, SAP elevations occurred during a reduction in plethysmograph amplitude; and where SAP and PLA oscillations were in phase, SAP pressure elevations were associated with an increase in plethysmograph amplitude (fig. 1).

Low frequency SAP and PLA fluctuations were not confined solely to the period of midazolam sedation but were present in at least one subject before drug administration. Indeed in this subject administration of midazolam caused a transient slowing or cessation of these waves for several minutes.

In three subjects oscillations in pneumogram amplitude were clearly observed in phase with the SAP waves; increased pneumogram amplitude occurred at the time of maximal increase in arterial pressure.

Discussion

The cardiovascular effects of midazolam have been investigated most frequently in patients with coronary artery disease [6, 8–11] and to a lesser extent in healthy subjects [12]. Midazolam causes a decrease in SAP, a small increase in HR, a reduction in cardiac output and little change or a decrease in systemic vascular resistance; ventricular filling pressures are usually decreased or may be unchanged and a direct cardiac depressant effect has been proposed. These haemodynamic changes most likely involve a reduction in SAP secondary to decreased systemic vascular resistance, decreased venous return caused by venodilatation and direct myocardial depression reducing cardiac output [13]. Small doses of diazepam have little effect on baroreflex function in patients with heart disease [14] whereas both diazepam 0.4 mg kg^{-1} and midazolam 0.3 mg kg^{-1}, when used for induction, cause significant but transient decreases in the pressor baroreflex slope which appears to be less than that induced by potent anaesthetic agents [6]. A compensatory, albeit blunted, baroreceptor-mediated increase in HR is therefore possible allowing haemodynamic status to be returned towards normal limits.

The respiratory effects of benzodiazepines are similarly modest but clinically important. Although having minimal effects on respiratory mechanics [15] they diminish central respiratory drive and the ventilatory response to inhaled carbon dioxide [16], and may induce both central apnoea and upper airway obstructive apnoea [17].

The autonomic circulatory and respiratory effects of benzodiazepines are largely mediated within the brain stem by modulation of GABAergic tone [18, 19]. GABA is involved in the endogenous regulation of SAP [20] and regulation of vagal outflow to the heart and respiratory tract [21]. Benzodiazepines are believed to attenuate vagal tone through a central parasympatholytic effect [5, 22–24]. The reduction in respiratory sinus arrhythmia (which is vagally mediated) by diazepam is believed to be mediated through the same mechanism. A vagolytic effect for midazolam can also be inferred both from its known ability to increase HR and the observed reduction in both absolute and proportional high frequency "ventilatory" beat-to-beat HRV in this study. HR periodicities within this frequency range (> 0.15 Hz) are mediated predominantly through fluctuations in vagal tone. Increased HR in concert with reduction in ventilatory induced HRV waves is seen after injection of midazolam.

An unexpected feature of midazolam sedation was the appearance of cardiovascular oscillations at frequencies < 0.025 Hz. Although these oscillations were most apparent in PLA and SAP they were also present in HR and in the pneumogram amplitude. The genesis of low frequency periodicities in HR at less than the Mayer wave or baroreflex frequency of approximately 0.1–0.15 Hz is generally ascribed to vasomotor fluctuations in peripheral vascular tone and indeed we observed them to be most apparent in the digital photoplethysmogram. These low frequency oscillations are well described in normal subjects [25, 26] and were clearly observed in one of our own subjects before sedation. We have observed [unpublished observations] similar fluctuations in unmedicated subjects who are warm and relaxed. Augmentation of these oscillations by ACE inhibitors suggests a modulatory role for the renin–angiotensin system [25] although some authors believe that they reflect an oscillation within a thermoregulatory reflex arc comprising peripheral thermoreceptors, afferent input, central integration and efferent sympathetic vascular response [27, 28]. It is of interest that some periodic SAP elevations were associated with a decrease in PLA while others were associated with an increase. The former probably reflect waves of sympathetic excitation which cause a secondary increase in arterial pressure while the latter may reflect a passive increase in PLA secondary to waves of SAP elevation, perhaps caused by constriction of other vasculature beds. Although these low frequency waves most likely represent sympathetic vasoconstriction, their appearance probably represents an overall decrease in peripheral cutaneous sympathetic tone from a relatively non-oscillatory tonic level at which vasoconstriction is more intense.

In several traces there was a clear association between respiratory activity and very low frequency oscillations in SAP and PLA; elevations in arterial pressure and decreased PLA occurring at the same time as increased ventilatory amplitude. Periodic ventilatory activity is well described in healthy adults under normal and hypoxic conditions, and in the elderly and neonates. In neonates, Waggener and colleagues observed periodic ventilatory patterns with short (approx. 20 s) and long (approx. 60 s) cycles [29]. In adults, Lenfant observed oscillations in healthy awake adults with periods of 2–6 breaths, 25–50 breaths and 150–200 breaths [30]. Ventilatory periodicity has been noted during sleep and is particularly marked during the early stages of sleep or sleep onset. It is possible that the ventilatory abnormalities of sleep apnoea may be an exaggerated form of this periodicity [31]. These ventilatory fluctuations may represent the activity of a Servo control loop oscillation in a chemoreceptor/ventilation arc, as postulated for the genesis of Cheyne–Stokes respiration. Indeed several theoretical and experimental studies having shown that prolonged circulatory times (e.g. heart failure) and enhanced chemoresponsiveness (e.g. altitude or hypoxic conditions) may lead to periodic patterns of breathing [32]. These mechanisms seem unlikely explanations for the observations in the present study however, as all subjects were healthy, the effects of midazolam on cardiac output are small and all subjects breathed oxygen which is a potent depressant of chemoreceptor activation. It seems probable that the slow periodic ventilatory effects were generated by a mechanism similar to that during light sleep and, as both cardiac and respiratory oscillations were coupled, they may have been generated within the interconnected respiratory and cardiovascular neurones of the brain stem [33]. Induction of these oscillations by midazolam and their reversal by flumazenil suggests they are mediated at least in part through brain stem GABAergic transmission. It is of interest that cardiovascular oscillations at these very low frequencies were seen far more commonly than ventilatory oscillations. This may indicate that cardiovascular oscillations within the brain stem are the primary source of ventilatory periodicity. The periodic ventilatory activity may be of clinical relevance to the observation of respiratory instability during benzodiazepine sedation and may warrant further study.

Administration of flumazenil to patients during benzodiazepine sedation results in few haemodynamic responses and minimal changes in SAP and HR [34]. Although these variables were changed little, administration of flumazenil was associated with return of periodic cardiorespiratory oscillations towards those before administration of midazolam.

In summary, we observed that midazolam caused changes in HR and HRV consistent with vagolysis, in some subjects provoked periodic (40–75 s) oscillations in HR, PLA and SBP and that these oscillations were at times coupled to periodic ventilatory activity. The study highlights the value of detailed time series analysis in demonstrating the significant effects of a drug on cardiorespiratory control when standard mean haemodynamic measures are changed little.

Anatomical configuration of the spinal column in the supine position. III. Comparison of adolescent and adult volunteers

Y. HIRABAYASHI, R. SHIMIZU, K. SAITOH, H. FUKUDA, T. IGARASHI AND M. FURUSE

Summary

To clarify the anatomical configuration of the spinal column in the adolescent in the supine position, we have studied 10 adolescent (13–17 yr) and 10 adult (26–38 yr) volunteers using magnetic resonance imaging. T1-weighted sagittal midline magnetic resonance images of the spinal column were obtained with subjects in the supine position. The maximum angles of decline of the lumbar spinal canal did not differ between the adolescent (mean 13.6 (SD 3.3)°) and adult (12.4 (3.8)°) groups. The maximum angles of incline of the upper thoracic spinal canal were smaller in the adolescent group (15.9 (4.7)°) than in the adult group (26.4 (5.8)°). The median highest point of the lumbar spinal canal was located at L4 (range L3–4 to L4–5) in both groups. The lowest points of the thoracic spinal canal in the adolescent and adult groups were located at T8–9 (T7 to T9) and T8 (T6–7 to T9), respectively. This study showed that thoracic kyphotic curvature in adolescents was reduced significantly in the supine position compared with that in adults. This minimized thoracic kyphosis may explain, in part, the enhanced cephalad spread of subarachnoid hyperbaric anaesthetic solutions in adolescents. (*Br. J. Anaesth.* 1996; **76**: 508–510)

Key words

Anatomy, spinal column. Age factors. Adolescents. Anaesthetic technique, subarachnoid. Measurement techniques, nuclear magnetic resonance. Position, supine.

Hyperbaric anaesthetic solutions injected into the midlumbar subarachnoid space spread to higher levels in adolescents than in adults [1, 2]. However, the reason for this is not yet known. Hyperbaric anaesthetic solutions migrating cephalad in the supine position pool in the thoracic hollow [3, 4], and the anatomical configuration of the spinal column may influence the distribution of this pool [5].

With the advent of magnetic resonance (MR) imaging, the anatomical configuration of the spinal column in adults [6] and parturients [7] has been studied. However, data relating to adolescents have been lacking. The aim of this study was to assess the anatomical configuration of the spinal column in adolescents using MR imaging, compared with that in adults.

Subjects and methods

The Institutional Review Board approved our study and informed consent was obtained from all subjects or parents. We studied 10 adolescent (13–17 yr, five boys) and 10 adults (26–38 yr, five men) Japanese healthy volunteers. Subjects with back complaints were excluded. MR imaging examinations were performed with the subject in the supine position, with the legs extended horizontally and a headrest (1 cm in thickness) placed under the head on the MR platform. T1-weighted sagittal images of the cervical, thoracic and lumbar spine were obtained using an MR imaging system (MRT-200/FXIII super version, Toshiba Corporation, Tokyo, Japan) operating at 1.5 T with a single conventional surface coil. Technical specifications included a repetition time of 320–430 ms, an echo time of 15 ms, a slice thickness of 4 mm, a number of slices of 11 and a field of view of 30 cm. The sagittal midline images of the cervical, thoracic and lumbar spine were aligned to determine the following: maximum angle of decline of the lumbar spinal canal in the cephalad direction against the plane of the MR platform, maximum angle of incline of the upper thoracic spinal canal against the plane of the MR platform, the highest and lowest points of the spinal canal, and the levels of termination of the spinal cord and dural sac. The nearest vertebral body and intervertebral disc were used in determining the highest and lowest points (e.g. L1 indicated the body of the first lumbar vertebra; L1–2 showed the intervertebral disc between the first and second lumbar vertebrae).

The adolescent and adult groups were compared by Student's unpaired *t* test for parametric data and by the Mann–Whitney *U* test for non-parametric data. In addition, to assess differences between males and females, maximum angles of decline and incline of the spinal canal were compared by Student's unpaired *t* test. $P < 0.05$ was considered statistically significant.

Results

There were no differences between the adolescent and adult groups in height, weight or body mass index (table 1).

Spinal cord	L1 (T12–L1 to L1)	L1 (T12–L1 to L1–2)
Dural sac	S2 (S2 to S2–3)	S2–3 (S2 to S3)

There was no difference between the adolescent and adult groups in the maximum angle of decline of the lumbar spinal canal. The maximum angle of incline of the upper thoracic spinal canal was smaller in the adolescent than in the adult group (table 2). There were no differences between the adolescent and adult groups in the highest and lowest points of the spinal canal or the levels of termination of the spinal cord and dural sac (table 2). There was no difference between males and females in the maximum angle of decline of the lumbar spinal canal (mean 11.7 (SD 2.4) (range 8–16)° *vs.* 14.3 (4.1) (8–20.5)°) or in the maximum angle of incline of the upper thoracic spinal canal (21.1 (7.4) (9–34.5)° *vs* 21.2 (8.0) (7.5–36)°). Figure 1 shows representative sagittal midline MR images of an adolescent girl and an adult woman.

Discussion

This study in healthy volunteers has demonstrated that thoracic kyphotic curvature in adolescents was reduced significantly in the supine position compared with that in adults.

In the adult in the standing position, it is widely accepted that the spinal column exhibits four curvatures in the sagittal plane: cervical—posterior concavity, thoracic—posterior convexity, lumbar—posterior concavity and sacral—posterior convexity [8]. Does the spinal column in the adolescent in the standing position exhibit the same four curvatures as in the adult? We cannot make definitive statements because no MR images in the standing position are available. What we can say, however, is that our study performed in the supine position demonstrated that the curvature of the spinal column in the adolescent differed significantly from that in the adult. The MR images from the adults verified the presence of the four curvatures in the supine position. In contrast, in the adolescents in the supine position, the thoracic kyphotic curvature was found to disappear substantially. Because the spinal column in the adolescent is expected to have a greater flexibility, it may become straight while the teenager is lying supine on a flat platform.

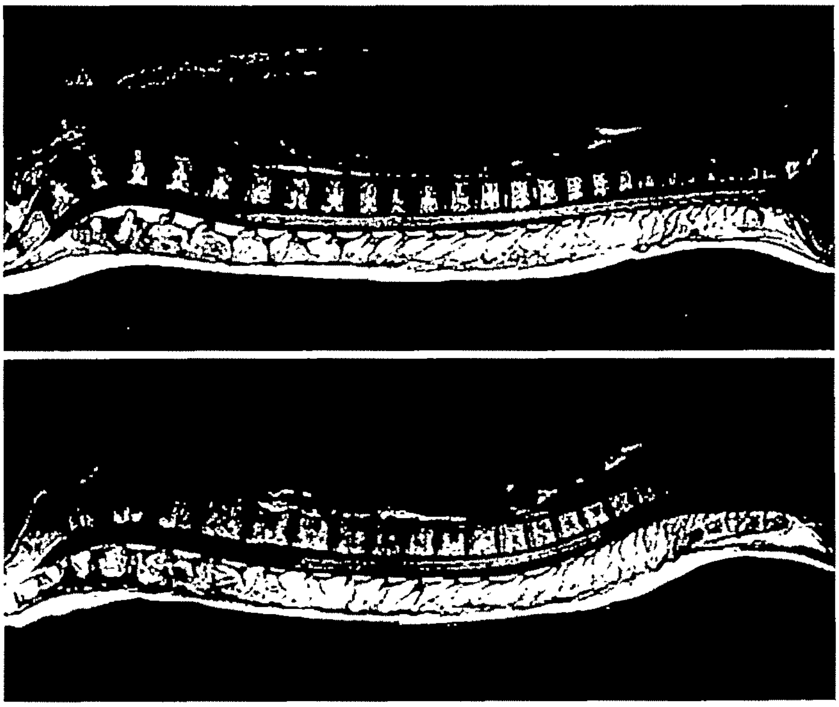

Figure 1 Sagittal midline MR images showing the spinal columns of a 13-yr-old girl (top) and a 31-yr-old woman (bottom). The spinal column in the adolescent becomes straight, particularly in the upper thoracic region, whereas that in the adult exhibits a typical thoracic kyphotic curvature.

When a patient is turned to the supine position after midlumbar subarachnoid injection of a hyperbaric solution, the solution spreads downwards from the injection site under the influence of gravity in both caudad and cephalad directions [3, 4]. The solution migrating to cephalad pools in the lowest region of the thoracic hollow and thus thoracic kyphotic curvature may affect the distribution of this pool [5]. Our study demonstrated that the adolescent has a minimized thoracic kyphotic curvature in the supine position. This minimal thoracic kyphosis may allow the drug to spread more easily to the higher thoracic segments. It has been found that hyperbaric amethocaine (tetracaine) [1] and cinchocaine (dibucaine) [2] injected into the midlumbar subarachnoid space spread to higher levels in adolescents than in adults. This suggests that the flatter thoracic curvature observed in supine adolescents is a likely reason for the higher levels of spinal anaesthesia with hyperbaric solutions in these teenagers.

Unlike hyperbaric anaesthetic solutions, isobaric anaesthetic solutions injected into the midlumbar subarachnoid space spread independently of the influence of gravity [9] and stay in the vicinity of the puncture site. In addition, hypobaric anaesthetic solutions tend to rise to the top of the lumbar lordotic curve [10]. Thoracic kyphotic curvature is therefore expected to have little effect on the spread of isobaric or hypobaric solutions. King and Wooten [11] compared spinal anaesthesia with isobaric amethocaine in adolescent and adult patients and found no difference in spread between the groups. The difference in thoracic kyphotic curvature between the adolescent and adult may not affect the spread of spinal anaesthesia with isobaric solutions.

In addition to the anatomical configuration of the spinal column, the level of termination of the spinal cord and volume of cerebrospinal fluid (CSF) is thought to influence the spread of anaesthetic solutions within the subarachnoid space in the adolescent [1]. It is well known that in young children the spinal cord is close to the sacral canal, and that as they grow, the end of the cord retracts cephalad relative to the spinal canal. In this study we failed to demonstrate any difference in the level of termination of the spinal cord between the adolescent and adult groups. The end of the spinal cord is expected to assume its adult position before 13–17 yr of age. In addition, our sagittal MR images provided no information on the volume of CSF below the termination of the spinal cord. Further studies, including quantitative axial MR images [12], are needed to clarify this issue.

This study was performed on subjects of Japanese origin. The results of this study can be applied directly only to people of the same race and within the age, height and weight range of the subjects in this study. Our volunteers were all of relatively small stature and weight compared with European or North American subjects. It is therefore possible that different results might be encountered in these populations.

Although in adolescents there is a very wide range of height and weight values compared with adult populations, we failed to demonstrate any differences between the two groups in height, weight or body mass index. This probably reflected a type 2 error, because the numbers studied were small. In addition, we failed to show any differences between males and females. However, the results of this study indicated a greater angle of decline in females, which is consistent with the larger buttocks of females. This difference was consistent with the results of our previous study [6]; however, it would be necessary to study a substantially larger population to confirm possible differences.

Convective warming combined with vasodilator therapy accelerates core rewarming after coronary artery bypass surgery

S. J. HARRISON AND J. PONTE

Summary

In a prospective, randomized, controlled study, we have investigated the effect of forced air warming on the rate of change of nasopharyngeal and rectal temperatures in 20 patients after coronary artery bypass grafting. All patients had nasopharyngeal temperatures less than 36 °C on arrival in the intensive care unit and received an infusion of glyceryl trinitrate 15 mg h^{-1}, but none received inotropes. Ten patients were warmed under an aluminized plastic "space" blanket (control group) and 10 were warmed under a "Bair Hugger" blanket connected to its power unit on "high" setting (Bair Hugger group). The rates of increase in nasopharyngeal temperature were 0.4 and 0.95 °C h^{-1}, respectively, in the control and Bair Hugger groups ($P < 0.01$) during the first 2 h after operation. Over the same period of time, rectal temperatures increased at a rate of 0.25 and 0.75 °C h^{-1} in the control and Bair Hugger groups, respectively ($P < 0.01$). (*Br. J. Anaesth.* 1996; **76**: 511–514)

Key words

Temperature, body. Temperature, monitoring. Surgery, cardiovascular. Equipment, blankets. Equipment, warming devices. Monitoring, temperature.

A decrease in body core temperature, termed "afterdrop", occurs frequently during the first 60–90 min of recovery after cardiac surgery; this is often the single factor for delaying return to spontaneous ventilation and tracheal extubation in this group of patients. Postoperative hypothermia may be attenuated by altering the management during cardiac surgery, such as adopting a "normothermic" technique during cardiopulmonary bypass, prolonging the rewarming period or infusing vasodilators while increasing pump flow [1, 2]. Often these measures are not successful and postoperative hypothermia occurs, especially if complications supervene (e.g. difficult haemostasis) which prolong the operative period after restoring normal circulation. Thus there is a clear need for a simple and effective tool to accelerate core rewarming during recovery.

Forced warm air devices are a proven, simple, safe and inexpensive means of preventing hypothermia during operation [3–5]. The available evidence that this type of warming device can be used to accelerate rewarming of core temperature after operation is controversial. In a recent study, Moors and colleagues [6] could not show that forced warm air, after coronary artery bypass surgery, accelerated the rate of increase in core temperature. In contrast, other authors found that in non-cardiac surgery, forced warm air was effective in rewarming the core of patients after operation [7]. We decided to perform this study to ascertain if the concomitant use of forced warm air and cutaneous vasodilatation is effective in accelerating core rewarming after coronary artery bypass surgery. Preliminary results have been published in abstract form [8].

Patients and methods

After obtaining hospital Ethics Committee approval and written informed consent, we studied 20 patients, allocated to two groups of 10 ("control" and "Bair Hugger") who were admitted for elective coronary artery bypass grafting and who had "good" left ventricular function (ejection fraction > 50 %). The general anaesthetic (based on propofol, fentanyl and vecuronium) and surgical techniques were similar for all patients. In each group, six patients had unilateral stripping of leg veins and subsequent wrapping of the leg with an elastic bandage. In four patients in each group, veins were not harvested for grafting, mammary arteries only were used for coronary bypass conduits. With the exception of one patient who was cooled to 28 °C, all other patients were cooled during cardiopulmonary bypass to nasopharyngeal temperatures of 30–32 °C and then rewarmed to 37.3–38.3 °C; bypass and cooling times were noted. After surgery, patients were transferred to the intensive care unit and included in the study only if their nasopharyngeal temperature was less than 36 °C on arrival and inotropic support was not required. Relevant data on the selected patients are shown in table 1; there were no significant differences between the two groups (overall ranges), using the unpaired *t* test or the Mann–Whitney *U* test, in bypass time (49–97 min), cooling time (24–61 min) and total operating time (3.5–5 h).

On arrival in the intensive care unit patients were randomized to receive either a "space" blanket (control group) or a Bair Hugger blanket (Actamed Ltd, Wakefield). In the control group an aluminized plastic "space" blanket (Universal Hospital Supplies Ltd, London) was placed above the sheet and beneath the conventional hospital blankets; in the

Table 1 Patient data (mean (SD) or median (range)). Comparisons between the two groups showed $P > 0.05$ for all variables. NPT = Nasopharyngeal temperature

	Control ($n = 10$)	Bair Hugger ($n = 10$)
Age (yr)	60.5 (49–73)	64.3 (51–73)
Weight (kg)	83.6 (12.1)	74.7 (10.0)
Body mass index (kg m^{-2})	27.8 (4.0)	26.1 (2.7)
NPT on arrival at ICU (°C)	35.7 (35.3–35.9)	35.5 (34.7–35.8)
Ambient temperature (°C)	22.3 (0.9)	22.6 (0.8)

Bair Hugger group a whole body Bair Hugger blanket was placed on top of the patient next to the skin, beneath conventional hospital sheets and blankets, and connected to a Bair Hugger 275E power unit on "high" setting. In both groups the patient's head, and the hand and foot from which temperature measurements were being taken were left uncovered.

TEMPERATURE MEASUREMENTS

Baseline temperature readings of nasopharyngeal, rectal, fingertip and toe temperatures were obtained 10 min after arrival in the intensive care unit and at 15-min intervals thereafter. Nasopharyngeal and rectal temperatures were measured with Yellow Springs 400 series thermistor probes, displayed and stored on a Marquette Tramscope 12C monitor. Fingertip and toe skin temperatures were measured using Mallinkrodt insulated skin thermocouple probes connected to a Mallinkrodt Hi-Lo Temp model 8200 three-channel temperature monitor. The rates of temperature change during the first 2 h after operation were compared between control and Bair Hugger groups for all four measurement sites using the Mann–Whitmey U test. Differences in the number of patients achieving core temperatures greater than 37 °C at 2 h were compared using the chi-square test with Yates' correction. Ambient temperature and humidity were recorded for each patient by means of a Vaisala HMI31 monitor. Ambient temperature ranged between 20.8 and 23.3 °C and relative humidity between 21 % and 38.2 % for all patients, with no differences between the two groups.

POSTOPERATIVE MANAGEMENT

All patients received an infusion of glyceryl trinitrate at a minimum rate of 15 mg h^{-1}. Systolic arterial pressure was maintained at 90–130 mm Hg in all patients. This was attained either by an i.v. infusion of gelatin (or blood if haemoglobin was < 8 g dl^{-1}) when systolic arterial pressure approached 90 mm Hg, or by increasing the glyceryl trinitrate infusion when pressure approached 130 mm Hg. Boluses of hydralazine 10 mg i.v. were used occasionally if glyceryl trinitrate 30 mm h^{-1} was insufficient to maintain systolic arterial pressure at or below 130 mm Hg. All i.v. fluids were warmed to 36.5 °C in a water bath. Blood lost through pericardial and mediastinal drains into an autotransfusion reservoir was returned to the patient at room temperature at a maximum rate of 600 ml h^{-1}. Patients were sedated with an infusion of propofol 50–200 mg h^{-1} and their lungs ventilated mechanically during the period of measurements, maintaining Pa_{CO_2} at 4.5–5.5 kPa. The occurrence of shivering was noted and, if present, was suppressed promptly first by increasing the infusion of propofol and then using morphine boluses (2–5 mg i.v.) supplemented with vecuronium boluses (2–4 mg i.v.) if morphine was ineffective. The incidence of shivering was compared between control and Bair Hugger using the chi-square test with Yates' correction.

Results

The rate of postoperative increase in temperature during the first 2 h was greater in the Bair Hugger

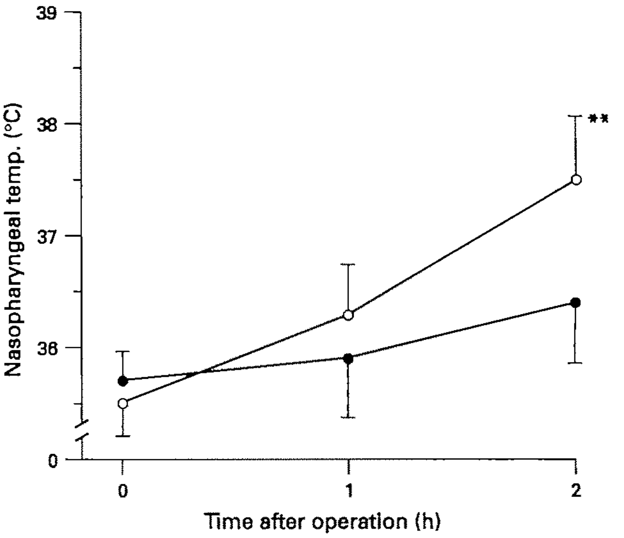

Figure 1 Mean (SD) nasopharyngeal temperature on arrival in the intensive care unit (0), and at 1 and 2 h after operation, in two groups of 10 patients each, after cardiac surgery. Patients in the control group (●) were managed with conventional blankets and an aluminium foil blanket, while those in the Bair Hugger group (○) were managed with a forced warm air device. Temperatures were significantly higher in the Bair Hugger group 2 h after operation. (** $P < 0.01$).

Table 2 Median (range) rate of increase in temperature (°C h^{-1}) during the first 2 h after operation at the four measuring sites in the two groups of patients. The Mann–Whitmey U test was used to compare the two groups

	Control ($n = 10$)	Bair Hugger ($n = 10$)	P
Nasopharyngeal	0.40 (0–0.75)	0.95 (0.70–1.15)	< 0.01
Rectal	0.25 (0–0.65)	0.75 (0.45–1.20)	< 0.01
Toe	−1.15 (−4.00 to 0.05)	0.75 (−0.55 to 4.90)	< 0.01
Fingertip	−2.25 (−4.35 to −0.20)	1.30 (−1.45 to 2.75)	< 0.01

group compared with the control group ($P < 0.01$) at all recorded sites (table 2). Patients in the Bair Hugger group often reached a nasopharyngeal temperature in excess of 37 °C at 2 h, thus forcing the end of the warming intervention. Although measurements were obtained during the first 4 h after operation in all patients, it was decided to confine the study period for the purpose of comparisons to the first 2 h after operation.

At the end of the second hour after operation, one patient in the control group and nine patients in the Bair Hugger group had reached a nasopharyngeal temperature of 37 °C or higher ($P < 0.01$) (fig. 1). Shivering was noted in five patients in the control group and in three patients in the Bair Hugger group but this difference was not significant. In the control group five patients were given morphine boluses, three were given hydralazine and another three vecuronium to suppress shivering. In the Bair Hugger group three patients were given morphine, one was given hydralazine and none needed vecuronium to suppress shivering.

Discussion

In contrast with a recent study in a similar group of patients [6], our results demonstrated that forced warm air, using a Bair Hugger system, accelerated the rate of warming not only of skin but also of nasopharyngeal and rectal temperatures in patients after coronary artery surgery with hypothermic bypass. This discrepancy may be explained by differences in study design; for example, the routine use of high doses of glyceryl trinitrate after operation in our patients may have caused cutaneous vasodilatation, modifying the exchange of heat between the warming device and the patient. It is also possible that the doses of glyceryl trinitrate used in our study accelerated cutaneous heat loss in the patients in the control group. This, however, seems unlikely as patients in this group did eventually warm up, despite the absence of shivering, at a rate close to that usually observed in the absence of glyceryl trinitrate.

Studies of heat transfer through the skin into the body are scarce. There are reports in awake normal subjects managed with surface warming devices [9] but none in unconscious patients undergoing ventilation. Our results should be regarded as preliminary in this respect; they indirectly suggest that heat transfer from the warming device into the patient is possible, compared with merely preventing heat loss. The rate of increase of temperature in the four measured sites is not easily accounted for by the physiological non-shivering thermogenesis expected in postoperative, sedated patients. In awake, normal, non-shivering subjects, metabolism generates approximately 100 W of which approximately 10 W is lost through breathing and 90 W through the skin. If skin loss could be abolished, one would expect mean body temperature to increase initially at a rate of 1 °C h^{-1}, assuming a specific heat of approximately 0.83 kCal kg^{-1} $°C^{-1}$ for the whole body. In sedated patients undergoing ventilation, metabolism is reduced and the rate of increase in mean body temperature during zero skin heat loss should be somewhat less than 1 °C h^{-1}. Although we did not monitor sufficient sites to compute mean body temperature changes, the rate of increase at all four sites measured was > 0.75 °C h^{-1} in the Bair Hugger group. This suggests that the Bair Hugger treated patients at least achieved zero heat loss through the skin, if not actual heat gain from the warming device. Ideally, we should have monitored temperature at another six sites to estimate mean body temperature and used indirect calorimetry during the rewarming period to calculate metabolic rate. This would have allowed calculation of the expected mean body temperature increase per hour as a function of the heat generated by metabolism and a comparison with the measured changes, from which it could be calculated whether heat gain in excess of metabolism was present. Thus, for a direct demonstration of heat transfer from the warming device to the patient, a differently designed study is needed. Heat flow probes strategically placed over the skin would also be necessary for such a study [9].

The discrepancy between our results and those of Moors and colleagues [6] in which it was suggested that forced air warming devices can only expand the volume of the body "core" rather than increase its temperature, may be explained by differences in study design other than the postoperative use of vasodilators not used routinely by these authors. The use of inotropes was not stated and, more importantly, the management of shivering was not addressed. In our view, studies failing to accurately report the use of inotropes during recovery should be interpreted with caution because of the well known thermogenic effects of catecholamines [10, 11]. We were meticulous in our efforts to promptly abolish shivering in our patients because of its contribution to total body heat generation. For this purpose morphine was used [12] and, if necessary, vecuronium, in addition to a routine background sedative dose of propofol. Such manoeuvres attenuated the physiological responses to hypothermia other than shivering [13] allowing for a clearer comparison of the effects of the warming strategy between the two groups of patients. Although the difference was not significant, five patients shivered in the control group compared with three in the Bair Hugger group. Had we not abolished shivering, we would have expected acceleration of the rate of warming in the shivering patients which might have blurred the difference between the two groups. To enhance further the expected difference between the two groups, the "high" setting (43 °C) on the Bair Hugger power unit was used routinely, as reported previously by others [3, 4].

Perioperative hypothermia remains a common problem in cardiac surgery and is associated with increased plasma catecholamine concentrations and an increase in metabolic rate (shivering), causing increased cardiovascular morbidity [14]. Our findings appear to illustrate the stressful effects of postoperative hypothermia: for example, more patients needed hydralazine, morphine and vecuronium in the control than in the Bair Hugger group. Although these differences did not reach significance we suspect that this was because of the small number of patients studied.

The recent trend towards a shorter postoperative period of mechanical ventilation and early extubation has highlighted the need for prevention and treatment of hypothermia. Despite careful temperature management during bypass, a proportion of patients is hypothermic at the end of surgery. The management of this condition has been based traditionally on preventing further heat losses by nursing the patient in a warm environment and covering the skin with thermal insulation devices such as aluminium foil. Despite these measures, core temperature often decreases further during the first hour after operation, as indeed we observed in several of our patients in the control group. Such "after-drop" in core temperature is possibly related to the redistribution of heat from the core to other body compartments, especially skeletal muscle [15]. Other types of heating devices have been tried in this setting; the oesophageal heat exchanger, for example, has been shown to be ineffective and radiant heaters to be effective only in warming the skin but at the expense of convenience [16].

Single-dose i.v. granisetron in the prevention of postoperative nausea and vomiting

A. J. WILSON, P. DIEMUNSCH, B. G. LINDEQUE, H. SCHEININ, H. S. HELBO-HANSEN, M. V. A. M. KROEKS AND K. L. KONG

Summary

In this randomized, double-blind, parallel group, placebo-controlled, dose-ranging study, we have compared three doses (0.1 mg, 1.0 mg and 3.0 mg) of the 5-HT$_3$ receptor antagonist, granisetron (Kytril), as prophylactic therapy for the prevention of postoperative nausea and vomiting. The aims were to determine the optimal dose of granisetron and to evaluate its safety profile. We studied 527 adult patients, undergoing elective open abdominal surgery or vaginal hysterectomy during general anaesthesia. Antiemetic prophylaxis with a single dose of granisetron 1.0 mg or 3.0 mg resulted in a significant reduction ($P < 0.001$ compared with placebo) in the numbers of patients experiencing postoperative vomiting, or nausea, or who achieved total control during the postoperative periods 0–6 h and 0–24 h. The two higher doses of granisetron (1.0 mg and 3.0 mg) provided effective prophylaxis against vomiting, with 78% and 77% of patients, respectively, being free from vomiting in the first 6 h after surgery, and 63% and 62% in the first 24 h. This compares with 50% and 34% at 0–6 h and 0–24 h, respectively, in the placebo group. Granisetron was well tolerated and the optimum dose was 1.0 mg (*Br. J. Anaesth.* 1996; **76**: 515–518)

Key words
Vomiting, nausea. Vomiting, antiemetics.

Granisetron (Kytril) is a highly selective and potent 5-HT$_3$ receptor antagonist [1]. It is believed to act specifically at 5-HT$_3$ receptors on the vagal afferent nerves of the gut. Studies have shown that granisetron (in contrast with ondansetron) produces irreversible block of the 5-HT$_3$ receptor [2, 3] which may account for the long duration of action of the drug. Furthermore, in studies comparing the potency of three different 5-HT$_3$ receptor antagonists, granisetron was shown to have a greater potency than tropisetron, which in turn had a greater potency than ondansetron [4]. Granisetron has proved to be safe and effective against nausea and vomiting induced by cancer chemotherapy when given as a single 3.0 mg dose [5]. Therefore, in this study we have determined the optimal dose of granisetron (0.1, 1.0 or 3.0 mg), given as a single i.v. injection for prevention of postoperative nausea and vomiting (PONV), and evaluated the safety profile of granisetron when given before surgery.

Patients and methods

This multinational, multicentre study was carried out in 35 centres in Denmark, Finland, France, Italy, The Netherlands, South Africa, Switzerland and the UK with the approval of the Ethics Committees in each centre. It was a randomized, double-blind, parallel group, dose-ranging study comparing three single doses of i.v. granisetron with placebo.

We studied patients of both sexes, over the legal age of consent, who were undergoing elective open cholecystectomy, open gynaecological procedures or vaginal hysterectomy during general anaesthesia. Exclusion criteria were ASA class IV or V, body weight 25% or more above ideal, breast feeding or pregnancy, known sensitivity to 5-HT$_3$ antagonists or if patients were already experiencing vomiting or moderate-to-severe nausea or had taken antiemetic drugs in the 24 h before surgery.

A history of susceptibility to motion sickness or past history of PONV was recorded. Among female patients, a menstrual history was also obtained, as the incidence of PONV is known to be affected by the phase of the menstrual cycle [6].

After giving written informed consent, patients were allocated to a treatment group to receive one of the three doses of granisetron or placebo using a computer-generated randomization schedule. Granisetron or placebo was given as an i.v. injection over 30 s, 5 min before induction of anaesthesia. The study was blinded by each syringe being preloaded with the same amount of fluid but a different dose of granisetron (0, 0.1 mg, 1.0 mg or 3.0 mg), depending

on the randomization code. Patients were scheduled to receive general anaesthesia with the following agents: no premedication or benzodiazepine premedication, i.v. barbiturate induction, maintenance with nitrous oxide and a volatile agent in oxygen, intraoperative opioid analgesics, neuromuscular block and antagonism of neuromuscular block as required, and postoperative analgesia with opioid or non-opioid analgesics, or both. Duration of operation and the time taken for patients to respond to verbal commands (recovery time) were also noted.

Patients were assessed by the investigators 1, 2, 6 and 24 h after operation. At each of these times, the incidence of nausea, vomiting, or both, and the patient's subjective assessment of pain were recorded. The time of onset of the first episode of nausea, vomiting, or both, was also noted. The major measures of efficacy were number of patients who did not report any nausea or vomiting 0–6 h and 0–24 h after recovery from anaesthesia. Patients who experienced nausea or vomiting, or both, such that further antiemetic treatment was deemed necessary by the attendant physician, were given rescue antiemetics (either prochlorperazine or metoclopramide) and classed as treatment failures. A patient with total control was defined as one who had no nausea, no vomiting, no rescue therapy and had not been withdrawn during the 24 h after anaesthesia.

Patients were followed up from 4 to 8 days after operation. Return of bowel function was assessed after 6 h and 24 h by recording the return of flatulence or evacuation of stool. Vital signs (heart rate, arterial pressure and temperature) were recorded. Blood samples were obtained before drug administration, at 24 h and at follow-up, for plasma creatinine, alkaline phosphatase and alanine aminotransferase concentrations, haemoglobin content, red blood cells, packed cell volume, white blood cells and platelet count.

The occurrence of adverse events during the study was monitored. For any event, the following details were recorded: time it started and stopped, or whether or not it was continuous; course; intensity; suspected relationship to study treatment; and whether or not corrective therapy was given.

Our aim was to recruit at least 480 patients into the study, with approximately 120 patients in each treatment group. This was the number needed in order to detect a 22% difference between active groups and placebo (90% power) assuming a "no vomiting" rate of 50% (based on previous observations of placebo no vomiting rates [6, 7]).

STATISTICAL ANALYSIS

The chi-square test was used to detect differences between treatment groups for "no vomiting", "no nausea", total control and adverse events. The Cox log rank test was used to detect differences between treatment groups in the survival distributions of the variables: time to less than total control, time to first episode of vomiting, time to first episode of nausea and time to first use of rescue antiemetics over the first 24 h. Pairwise comparisons were made between placebo and each of the granisetron treatment groups using the modified Bonferroni correction to maintain an overall significance level of 5%. Logistic regression analysis (at a significance level of 10%) was used to investigate the presence of any treatment-by-factor interaction.

Results

A total of 527 patients (96% women) were recruited and allocated randomly to receive placebo ($n = 133$), granisetron 0.1 mg ($n = 132$), granisetron 1.0 mg ($n = 134$) or granisetron 3.0 mg ($n = 128$). There were no significant differences in patient characteristics between the four groups (table 1).

The groups were comparable in the type of surgery performed, anaesthetic agents and technique used, duration of operation and perioperative use of opioid analgesics (table 2).

The two larger doses of granisetron (1.0 mg and 3.0 mg) provided effective prophylaxis against vomiting: 63.4% and 61.7% of patients, respectively, were free from vomiting in the first 24 h after surgery ($P < 0.001$ *vs* placebo), and 78.4% and 76.6%, respectively, in the first 6 h ($P < 0.001$ *vs* placebo). The results are summarized in table 3.

Significantly more patients did not require rescue antiemetics (prochlorperazine or metoclopramide) in the granisetron 1.0 mg ($P = 0.007$) and granisetron 3.0 mg ($P = 0.003$) groups than in the placebo group. Overall, the distribution of survival times to first episode of vomiting, first episode of nausea, less than total control and first use of rescue antiemetic therapy differed significantly ($P < 0.01$) between the granisetron 1.0 mg and 3.0 mg groups and the placebo group, with the granisetron groups performing better.

There were no significant treatment-by-factor interactions for age, weight, previous history of PONV–motion sickness, menopausal status, duration of anaesthesia or study country (table 4). Only two significant treatment-by-factor interactions emerged from the analysis: type of surgery and use of opioid analgesics (table 4). In both cases, the treatment groups were well matched for these factors (table 2). Of those patients who did not receive an opioid analgesic, 69.75% vomited, while only 40% of those who received an opioid analgesic vomited. There were no differences in patients' assessment of pain in the four groups. In general, no more than 15% of patients in each group experienced severe pain at any time.

The groups were comparable in time taken after operation to respond to verbal commands and time taken for return of bowel function. Similarly, there were no significant differences between the treatment groups in vital signs during the study or in haematological or biochemical variables. Nine patients had a two-fold elevation in hepatic enzymes after operation. Although this was of some clinical concern to the investigators, the incidence of increased concentrations of hepatic enzymes was well distributed among the four treatment groups. The most common adverse events were constipation,

headache and abdominal pain, but there were no significant differences in their occurrence between the treatment groups.

Discussion

This double-blind study was designed to determine the efficacy of three different single doses of i.v. granisetron (0.1 mg, 1.0 mg, and 3.0 mg) compared with placebo in the prevention of PONV in patients undergoing open abdominal surgery or vaginal hysterectomy. Patients recruited into the study were a homogeneous group of mainly women undergoing gynaecological procedures, for whom PONV constitutes a well recognized problem [8–12]. The groups were well matched for known risk factors, such as sex, age, surgical and anaesthetic procedures, and the use of opioid analgesics. There was a slight imbalance between the groups with respect to history of PONV and motion sickness; this, however, did not affect the results of the study, as demonstrated by the treatment-by-factor analysis.

The results confirmed that PONV is common in these patients undergoing mainly gynaecological surgery, if no prophylactic antiemetic treatment is given, using a standard anaesthetic technique. Prophylactic administration of granisetron 1.0 mg or 3.0 mg resulted in a significant reduction in the numbers of patients who experienced postoperative vomiting during the periods 0–6 h and 0–24 h. The first episode of vomiting also occurred significantly later in the granisetron 1.0 mg and 3.0 mg groups than in the placebo group. Similar significant differences were seen in those patients who experienced no nausea or who achieved total control: doses of 1.0 mg and 3.0 mg were equally effective and both were significantly more effective than placebo. The granisetron 0.1 mg group was not significantly superior to placebo for any of the efficacy variables.

Use of rescue medication over the first 24-h period was less common in the granisetron 1.0 mg and 3.0 mg groups (24.6% and 22.7% of patients, respectively) than in the placebo group (39.8% of patients). Also, distribution of survival times to first use of rescue antiemetics differed significantly between the granisetron 1.0 mg and 3.0 mg groups and the placebo group, in favour of granisetron.

The majority of patients in each of the groups received opioid analgesics, but granisetron appeared to be effective whether or not opioids had been given. In either case, the response was most marked in the granisetron 1.0 mg group. The reduction by granisetron in the proportion of patients who vomited was less marked in patients who had received opioids because there was less likelihood of vomiting in these patients (as indicated by the placebo group) despite the known emetogenic potential of opioids. Evidence that effective pain relief can prevent nausea and vomiting may account for this finding [13].

An important side effect of currently used antiemetics (droperidol, metoclopramide and prochlorperazine) in the perioperative period is sedation, which has the potential for delaying recovery from anaesthesia. None of the three doses of granisetron used in this study caused any delay in recovery from anaesthesia. The study raised no concerns about the safety of granisetron. The safety profiles of the three doses of granisetron used in this study were similar to placebo in terms of adverse events and changes in vital signs, and haematological and biochemical variables. The side effects most commonly encountered were constipation and headache. Although both of these complaints are known to be associated with 5-HT_3 receptor antagonists [14], the incidence and severity of both events were similar to those in the placebo group.

These encouraging results are similar to those obtained with another 5-HT_3 receptor antagonist, ondansetron [7, 12, 15]. Moreover, direct comparison of granisetron and a classic antiemetic, the dopamine receptor antagonist, metoclopramide, has clearly demonstrated the superiority of granisetron [16]. Extrapyramidal effects may be a problem with dopamine antagonists and their absence with selective 5-HT_3 antagonists is a distinct advantage.

In conclusion, granisetron proved effective in the prevention of PONV. Our data do not suggest that increasing the dose from 1.0 mg to 3.0 mg confers any additional benefit; a dose–response plateau appeared to have been reached. We conclude, therefore, that 1.0 mg is the optimum dose. Further studies are required to compare the efficacy of granisetron with other commonly used antiemetics, and to define its role in patients undergoing different surgical procedures, particularly day surgery.

Rheological properties of commonly used plasma substitutes during preoperative normovolaemic acute haemodilution

G. FREYBURGER, M. DUBREUIL, M. R. BOISSEAU AND G. JANVIER

Summary

Preoperative normovolaemic acute haemodilution (PNAH) is used to reduce major blood loss during elective surgery. Considerable attention has been paid to colloid osmotic pressure, index of diffusibility and intravascular half-life of the currently available substitutes, but there is little information on their rheological properties from *in vivo* studies. Forty patients undergoing elective aortic reconstruction were given 4% human albumin (HA), 3.5% dextran 40 (Dxt 40), 6% dextran 60 (Dxt 60), 6% hydroxyethylstarch 200 (HES) or modified fluid gelatin (Gel) during PNAH to produce a packed cell volume (PCV) of approximately 30%. Mean volumes of more than 1000 ml were infused. Blood samples were obtained before infusion, immediately after, and 1.5 h after the end of haemodilution. The following variables were measured: PCV, plasma viscosity, whole blood viscosity at measured and corrected PCV (0.45), and erythrocyte aggregation. Haemodynamic and metabolic variables were determined at the same time. The five substitutes had very different effects on red blood cell aggregation and low shear rate viscosity at corrected PCV. Red blood cell aggregation was reduced in the presence of HA, Dxt 40, but was increased moderately to markedly in the presence of the other substitutes in the following order: HES < Dxt 60 < Gel. The influence of the rheological conditions on tissue oxygenation was assessed by measuring the concentration of lactic acid; this was unchanged after PNAH with HA or Dxt 40, but was increased in the presence of HES, Dxt 60 or Gel. (*Br. J. Anaesth.* 1996; **76**: 519–525)

Key words

Blood, haemodilution. Blood, substitutes. Blood, replacement. Surgery, vascular.

Preoperative normovolaemic acute haemodilution (PNAH) helps to reduce blood transfusion requirements in patients undergoing major surgery. PNAH reduces mean packed cell volume (PCV) leading to a decrease in blood viscosity. This in turn increases blood flow, assuming that the Hagen–Poiseuille equation is obeyed. The linear decrease in PCV results in an exponential improvement in the rheological properties of blood, particularly in the PCV range 30–46 %, with conservation of oxygen delivery from increased cardiac output despite the dilutional reduction in blood oxygen capacity [1]. As a result of dilution, blood lost during surgery contains plasma substitute, but fewer cells and plasma elements. The effective loss of blood constituents is thus considerably attenuated. Furthermore, autologous blood can be re-transfused after surgical bleeding has been controlled. In order to maintain normovolemia at reduced PCV, colloid diluents are required for intentional haemodilution.

PNAH has two main rationales: first, reduction in transfusion requirements (avoiding the risks of homologous transfusion) and second, improvement in circulatory state, particularly for patients at risk of ischaemia. Four main classes of colloid are used: (1) fractionated human albumin, (2) dextrans, (3) hydroxyethylstarch and (4) gelatins. Distribution, tissue storage, concentration half-life and effects on volume expansion and tissue oxygenation, and the relationship with haemostasis have been investigated for most of the current substitutes, but there is little information on their influence on blood rheology, a critical factor in microcirculatory perfusion. Blood rheology is influenced by quantitative factors, the concentration of red cells and proteins in plasma, but also by qualitative factors such as cell deformability and aggregation. Deformability has been found to be influenced little by pathological or pharmacological conditions.

In contrast, erythrocyte aggregation is commonly modified in certain conditions. It tends to occur at the very low shear rates encountered in the venous circulation, where most thrombi occur. In whole blood, red blood cell aggregation results from cross-linking of cells via interactions of their membranes with plasma fibrinogen, globulins and macromolecules. An energetic equilibrium is set up between the aggregation forces (adhesive properties of the macromolecules, where plasma substitutes operate) and repulsive forces (electrical charges on the red blood cell surface and shear stress). Erythrocyte aggregation is in fact a complex variable because of its relationship with blood flow. Thus any variable

modifying red blood cell aggregation may influence tissue perfusion by slowing down circulation and reducing capillary flow.

In this study, we assessed, in patients undergoing elective surgery, the intrinsic rheological effects of different plasma substitutes, chosen from the four major families of plasma substitutes. PNAH is a good condition for the investigation of plasma substitutes *ex vivo*, in view of the standardized operative conditions, the large volumes of infusion required to attain the desired PCV and the requirement for optimal microcirculatory flow.

Patients and methods

After obtaining approval from the Institutional Human Investigation Committee and written informed consent, we studied 40 male patients undergoing elective aortic reconstruction (32 aortic aneurysms, eight arterial occlusions, mean age 62 (range 35–79) yr. Exclusion criteria were: unstable coronary disease, severe hypertension (i.e. treated with a combination of two different types of antihypertensive drugs), past history of cerebrovascular accident, chronic renal failure, haematological diseases, preoperative PCV $< 30\,\%$ and antiplatelet agents or antithrombotic treatment.

A standardized anaesthetic technique was used comprising propofol 2 mg kg^{-1}, fentanyl 5 μg kg^{-1} and atracurium 0.5 mg kg^{-1} at induction. After tracheal intubation, the lungs were ventilated (100–120 ml kg^{-1} min^{-1}) using a Siemens Servo 900B (Siemens Malmø, Sweden) with an FI_{O_2} of 0.5 (air/oxygen). Propofol 300–500 mg h^{-1}, fentanyl 0.25–0.5 mg h^{-1} and atracurium 0.2 mg kg^{-1} (when T4/T1 > 25 %) were used for maintenance of anaesthesia. Monitoring included ECG with ST segment analysis, Sp_{O_2}, capnography, pulmonary arterial catheter and radial artery cannula. Blood was obtained from a large venous catheter. PNAH was started 10 min after induction to produce a PVC of $\approx 30\,\%$, as calculated according to the rule of Manel and colleagues [2]. Volumes of blood withdrawn were replaced by equivalent volumes of substitutes and re-transfused at the end of surgery.

Fifty patients were allocated randomly to one of five groups. Incomplete medical records in 10 patients (three in each of the dextran and gelatin groups and one in the human albumin group) were discarded. Each group received a different plasma substitute: 4 % human albumin (HA) (Crts Bordeaux, France); 40000 molecular weight 3.5 % dextran (Plasmacair) (Dxt 40); 60000 molecular weight 6 % dextran (Hemodex) (Dxt 60); 6 % hydroxyethylstarch 200000 (Elohes) (HES) and modified 3 % gelatin (Plasmion) (Gel). The solvent for all solutions was normal saline. Patients given Dxt 40 and Dxt 60 received 20 ml of monovalent hapten dextran (average molecular weight = 1000 Da) (Promit), before infusion of the substitute. PCV was determined during haemodilution in the operating room by a micro-method (Autocrit II, Microspin Anaesthesia). Figure 1 shows the monitoring schedule for the haemodynamic measurements and blood sampling. Haemodynamic and lactic acid measurements were made before induction of anaesthesia and before PNAH (Ta), after induction of anaesthesia and before PNAH (Tb) and half-way through (Tc) and at the end of PNAH (Td). Measurements included: heart rate, mean arterial pressure, cardiac output, Sv_{O_2} and Sa_{O_2}. Blood samples for laboratory tests (anticoagulated with EDTA for the rheological tests) were obtained before PNAH (T0), at the end of PNAH, which lasted for approximately 30 min (T1), and 1.5 h after the end of PNAH (T2), as there appears to be some latency in haemostatic [3] or rheological [4, 5] effects.

Plasma and blood viscosity were measured at 37 °C in a Contraves LS 30 rotational viscometer. Whole blood viscosity was evaluated over a wide range of shear rates (seven shear rates) to cover all physiological conditions, but only "low" (1 s^{-1}) and "high" (128.5 s^{-1}) shear rates are shown in the results. The low shear rate is found in the venous circulation where aggregation mechanisms are predominant, and high shear rates are encountered in the arterial circulation where cell deformability is the predominant mechanism. Plasma, a Newtonian fluid, was examined at a single shear rate (128.5 s^{-1}). Because of the primary dependence of whole blood viscosity on PCV, viscosity was calculated at standardized PCV (0.45) according to the mathematical model described by Matrai, Whittington and Ernst [6] from the expression $\eta \times (\text{rel } 0.45) = (\eta \ (\text{rel PCV}))^{(0.45/\text{PCV})}$ where $\eta \times (\text{rel } 0.45)$ and η (rel PCV) are the viscosities of whole blood relative to plasma at standardized (0.45) and measured PCV, respectively. This model provides an estimate of the qualitative effects of the plasma substitutes independently of the quantitative effect of the decrease in cell concentration.

Erythrocyte aggregation at 37 °C was measured in a Sefam erythro-aggregometer (Vandoeuvre-les-Nancy, France) [7]. The main characteristics of the device and the significance and calculation of the variables studied have been described previously [8]. This apparatus measures the change in back-scattered light on abrupt cessation of suspensions of red blood cells (at different shear rates). The formation of red blood cell aggregates is indicated by a decrease in the optical signal. Several variables can be derived from the plot of light intensity as a function of time, and we determined: primary aggregation time (PAT), corresponding to the reverse of the slope of the curve between 0.5 and 2 s after cessation of maximum shear. This value decreases with increasing erythro-aggregation; partial disaggregation threshold (PDT) corresponds to dissociation of "*rouleaux*", and is calculated from the maximum intensity of back-scattered light as a function of shear rate. PDT increases as erythro-aggregation increases. The normal ranges for our laboratory have been established from samples taken from 20 normal volunteers (aged 20–60 yr); for PAT and PDT, they are 3 (0.5) s and 55 (10) s^{-1} respectively.

Erythrocyte deformability was studied using a Technicon helium–neon laser ektacytometer (Bayer-Technicon, Tarrytown, New York) combining a concentric viscometer and a light scattering device

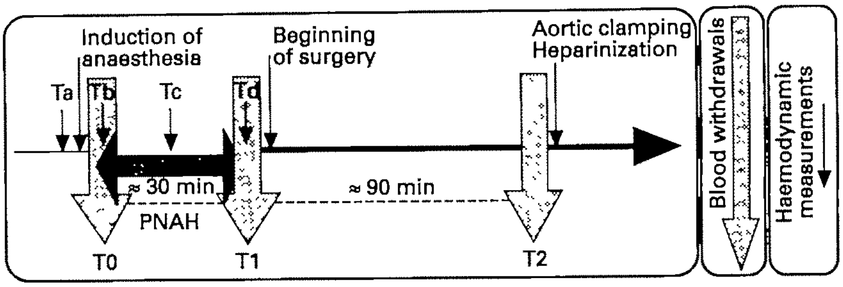

Figure 1 Monitoring schedule for haemodynamic measurements and blood sampling. Haemodynamic and lactic acid measurements were made before induction of anaesthesia and before PNAH (Ta), after induction of anaesthesia and before PNAH (Tb), and half-way through (Tc) and at the end of PNAH (Td). Blood samples were obtained before PNAH (T0), at the end of PNAH (T1) and 1.5 h after the end of PNAH (T2).

allowing calculation of an elongation index (EI) reflecting the deformation capacity of erythrocytes subjected to a well-defined shear force [9]. PCV was measured by microcentrifugation (Autocrit II).

Lactic acid was assessed by pyruvate peroxidation (normal range 0.6–2.2 mmol litre^{-1}). Plasma proteins have been shown to interfere with the haemorheological tests, and therefore total protein (Lowry method) and fibrinogen (Von Clauss method) were measured.

For each laboratory variable, two-way analysis of variance for repeated measures was carried out to assess the "group", "time" and "group × time" effects. The F ratios of the mean squares were calculated with respect to the residual mean of the square, and each ratio was tested against the critical F value (as a function of the different degrees of freedom), to measure the significance of each test. $P < 0.05$ was considered significant for ANOVA. Values at T1 and T2 were compared with those at T0 in each group of patients using Student's t test for paired samples. Unpaired Student's t test was also used to compare the different substitutes with albumin at each time of sampling.

Results

The mean volumes infused were highly comparable between the groups, despite the intra-group dispersion because of the large inter-individual differences in weight and size. Thus high mean volumes (> 1000 ml) were infused (table 1).

Table 2 shows the rheological variables at different times for the five groups. The results of ANOVA are summarized, indicating the influence of the time of withdrawal, or of the substitute, or both, on the different variables studied. For the whole patient series, time of blood withdrawal influenced most of the variables studied, with the exception of the variables unaffected by dilution, such as viscosity at corrected PCV and the erythrocyte deformability index. The major effect of haemodilution was seen as a decrease in PCV, which had decreased to 26–29 % by the end of the procedure (after careful application of Manel's rule). PCV remained close to this level for at least 90 min. ANOVA did not suggest any differences between the groups.

Plasma viscosity was reduced significantly in the presence of HA and increased significantly in the presence of Dxt 60. Thus ANOVA showed a significant "substitute" effect but no "time" effect resulting from the different effects of the various substitutes at T1 and T2 (hypoviscous (HA) or hyperviscous (Gel, HES, Dxt 60) compared with plasma viscosity). These alterations arise from the direct effect of the intrinsic viscosities of the substitutes on overall plasma viscosity. The measured viscosities of these substitutes are given in table 3.

The elongation index, which reflects erythrocyte deformability, was not influenced by haemodilution. The effects of the blood substitutes on whole blood viscosity were evaluated over the two phases illustrated in figure 2.

The primary effect of haemodilution was a decrease in PCV, leading to a reduction in whole blood viscosity. HA, Dxt 40 and HES produced the greatest reductions in whole blood viscosity (approximately 70 % of the initial value at low shear rate, and 30–40 % of the initial value at high shear rates), while Dxt 60 and Gel had smaller effects, despite the comparable decrease in PCV. This discrepancy was attributed to the differences in intrinsic viscosities of the substitutes. Comparison of whole blood visco-

Table 1 Patient characteristics and volumes of the five blood substitutes infused (mean (SD) [range]). No significant differences between groups

sities at corrected PCV, that is at constant PCV at the three times (T0, T1, T2), demonstrated more clearly the differences in intrinsic rheological effects of the different substitutes. The substitutes could be split into two main groups: HA, Dxt 40 and HES induced a dramatic reduction in corrected whole blood viscosity at low shear rates, whereas Dxt 60 and Gel markedly increased viscosity. At high shear rates there was no significant difference between the two groups of substitutes. Thus the major difference in the rheological effects of these substitutes was an effect on erythrocyte aggregation, a process occurring primarily at low shear viscosity.

Direct measurement of the characteristics of the erythrocyte aggregates (time to reform after dissociation and the force required to dissociate them) supported the viscosimetric findings. Two of the three substitutes from the first group (HA and Dxt 40), which reduced whole blood viscosity at corrected PCV, tended to increase the primary aggregation time and, to a lesser extent, reduce the forces required to dissociate the aggregates. In contrast, the second group of substitutes (Dxt 60 and Gel) induced hyperaggregation, reflected by the decrease in primary aggregation time for Gel and by

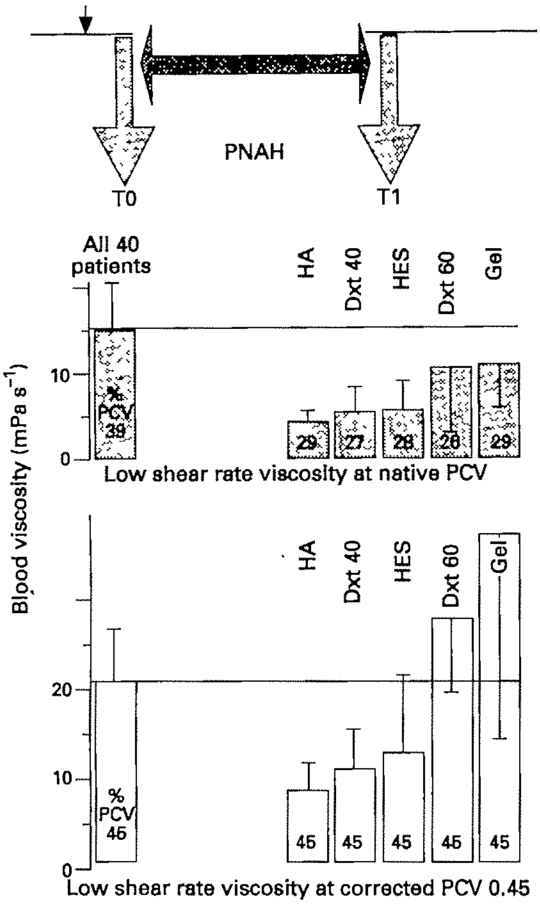

Figure 2 Modification of whole blood viscosity at low shear rate (1 s^{-1}) for native (top) and corrected (0.45 bottom) packed cell volume (PCV). Whole blood viscosity decreased as PCV decreased dramatically with haemodilution. The bottom histograms show the dramatic increase in whole blood viscosity at corrected PCV in the presence of Dxt 60 and Gel, demonstrating an intrinsic effect of these substitutes on red blood cell aggregation.

the increase in the partial dissociation threshold for both Dxt 60 and Gel. On the other hand, HES reduced whole blood viscosity (either at measured or corrected PCV), but tended to increase erythrocyte aggregation, as demonstrated by the significant increase in partial dissociation threshold observed. ANOVA showed the specific effect of the different substitutes on the variables involved in erythro-aggregation, namely low shear rate viscosity at corrected PCV, primary aggregation time and partial dissociation threshold.

Some variables that may interfere with the haemorheological test results were measured. Total protein and fibrinogen represent major determinants of plasma viscosity and erythrocyte aggregation, respectively. ANOVA showed a "time of withdrawal" effect but little difference between subgroups. The only difference was a smaller decrease in total protein content in the presence of albumin compared with the other substitutes.

The haemodynamic and metabolic data were analysed in the same way as the laboratory data. These variables obeyed their recognized time course during PNAH. ANOVA revealed few inter-group differences at either the first withdrawal (before anaesthesia and haemodilution) or on withdrawal at the end of haemodilution (T1) (table 4). There was a difference in heart rate between the groups at T1, because of the higher heart rate in the presence of Dxt 60 (compared with HA). Initial heart rate was also higher in this group before haemodilution (Ta), although the difference was not significant. Mean arterial pressure was lower after infusion of gelatin.

The influence of the different substitutes used during PNAH on tissue oxygenation was evaluated from the concentration of lactic acid, which reflects overall cellular oxygenation (table 5). Thus lactic

acid was increased significantly at the end of haemodilution by two (HES and Gel) of the three substitutes which had been shown to increase erythrocyte aggregation at T1. It was also increased by Dxt 60, although this was not statistically significant, mainly because of the higher initial values in this group of patients. Neither HA nor Dxt 40 had any effect on arterial lactic acid concentrations.

Discussion

We found that the salient effect of haemodilution was a significant improvement in whole blood rheology reflected by the immediate and sustained decrease in PCV and blood viscosity. The dramatic decrease in PCV was caused mainly by the high volumes infused (more than 1 litre). Albumin was chosen as a reference substitute as it is the closest substitute to plasma, with a homogeneous molecular weight. Because of the PCV value targeted (0.30), the need to maintain predilution blood volume to preserve an appropriate right heart filling pressure prevented us from using Ringer's solution as a control in view of the lack of volume-sustaining capacity of crystalloids.

The main finding was the markedly different effects of the different substitutes on whole blood viscosity as a result of their differing influences on red blood cell aggregation. Measured whole blood viscosity depends primarily on red cell concentration, which evaluated simply by measurement of PCV. Thus the effect of PCV needs to be taken into account in order to assess the other determinants of blood viscosity, such as red blood cell deformability and aggregation. We therefore calculated blood viscosity at a standardized PCV (0.45). Two (HA and Dxt 40) of the five substitutes were shown to improve the rheological properties, and two others (Dxt 60 and Gel) led to significant alterations. Similar results have been obtained by Audibert and colleagues [10] with HA, Dxt 40 and Gel. The low aggregating effect of Dxt 40 *in vitro* has been reported by Seike and Maeda Shiga [11]. On the other hand, Dxt 60 and Gel have also been shown to facilitate red blood cell aggregation *in vitro* by reducing the electrostatic repulsive forces after adsorption on the cell membranes [12, 13].

HES had a less consistent rheological effect with a decrease in low shear rate viscosity at corrected PCV and no change in aggregation time, in spite of increased cohesion of the aggregates (increased PDT). In ASA I patients, Dewachter and colleagues [5] reported no effect on blood viscosity at corrected PCV or on erythrocyte aggregation after infusion of HES 500 ml. Audibert and colleagues [10] observed results similar to ours on erythrocyte aggregation (also measured by the SEFAM instrument) after infusion of 1000 ml. The rheological response to HES may therefore depend on the amount infused. In a similar study in atherosclerotic patients, Ehrly Seebens and Saeger-Lorenz [14] demonstrated an increase in erythro-aggregation in the presence of 10% HES 200 500 ml (HES 50 g), although no comparable effect was observed in the presence of 6% HES 200 (HES 30 g). In our study, patients received a mean infusion volume of 1185 ml of 6% HES 200 (HES 71 g). An increase in red blood cell aggregation may thus occur above a critical concentration. Adding the same proportion of 6% HES 200 or of autologous plasma to a control blood (final PCV = 0.34) *in vitro*, there was a marked change in the aggregation variables in the presence of HES with a decrease in the primary aggregation time (1.87 s in the presence of HES *vs* 2.87 s in the presence of autologous plasma) and an increase in the partial dissociation threshold (97 s^{-1} *vs* 47.5 s^{-1}). As aggregation time was unchanged in our *ex vivo* study in spite of an increased dissociation threshold, there may be qualitative changes in the interactions between red blood cells and HES macromolecules transformed *in vivo* [15]. Goto and colleagues showed that in dogs, apart from an immediate and slight increase in the electrophoretic mobility of red cells indicating increased electronegativity, HES induced a delayed (after 12 h) reduction in electronegativity [16]. Gelatin has also been shown to interact specifically with plasma proteins such as fibronectin, and so may enhance the formation of bridges between red blood cells [17].

The rheological alterations and the influence of macromolecules on oxygen diffusion have an overall impact on tissue oxygenation, which should be reflected by the concentration of lactic acid. Changes caused by Dxt 60 were difficult to interpret because of the high initial concentrations of lactic acid in this group, but HES and Gel were found to induce a significant increase in lactic acid concentrations. This could be related to a reduction in oxygen flux to peripheral cells. HES, by increasing the forces required to dissociate the aggregates, might also reduce oxygen flux from red cells to tissues by impeding its diffusion [18]. On the other hand, Gel increased dramatically whole blood viscosity at corrected PCV, enhancing erythrocyte aggregation and capillary plugging. Vicaut and colleagues recently described a significant decrease in the density of perfused capillaries in the presence of hyper-erythro-aggregation *in vivo* [19].

Our data indicated that Dxt 40 and HA were the most efficient substitutes in respect of blood rheology and lactic acid concentrations. The concentrations of lactic acid, an indicator of cellular function, would be worth monitoring during PNAH. The rheological properties of a plasma substitute should be taken into consideration together with its volume expansive action. HES has questionable rheological qualities (partly because of its high substitution ratio) despite its well demonstrated and unchallenged expansive qualities. However, new hydroxyethylstarches with lower substitution ratios (0.4–0.5), equivalent concentration and low molecular weight will soon be available and these new products may demonstrate both acceptable rheological and wide-ranging qualities.

Rocuronium pretreatment reduces suxamethonium-induced myalgia: comparison with vecuronium

G. P. FINDLAY AND M. J. SPITTAL

Summary

We have studied, in 150 patients undergoing elective oral surgery, the effectiveness and sequelae of pretreatment with rocuronium for reducing myalgia after suxamethonium. Patients were allocated randomly to one of three groups: anaesthesia was induced with propofol and fentanyl, and group V received vecuronium 1 mg, group R rocuronium 6 mg and group P placebo pretreatment. Suxamethonium 1.5 mg kg^{-1} was given 60 s after the pretreatment agent. All patients received ketorolac 10 mg i.v. and morphine 10 mg i.m. for analgesia. The incidence of postoperative myalgia on day 1 after rocuronium (20%) was significantly less than after vecuronium (42%) ($P < 0.05$) or placebo (70%) ($P < 0.01$). By day 4 the incidence of myalgia was 28.6% in the rocuronium group, 46.3% in the vecuronium group and 95% in the placebo group. Intubating conditions were not affected adversely by any pretreatment regimen. (*Br. J. Anaesth.* 1996; **76**: 526–529)

Key words

Neuromuscular block, suxamethonium. Neuromuscular block, rocuronium. Neuromuscular block, vecuronium. Complications, myalgia.

Despite the recent introduction of short-acting, non-depolarizing neuromuscular blockers, suxamethonium, with its rapid onset of action, short duration of effect, complete and predictable paralysis, remains unsurpassed in providing ideal intubating conditions for tracheal intubation. However, since its introduction into clinical practice it has been recognized that myalgia occurs frequently in the postoperative period [1, 2]. Several strategies have been advocated to decrease the incidence of myalgia, one of the most successful being the administration of a small dose of non-depolarizing neuromuscular blocking drug before administration of suxamethonium [3, 4]. Various factors influence the efficacy of pretreatment, including the choice of non-depolarizing agent [5, 7], degree of prejunctional receptor block, interval between administration of pretreatment agent and suxamethonium, and speed of onset of the non-depolarizing drug. Rocuronium, which has a more rapid onset of action compared with established non-depolarizing agents [8], providing good intubating conditions within 60 s, has not yet been evaluated for the purpose of reducing suxamethonium-induced myalgia. As the optimum time interval for pretreatment with pre-existing drugs is approximately 3 min, this property of rocuronium may be relevant to its use in the prophylaxis of myalgia after suxamethonium.

The aim of this prospective, randomized, double-blind study was to assess the effect of rocuronium pretreatment on the frequency of suxamethonium-induced myalgia and to compare it with probably the most effective current pretreatment agent [4, 5, 7].

Patients and methods

After approval by the Hospital Ethics Committee and completion of written, informed consent, we studied 150 patients, aged 16–65 yr, ASA I or II. All patients were undergoing elective oral surgery under general anaesthesia necessitating tracheal intubation. We excluded patients who were assessed as possibly posing difficulty with tracheal intubation, using a combination of Mallampati's test and thyromental distance, and those considered unsuitable to receive the standard study anaesthetic technique.

All patients were premedicated with temazepam 0.3 mg kg^{-1}, to the nearest 10 mg, 1 h before operation. Anaesthesia was induced with fentanyl 1 μg kg^{-1} and a sleep dose of propofol. Patients then received vecuronium 1 mg (group V), rocuronium 6 mg (group R) or normal saline (group P), each made up to 2 ml. Fifty patients were allocated randomly to each pretreatment group and 60 s after pretreatment, patients received suxamethonium 1.5 mg kg^{-1}. Direct laryngoscopy was performed and the patient's trachea was intubated via the nasal route using an appropriately sized Magill tracheal tube, 60 s after suxamethonium. Anaesthesia was maintained with 1–2% isoflurane in oxygen-enriched air. Manual ventilation was adjusted to maintain normocapnia (Ohmeda 5200 carbon dioxide monitor) until commencement of spontaneous respiration. After induction of anaesthesia all patients received ketorolac 10 mg i.v. and morphine 10 mg i.m. for analgesia, and droperidol 500 μg i.v. as an antiemetic. The presence of fasciculations and their severity after suxamethonium were assessed on a four-point scale as: nil = no visible fasciculations,

Table 1 Grading system for postoperative myalgia (after White [11])

Nil	No muscle pains or stiffness
Mild	Muscle pains or stiffness at one site but not causing disability or limiting activities
Moderate	Muscle pains or stiffness at more than one site but not causing disability or limiting activities
Severe	Muscle pains or stiffness at one or more sites and causing disability or limiting activities, e.g. difficulty getting out of bed or turning head

mild = very fine fingertip or facial muscle movements, moderate = minimal fasciculations on trunk and extremities, severe = vigorous fasciculations on trunk and extremities [9]. Overall intubating conditions were assessed as: excellent = intubation easy, no reaction from the patient, good = intubation resulting in slight coughing or bucking, poor = intubation possible, but resulting in more marked patient response [10]. The time taken to resumption of spontaneous respiration and duration of anaesthesia were noted.

Patients were visited on the first postoperative morning before discharge from hospital and interviewed by an investigator, blind to the pretreatment agent used, according to a structured questionnaire, as described by Erkola [5]. The presence and severity of myalgia were noted. Myalgia was graded on a four-point scale using the system described by White [11] (table 1). At the end of the interview, patients were given a second questionnaire, which was to be completed on day 4 after operation, and was designed to evaluate the incidence and severity of myalgia after discharge.

Patient characteristics and operative details were analysed using the independent samples *t* test. The incidence of myalgia and fasciculations was analysed using Fisher's exact test. Intubating conditions, severity of myalgia and severity of fasciculations were analysed initially using the Kruskal–Wallis test. If the Kruskal–Wallis test showed that significant differences existed between the groups then Dunn's multiple comparisons were performed to demonstrate which groups differed. $P < 0.05$ was considered significant.

Results

There were no significant differences in patient characteristics or operative details between the three groups (table 2).

Table 2 Patient data and operative details (mean (range or SD) or number). No significant differences (independent samples *t* test)

	Group V ($n = 50$)	Group R ($n = 50$)	Group P ($n = 50$)
Age (yr)	24.9 (17–46)	25.1 (19–40)	24.6 (17–48)
Weight (kg)	76.7 (11.6)	75.6 (12.2)	78.8 (13.5)
Sex (M:F)	39:11	38:12	40:10
Propofol induction dose (mg)	194 (26)	198 (28)	203 (30)
Duration of surgery (min)	26 (9)	28 (7)	25 (8)
Duration of apnoea (min)	7.1 (1.9)	7.1 (2.9)	7.3 (2.1)

Table 3 Incidence and severity of fasciculations. **$P < 0.01$ *vs* groups V and P (Fisher's exact test)

	Group V ($n = 50$)	Group R ($n = 50$)	Group P ($n = 50$)
None	8	46	0
Mild	11	4	10
Moderate	13	0	21
Severe	18	0	19
Total incidence (%)	84	8**	100

Table 4 Intubating conditions. No significant differences (Kruskal–Wallis test)

	Group V ($n = 50$)	Group R ($n = 50$)	Group P ($n = 50$)
Good	47	47	49
Adequate	2	3	1
Poor	1	0	0

The incidence of fasciculations in group R was significantly less than that in groups V and P ($P < 0.01$) (table 3). Analysis of the severity of fasciculations revealed highly significant differences (Kruskal–Wallis statistic $H = 81.91$, $P < 0.001$) between the three groups. This test was logically followed by Dunn's multiple comparisons which showed significant differences in the severity of fasciculations between groups V and R ($P < 0.01$) and between groups R and P ($P < 0.01$), but no significant difference between groups V and P.

There were no significant differences in intubating conditions between the three groups (table 4). Analysis of the incidence of myalgia on the first postoperative day (table 5) revealed significant differences between groups V and R ($P < 0.05$), groups V and P ($P < 0.01$) and groups R and P ($P < 0.0001$). There were highly significant differences in the severity of myalgia on the first postoperative day between the three groups (Kruskal–Wallis statistic $H = 18.11$, $P < 0.001$) and therefore Dunn's multiple comparisons were performed which showed that only the difference between groups R and P was statistically significant ($P < 0.01$).

There were no significant differences in the response rate to the questionnaire on day 4 after operation with 41, 42 and 40 patients from groups V, R and P, respectively, returning completed questionnaires. Analysis of the incidence of myalgia by day 4, using pooled information from questionnaires on days 1 and 4 (table 5), revealed significant differences between groups V and P ($P < 0.0001$) and groups R and P ($P < 0.0001$). The difference between groups V and R was not significant. The Kruskal–Wallis test indicated highly significant differences in the severity of myalgia by day 4 between the three groups (Kruskal–Wallis statistic $H = 25.8$, $P < 0.001$) and therefore Dunn's multiple comparisons were performed which revealed that only the differences between groups V and P ($P < 0.025$) and groups R and P ($P < 0.001$) were statistically significant.

Discussion

Suxamethonium is the best drug for rapidly providing ideal intubating conditions for short procedures. However, the usefulness of suxamethonium is limited by the frequent occurrence of postoperative myalgia. This is often listed as a minor side effect of the drug but it may be one of the most distressing consequences of minor surgery for the patient. The incidence of myalgia varies from 20% to 85% [12, 13]. This is undoubtedly a reflection of the many factors which influence the occurrence of pain.

Of the many regimens which have been proposed as a means of reducing the incidence of myalgia [9, 14–19], the most effective and widely used method is pretreatment with a small dose of non-depolarizing neuromuscular blocker [20]. A review of the literature revealed that vecuronium was probably the best agent in this respect [4, 5, 7] and for this reason we chose to compare rocuronium with vecuronium. Previous studies have used vecuronium 1 mg [7]. We therefore accepted that dose and, based on potency ratios, calculated a rocuronium dose of 6 mg. Administration of pretreatment agents both on a weight-related basis [21] and on a fixed-dose regimen [6, 7] has been recommended, but we chose a fixed-dose regimen for ease of routine administration.

One of the main concerns regarding pretreatment with non-depolarizing agents is that intubating conditions may be affected adversely. It is therefore recommended that a larger dose of suxamethonium be given to those who are pretreated [22]. In this study we used suxamethonium 1.5 mg kg^{-1} and found that pretreatment had no effect on intubating conditions. It has been suggested that increasing the dose of suxamethonium is not associated with accentuation of its adverse effects [23] but recent work has refuted this [24]. We therefore acknowledge that the use of such a dose of suxamethonium in the placebo group may be responsible for the high incidence of myalgia.

Rocuronium pretreatment is particularly effective in reducing fasciculations after suxamethonium. In 92% of patients, fasciculations were absent and in this respect rocuronium was superior to vecuronium ($P < 0.01$). However, as in many previous studies, we found no correlation between strength of fasciculations and myalgia.

There has been much discussion about the interval between administration of the pretreatment agent and suxamethonium. Intervals of 2, 3 and 4 min, or longer, have been recommended [11, 23, 25]. Obviously such lengthy intervals, required by slow onset drugs, are impractical on busy operating lists. Our hypothesis that rocuronium, because of its rapid onset of action, would be effective at reducing myalgia when only a short interval was allowed appears to have been substantiated.

Rocuronium pretreated decreased the incidence of myalgia to 20% on the first postoperative day and to 28.6% by day 4. Compared with vecuronium this was significant on day 1 but not by day 4 ($P < 0.05$, $P = 0.15$, respectively). This may be a reflection of the small sample size as a reduction in myalgia from 46.3% with vecuronium pretreatment to 28.6% with rocuronium pretreatment may be considered clinically significant. A larger sample size may clarify this issue.

Using reduced doses of suxamethonium alone can decrease the incidence of myalgia. Using suxamethonium 0.5 mg kg^{-1}, Stewart, Hopkins and Dean [24] reported that 41% of patients complained of myalgia while Nimmo and colleagues [26], using suxamethonium 0.25 mg kg^{-1}, reported an incidence of 20%. Intubating conditions in both studies were good. It may be seen that the use of rocuronium pretreatment and suxamethonium 0.25 mg kg^{-1} alone produce very similar incidences of myalgia while providing satisfactory intubating conditions. We plan a future prospective study to evaluate which strategy is superior. It is interesting to note that the study by Nimmo and colleagues [26] included a group in which no neuromuscular blocking drugs were used and who experienced an incidence of myalgia of 28%. It may be that, no matter which strategy is used to reduce suxamethonium myalgia, significant reductions below this value are unlikely. Against this background the results obtained in our rocuronium group appear to be excellent.

Carbon dioxide output in laparoscopic cholecystectomy

T. KAZAMA, K. IKEDA, T. KATO AND M. KIKURA

Summary

In pneumoperitoneum, carbon dioxide eliminated in expired gas (carbon dioxide output) contains both metabolic and absorbed carbon dioxide from the peritoneal cavity. When elimination of carbon dioxide is much higher than carbon dioxide output, storage of tissue carbon dioxide and arterial carbon dioxide concentrations change. Finally, the rate of carbon dioxide eliminated in expired gas is not a match for the real rate of metabolic production and absorbed carbon dioxide from the peritoneal cavity. During and after insufflation of carbon dioxide, changes in carbon dioxide output were elucidated under constant arterial carbon dioxide pressure (Pa_{CO_2}), the same as the preinduction level. We studied patients undergoing elective laparoscopic cholecystectomy. Carbon dioxide output, oxygen uptake, respiratory exchange ratio (RER), expired minute ventilation ($\dot{V}E$), deadspace to tidal volume ratio ($VD/\dot{V}T$ ratio) and arterial to end-tidal carbon dioxide partial pressure difference ($Pa_{CO_2}-PE'_{CO_2}$) were determined before induction, and during anaesthesia, pneumoperitoneum and recovery. By controlling ventilatory frequency (*f*) every 1 min, Pa_{CO_2} was adjusted to concentrations before induction. Constant monitoring of end-tidal carbon dioxide partial pressure (PE'_{CO_2}) and intermittent measurement of ($Pa_{CO_2}-PE'_{CO_2}$) (15-min intervals) were conducted to predict Pa_{CO_2}). Carbon dioxide output and oxygen uptake decreased significantly from mean values of 83.5 (SEM 5.2), 101.6 (5.1) to 68.5 (4.2), 81.1 (4.6) ml min^{-1} m^{-2} (ATPS, $P <$ 0.05) with sevoflurane anaesthesia, and RER did not change. During carbon dioxide pneumoperitoneum (intra-abdominal pressure 8 mm Hg), carbon dioxide output increased by 49% (102.4 (5.0) ml min^{-1} m^{-2}) ($P < 0.05$) while oxygen uptake remained stable and RER increased from 0.84 (0.02) to 1.16 (0.03) ($P < 0.05$). It was necessary to increase $\dot{V}E$ during pneumoperitoneum by 1.54 times that during anaesthesia to maintain individual Pa_{CO_2} values constant. After removal of carbon dioxide from the abdominal cavity, the regression equation of excess carbon dioxide output/BSA best fitted a two-compartment model. The time constants of the rapid and slow compartments were 8.2 and 990 min, respectively. Excess carbon dioxide output/BSA was still 5.5 ml min^{-1} m^{-2}, 30 min after pneumoperitoneum. (*Br. J. Anaesth.* 1996; **76**: 530–535)

Key words

Surgery, laparoscopy. Anaesthetics, volatile, sevoflurane. Ventilation, carbon dioxide response. Ventilation, deadspace. Oxygen, uptake.

Laparoscopic gynaecological procedures involve a short duration of intraperitoneal carbon dioxide insufflation and are performed usually in young or otherwise healthy female patients. Changes in haemodynamic state and arterial blood-gas tensions with insufflation of carbon dioxide have been studied extensively and found to be relatively insignificant [1–6]. However, peritoneal insufflation for laparoscopic cholecystectomy may be longer than that for gynaecological procedures.

Insufflation of the abdominal cavity with carbon dioxide may be associated with pulmonary atelectasis, decreased functional residual capacity and high peak airway pressures. Absorption of carbon dioxide via the peritoneum causes hypercapnia but not impaired ventilation in healthy patients [7, 8]. Significant carbon dioxide retention has been demonstrated in patients with cardiopulmonary impairment during carbon dioxide pneumoperitoneum for extended procedures such as laparoscopic cholecystectomy [7, 9], with possibly consequent cardiac arrhythmias [10]. In pneumoperitoneum, carbon dioxide eliminated in expired gas (carbon dioxide output) contains both carbon dioxide of metabolic production and also absorbed carbon dioxide from the peritoneal cavity. Although there has long been interest in the rate of carbon dioxide output during long-lasting laparoscopic procedures, the reported data [5, 10–12] are not consistent, possibly because storage of carbon dioxide may be variable.

This study was conducted to assess excess carbon dioxide output evoked by pneumoperitoneum with stable carbon dioxide storage maintained by keeping arterial Pa_{CO_2} constant at preinduction levels and to investigate continued carbon dioxide load after pneumoperitoneum using a pharmacokinetic model.

Patients and methods

We studied 12 consenting, ASA I or II patients, undergoing elective laparoscopic cholecystectomy.

Approval was obtained from the Human Studies Committee at Hamamatsu University Hospital. Patients were in good general health, with no signs or laboratory findings of renal, pulmonary or hormonal disease, or obesity (defined as a body mass index > 29). All patients fasted overnight and were premedicated with hydroxygine 50 mg and atropine 0.5 mg 1 h before induction of anaesthesia. An i.v. cannula was inserted during local anaesthesia. I.v. infusion of sodium lactate solution was started, and the rate of infusion was adjusted to 8–10 ml kg^{-1} h^{-1} during the study. Heart rate and ECG were monitored continuously. An arterial cannula was inserted into the radial or dorsalis pedis artery during local anaesthesia for arterial pressure monitoring. An arterial blood sample was obtained from the indwelling arterial cannula anaerobically and analysed immediately (ABL 300 blood-gas analyzer, Radiometer, Copenhagen, Denmark). Rectal temperature was displayed continuously on a temperature module (Hewlett-Packard) using a thermistor probe inserted 10 cm into the rectum. Body temperature was maintained at 36–37 °C by external heating. The temperature of the operating room was maintained at 24–26 °C.

The sampling cannula for measuring end-tidal anaesthetic gas, oxygen, nitrogen and carbon dioxide concentrations was inserted between a micro-pore filter (Gambro Enström AB, Sweden) and the tracheal tube. Mean inspired and expired gas samples were obtained from bypass mini-mixing chambers mounted in each inspiratory and expiratory limb of the breathing circuit. These chambers have been described previously [13]. Gas samples from each chamber, and sampling cannula for end-tidal gas measurement were introduced individually into a mass spectrometer (MGA 1100, Perkin Elmer) calibrated against certified gas mixtures. The concentrations of oxygen, nitrous oxide, sevoflurane and nitrogen were measured at 1-min intervals. Expired minute volume was measured with an electric Wright respirometer placed in the expiratory limb, and calibrated previously against a dry gas of known composition at physiological flow. The accuracy was the same as that of the Fleisch pneumotachograph (Gould). Expired minute volume normalized for body surface area (BSA) was expressed at BTPS, and carbon dioxide output and oxygen uptake were expressed at STPD. Inspired minute volume was calculated by an inert tracer gas dilution technique [14–17]. Nitrogen was used as the "inert" gas and was included in the inspired gas during anaesthesia [16]. Pulmonary gas exchange was computed as follows: $\dot{V}\text{CO}_2 = \dot{V}\text{E}(F\text{E}_{\text{CO}_2} - F\text{I}_{\text{CO}_2} \times F\text{E}_{\text{N}_2}/F\text{I}_{\text{N}_2})$; $\dot{V}\text{O}_2 = \dot{V}\text{E}(F\text{I}_{\text{O}_2} \times F\text{E}_{\text{N}_2}/F\text{I}_{\text{N}_2} - F\text{E}_{\text{O}_2})$; $\text{RER} = \dot{V}\text{CO}_2/\dot{V}\text{O}_2$; where $\dot{V}\text{CO}_2$ = carbon dioxide output, $\dot{V}\text{O}_2$ = oxygen uptake, $F\text{I}$ and $F\text{E}$ = fractional mean concentrations of mixed inspired and expired gas, respectively; $\dot{V}\text{E}$ = expired minute volume and RER = respiratory exchange ratio. $F\text{I}_{\text{CO}_2}$, sampled from the mixing chambers, was measured by mass spectrometer in order to exclude the effect of ageing on carbon dioxide absorber. The equations for calculation are valid even in the presence of anaesthetic gas [15, 18]. The ratio of deadspace to tidal volume ($V\text{D}/V\text{T}$) was calculated using Bohr's equation [19]; $V\text{D}/V\text{T} = (P\text{a}_{\text{CO}_2} - P\text{E}_{\text{CO}_2})/P\text{a}_{\text{CO}_2}$, where $P\text{E}_{\text{CO}_2}$ = carbon dioxide partial pressure of mixed expired gas.

Before induction of anaesthesia, all subjects were permitted to breathe room air through the anaesthesia mask for 20 min and mean expired and inspired concentrations of oxygen, carbon dioxide, nitrogen and expiratory minute volume were measured to obtain baseline carbon dioxide output and oxygen uptake. Anaesthesia was induced with thiopentone 5 mg kg^{-1} i.v. and non-depolarizing neuromuscular blocker (vecuronium 0.1 mg kg^{-1}). Tracheal intubation was performed orally using a cuffed tracheal tube. Inspired concentrations of oxygen, nitrogen and nitrous oxide were adjusted to 30%, 20% and 50%, respectively, during anaesthesia. The inspired sevoflurane mixture was adjusted to give an end-tidal sevoflurane concentration of 1.37% (0.8 MAC). The fresh gas flow rate was 6–7 litre min^{-1}. The lungs of all patients were ventilated mechanically with the same ventilator equipped with an anaesthesia machine (Narcomed3, North American Drager, USA). Tidal volume was set at 10 ml kg^{-1}. Ventilatory frequency (f) was adjusted mainly each minute to maintain $P\text{a}_{\text{CO}_2}$ at preinduction levels with continuous monitoring of end-tidal carbon dioxide pressure ($P\text{E}'_{\text{CO}_2}$) and intermittent measurement of arterial to end-tidal carbon dioxide partial pressure difference ($P\text{a}_{\text{CO}_2} - P\text{E}'_{\text{CO}_2}$). Arterial blood samples were obtained every 15 min after stabilization of the ventilator settings and analysed for pH, $P\text{a}_{\text{CO}_2}$, $P\text{a}_{\text{O}_2}$ and base excess. Before skin incision, baseline carbon dioxide output and oxygen uptake were obtained after they reached steady state. Neuromuscular block was maintained with additional increments of vecuronium 0.025 mg kg^{-1} when the train-of four ratio exceeded 75%. Carbon dioxide was introduced into the peritoneal cavity by a carbon dioxide Pneu (Wisap, Germany) pressure limiting automatic insufflation apparatus and abdominal pressure was maintained at 8 mm Hg in all patients. After insufflation, multiple incremental changes in minute volume were made to maintain $P\text{a}_{\text{CO}_2}$ at preinduction levels. The table was tilted about 5° of the reverse. Trendelenburg position and then slightly to the left lateral position. Laparoscopic cholecystectomy was performed by a standard procedure. Intraperitoneal gas was evacuated after cholecystectomy and regression of carbon dioxide output in the post-insufflation state was measured 30 min under stable $P\text{E}'_{\text{CO}_2}$ every 1 min by manual control of ventilatory frequency. After carbon dioxide output returned to control level, neuromuscular block was antagonized with neostigmine 2.0–2.5 mg i.v. and atropine 1.0 mg i.v. The trachea was then extubated.

Anaesthesia was divided into five periods: (1) preinduction phase, (2) anaesthesia phase (control period of anaesthesia before skin incision), (3) pneumoperitoneum phase (during laparoscopy at intra-abdominal pressure of 8 mm Hg), (4) post-pneumoperitoneum phase (0–30 min after evacuation of carbon dioxide from the peritoneal cavity), and (5) recovery phase (40 min after extubation).

To fit the regression curve for carbon dioxide output during the post-pneumoperitoneum phase to multicompartment models, the least squares method was used and the number of compartments was determined by minimum AIC (an information criterion) based on the maximum likelihood estimation method [20].

Statistical analysis was carried out using analysis of variance (ANOVA), Fisher's test and Student's *t* test, where appropriate. $P < 0.05$ was considered statistically significant. All values are expressed as mean (SEM).

Results

We studied 12 premedicated patients, who were essentially normal in the pre-anaesthesia state (table 1). Steady states for $\dot{V}CO_2$/BSA and $\dot{V}O_2$/BSA were obtained during the following phases: preinduction, anaesthesia, pneumoperitoneum and recovery. Although it was difficult to maintain Pa_{CO_2} constant during the 10 min after tracheal intubation and the start of surgery, $P\text{E}'_{CO_2}$ concentrations were maintained at 5.0–5.4 kPa.

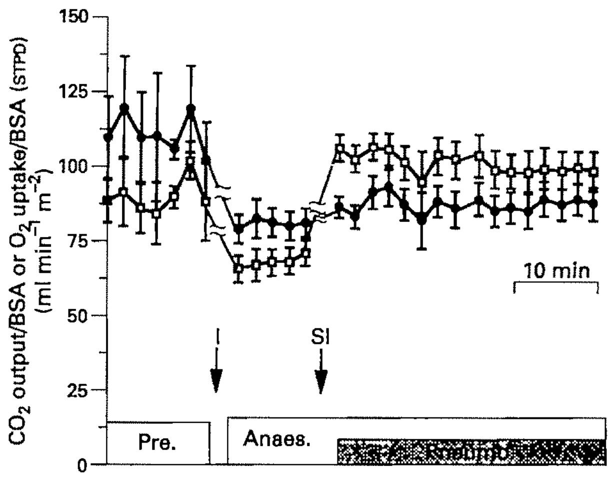

Figure 1 Changes in carbon dioxide output (□) and oxygen uptake (●) in the pre-induction (Pre.) anaesthesia (Anaes.) and pneumoperitoneum (Pneumo.) phases while maintaining $P\text{E}'_{CO_2}$ constant at the normal value for the preinduction phase (mean, SEM; $n = 12$). I = Intubation, SI = skin incision.

Compared with the preinduction phase, minute ventilation ($\dot{V}\text{E}$) decreased from 5.26 (0.33) to 3.33 (0.27) litre min^{-1} ($P < 0.05$) in the anaesthetic phase and increased to 5.14 (0.30) litre min^{-1} in the pneumoperitoneum phase ($P < 0.05$). Respiratory minute volume during pneumoperitoneum thus had to be made 1.54 times that in the anaesthesia phase to maintain Pa_{CO_2} constant (table 2). Carbon dioxide output and oxygen uptake decreased, respectively, from 83.5 (5.2), 101.6 (5.1) to 68.5 (4.2), 81.1 (4.6) ml min^{-1} m^{-2} (ATPS, $P < 0.05$) with sevoflurane anaesthesia and RER did not change. During pneumoperitoneum, carbon dioxide output increased 49 % (102.4 (5.0) ml min^{-1} min^{-2}, $P < 0.05$) while oxygen uptake remained stable and RER increased from 0.84 (0.02) to 1.16 (0.03) ($P < 0.05$, table 2, figs 1, 2). These variables returned to preinduction levels during recovery. Pa_{CO_2}, pH, base excess and Sa_{O_2} in the preinduction phase were normal (table 2) and were maintained throughout the experiment.

Table 1 Characteristics of patients, pneumoperitoneum (pneumo.) and anaesthesia (mean (SEM or range))

Age (yr)	Sex (M:F)	Weight (kg)	Height (cm)	Duration of anaesthesia (min)	Duration of pneumo. (min)	CO_2 volume for insufflation (litre)
52.5 (37–69)	5:7	57.1 (16.7)	154.1 (11.0)	196.2 (5.4)	89.3 (4.4)	77.2 (5.1)

Table 2 Metabolic and respiratory variables during the four phases of the procedures (mean (SEM)). $P\text{E}'_{CO_2}$ = end-tidal carbon dioxide pressure; $\dot{V}\text{E}$ = expired minute volume; $\dot{V}CO_2$/BSA = carbon dioxide output/body surface area; $\dot{V}O_2$/BSA = oxygen uptake/body surface area; RER = respiratory exchange ratio; $V\text{D}/V\text{T}$ = deadspace to tidal volume ratio; $(Pa_{CO_2} - P\text{E}'_{CO_2})$ = arterial to end-tidal carbon dioxide tension. * Significant difference from pre-induction, ** significant difference from anaesthesia

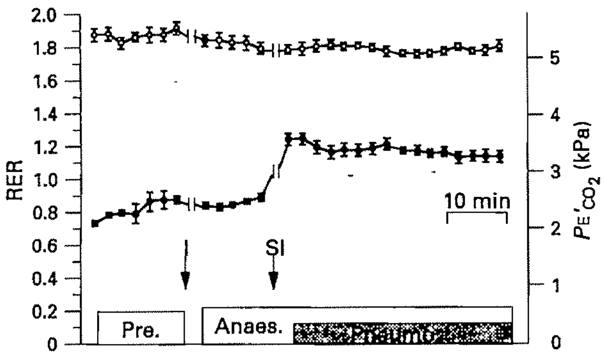

Figure 2 Changes in $P\text{E}'_{CO_2}$ (○) and respiratory exchange ratio (RER) (●) in the preinduction (Pre.), anaesthesia (Anaes.) and pneumoperitoneum (Pneumo.) phases (mean, SEM; $n = 12$). I = Intubation, SI = skin incision.

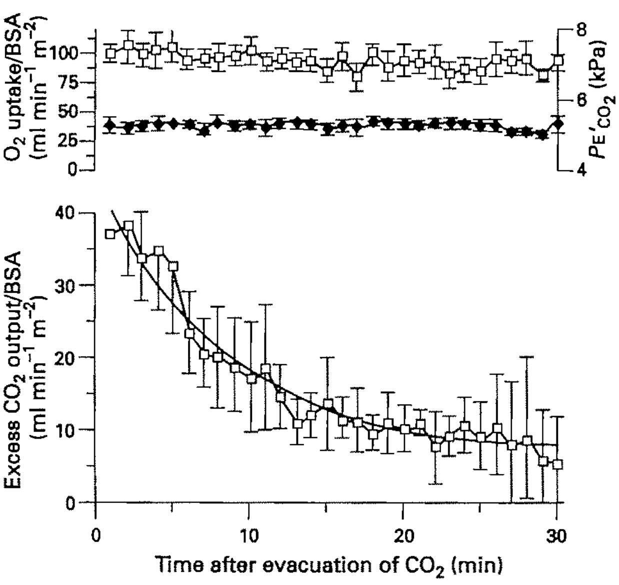

Figure 3 Changes in excess carbon dioxide output (□) after removal of carbon dioxide from the abdominal cavity. Oxygen uptake (□, top) and $P\text{E}'_{CO_2}$ (◆) were stable (mean, SEM; $n = 12$). ($Y = 39.4\,e^{-t/8.18} + 6.07e^{-t/990.13}$).

The results for haemodynamic state and temperature are summarized in table 3. After induction of anaesthesia there were decreases in heart rate, systolic arterial pressure, mean arterial pressure and diastolic arterial pressure. Significant increases in arterial pressure in the pneumoperitoneum phase were noted, but no cardiac arrhythmia was detected during induction, pneumoperitoneum or after pneumoperitoneum.

The regression equation for excess $\dot{V}CO_2$/BSA after removal of carbon dioxide from the abdominal cavity is shown in figure 3. $\dot{V}O_2$ and $P\text{E}'_{CO_2}$ were stable. A two-compartment model was judged to give the best fit by AIC. Excess carbon dioxide output pharmacokinetic variables and AIC values in each model are shown in table 4. Time constants of the first (rapid) and second (slow) compartments were 8.2 and 990 min, respectively. At the end of pneumoperitoneum, the rapid compartment was thought to be equilibrated, as $T_{\frac{1}{2}}$ was short (5.7 min) and carbon dioxide output was constant. The excess rate of carbon dioxide output/BSA was still 5.5 ml min^{-1} m^{-2}, 30 min after removal of carbon dioxide from the peritoneal cavity.

There was no clinical evidence of hypoxaemia, no change in standard bicarbonate before and after peritoneal insufflation, and no postoperative complications.

Discussion

During laparoscopy, the large volume of carbon dioxide for pneumoperitoneum is passively absorbed from the peritoneal cavity into the blood and most of it is removed from the circulation by hyperventilation. The respiratory effects of carbon dioxide absorbed from the peritoneal cavity into the blood have been studied previously [7, 21–27]. The quantity of carbon dioxide and bicarbonate ion in the body is large. When ventilation is not in accord with carbon dioxide output, hypercapnia continues. Sustained elevation in Pa_{CO_2}, typical of that associated with pneumoperitoneum, probably recruits whole-body storage depots, such as skeletal muscle and bone [28], in addition to intraperitoneal organs. Thus to study carbon dioxide output during laparoscopic cholecystectomy, the body storage of carbon dioxide must not be allowed to change. Although it is not certain that a constant Pa_{CO_2} necessarily implies constant storage, it is a reasonable assumption.

In the present study, $\dot{V}\text{E}$ was adjusted to maintain Pa_{CO_2} constant at the preinduction level with constant monitoring of $P\text{E}'_{CO_2}$ and intermittent measurement of (Pa_{CO_2}–$P\text{E}'_{CO_2}$). This method for estimating Pa_{CO_2} is invalid if the alveolar deadspace increases with ($Pa_{CO_2} - P\text{E}'_{CO_2}$), a situation that may occur during the period of carbon dioxide insufflation. Bramton

Table 3 Haemodynamic variables and temperatures during the four phases of the procedures (mean (SEM)). SAP = systolic arterial pressure; MAP = mean arterial pressure; DAP = diastolic arterial pressure; HR = heart rate. * Significant difference from preinduction; ** significant difference from anaesthesia

and Watson reported that monitoring of $P\text{E}'_{CO_2}$ during laparoscopy could be used to reflect Pa_{CO_2}, except at the start of pneumoperitoneum [29]. Fitzlerald and colleagues demonstrated that there were no changes in ($Pa_{CO_2} - P\text{E}'_{CO_2}$) during He pneumoperitoneum in mechanical ventilation [7]. In the present study, $V\text{D}/V\text{T}$ was almost constant except during preinduction when an anaesthesia mask was used for ventilation. Pa_{CO_2} during pneumoperitoneum was thought to be nearly constant, since $P\text{E}'_{CO_2}$ and $Pa_{CO_2} - P\text{E}'_{CO_2}$) were nearly constant (table 2, fig. 2).

During anaesthesia, the metabolic rate is reduced by about 15–30 % below that of the awake state [16, 30]. In this study, oxygen uptake and carbon dioxide output decreased 20.2 % and 18.0 % respectively. Thus RER remained constant, even during anaesthesia. Surgical stimulation may alter carbon dioxide output and oxygen uptake by increasing metabolic rate. End-tidal total MAC multiples of sevoflurane and nitrous oxide during pneumoperitoneum were maintained at 1.39, which was sufficient to prevent the effect of surgical stimulation on metabolism, as oxygen uptake did not change during surgery. The increased intra-abdominal pressure may have interfered with the elimination of carbon dioxide from abdominal organs and lower extremities by causing the veins to collapse. Carbon dioxide output and oxygen uptake increase after completion of pneumoperitoneum in this situation. However, an intra-abdominal pressure of 8 mm Hg, which was maintained automatically, did not hinder elimination of carbon dioxide, as oxygen uptake during and after pneumoperitoneum remained stable.

Marked increases in Pa_{CO_2} and excess carbon dioxide output, 66.9 mm Hg and 41 ml min^{-1}, respectively, 12 min after pneumoperitoneum were reported by Lewis and co-workers in young gynaecological patients anaesthetized with halothane during spontaneous ventilation [10]. Mullet and colleagues reported excess carbon dioxide output to be 32 ml min^{-1} with a 25 % increase in Pa_{CO_2} [12]. Wurst, Schulte-Steinbberg and Finsterer noted a 30–40 % increase in carbon dioxide output during pneumoperitoneum [11]. These values are less than the carbon dioxide output of 102.4 (5.0) ml min^{-1} m^{-2} and excess carbon dioxide output of 34.1 (3.9) ml min^{-1} m^{-2} (54.0 (4.6) ml min^{-1}) observed in the present study, possibly because of the following three factors: a decrease in tissue storage of carbon dioxide as a result of hyperventilation before insufflation of carbon dioxide, hypoventilation after insufflation and unstable conditions for measuring carbon dioxide output. Viale and colleagues demonstrated that the transient increase in RER at the start of anaesthesia was caused by increased carbon dioxide output during mechanical ventilation, as the standard controlled ventilation used (tidal volume = 10 ml kg^{-1}, ventilatory rate = 12 b.p.m.) may have caused alveolar hyperventilation. They found that 60 min was necessary to attain steady state after starting mechanical ventilation [15].

The regression equation for excess $V\text{CO}_2$/BSA showed the best fit with the two-compartment model (rapid and slow compartments) after removing carbon dioxide from the abdominal cavity. The half-times of the rapid and slow compartments were 5.7 and 686 min, respectively. A very small pressure difference causes carbon dioxide diffusion because carbon dioxide diffuses rapidly into the tissues. $P\text{CO}_2$ of arterial blood entering the tissues is 5.3 kPa; tissue capillary blood reaches almost complete equilibrium with interstitial $P\text{CO}_2$ when venous blood leaves the tissues [31]. The carbon dioxide insufflated to establish pneumoperitoneum diffuses into the abdominal organs and abdominal wall through the peritoneum, partly accumulates in tissue, and is then carried by the blood to the lungs. Therefore, the rapid compartment represents abdominal circulatory blood, liver, kidneys and other well-perfused tissues. The slow compartment represents tissues with low blood flow. Although the carbon dioxide load in the present study was clinically safe in patients without cardiac or pulmonary disease with controlled ventilation during and after pneumoperitoneum, excess $\dot{V}\text{CO}_2$/BSA was still 5.5 ml min^{-1} m^{-2}, 30 min after pneumoperitoneum. Therefore, patients receiving sedative drugs, patients with significant cardiac or pulmonary disease, or those with impaired ventilation in the pneumoperitoneum phase may be adversely affected by hypercapnia associated with carbon dioxide insufflation, even in the postoperative phase [9, 7].

LABORATORY INVESTIGATIONS

Effect of propofol and thiopentone on free radical mediated oxidative stress of the erythrocyte†

P. G. MURPHY, M. J. DAVIES, M. O. COLUMB AND N. STRATFORD

Summary

Propofol has free radical scavenging properties similar to those of recognized phenol-based antioxidants. We have examined these properties in an *in vitro* model of radical-induced cellular injury, comparing its activity with that of thiopentone (which has also been shown to have radical scavenging activity). Haemolysis of human erythrocytes was induced using the azo compound 2,2′-azo-bis(2-amidinopropane) dihydrochloride (ABAP). This was achieved by incubating a 10% suspension of erythrocytes with ABAP 100 mmol litre^{-1} at 37 °C. For propofol, at concentrations of 12.5, 25 and 50 μmol litre^{-1}, the times to achieve 50% haemolysis were mean 126 (SEM 7) min (95% confidence interval 108–144 min), 150 (8) (129–170) min and 182 (12) (160–180) min, respectively (Intralipid control 107 (7) (90–125) min, ANOVA $P < 0.0001$). For thiopentone, at concentrations of 62.5, 125 and 250 μmol litre^{-1}, the values were 117 (2) (112–121) min, 126 (3) (119–133) min and 138 (2) (132–144) min, respectively (saline control 109 (2) (104–113) min, ANOVA $P < 0.0001$). Spectroscopic analysis in the visible and ultraviolet spectra demonstrated a steady increase in the proportion of methaemoglobin during haemolysis, with the highest concentrations in the propofol-containing flasks. The formation of methaemoglobin was preceded by the generation of ferrylhaemoglobin (a Fe^{4+} haemoglobin species). Further experiments examining oxidation of purified methaemoglobin to ferrylhaemoglobin by hydrogen peroxide suggested that propofol, but not Intralipid or thiopentone, reduced ferrylhaemoglobin back to the met- state, and thereby explained the higher concentrations of methaemoglobin in the propofol-containing erythrocyte suspensions. We conclude that propofol is a more potent free radical scavenger in this model of oxidant stress than thiopentone, and that reduction of high oxidation states of haemoglobin may contribute to such activity. (*Br. J. Anaesth.* 1996; **76**: 536–543)

Key words

Anaesthetics i.v., propofol. Anaesthetics i.v., thiopentone. Blood, haemoglobin. Blood, erythrocytes. Blood, haemolysis.

Membrane peroxidation is regarded as a major mechanism whereby free radicals damage biological tissue [1]. Radical-mediated peroxidation of erythrocyte membranes leads to haemolysis and can be induced by a variety of reactive oxygen species, such as hydrogen peroxide [2] superoxide anion [3] and peroxyl radicals derived from the thermal decomposition of water-soluble and lipid-soluble azo compounds [4, 5]. The latter compounds provide an easily reproducible and reliable model of radical-induced haemolysis [4] and have demonstrated the importance of the endogenous lipid-soluble free radical scavenger α-tocopherol (vitamin E) in protecting the erythrocyte membrane against such injury [6]. The intracellular contents of the erythrocyte may also be susceptible to oxidant stress. For example, the haem-based iron of ferrous haemoglobin (Hb-Fe^{2+}) undergoes electron transfer reactions to form higher oxidation states such as met- (Hb-Fe^{3+}) and ferryl- (Hb-Fe^{4+}) haemoglobin species:

$$\text{Hb-Fe}^{2+} \leftrightarrow \text{Hb-Fe}^{3+} + e^- \leftrightarrow \text{Hb-Fe}^{4+} + e^- \quad (1)$$

The formation of higher oxidation states of haemoglobin has been described when erythrocytes are exposed to superoxide anion [3] and hydrogen peroxide [3, 7], although not when haemolysis is initiated by azo compounds [6].

The anaesthetic agent 2,6-diisopropylphenol is a potent antioxidant, chemically similar to α-tocopherol [8–10], and as such is a potent inhibitor of lipid peroxidation [8, 9]. In the *in vitro* experiments reported here, we have examined the effect of the clinical formulation of 2,6-diisopropylphenol, that is propofol, on peroxidation of erythrocytes induced by the water-soluble azo compound 2,2′-azo-bis(2-amidinopropane) dihydrochloride (ABAP). This has been evaluated in terms of haemolysis (as a measure of membrane integrity) and the haemoglobin redox state (as a measure of intracellular oxidant stress). The latter experiments showed that considerable quantities of met- and ferrylhaemoglobin are formed during ABAP-induced haemolysis, and that propofol significantly interferes with such redox reactions. order to characterize this hitherto unreported property, we have examined the effect of propofol on the oxidation of purified methaemoglobin by hydrogen peroxide. As thiopentone has also been shown to have antioxidant properties (inhibiting lipid peroxidation *in vitro* [11]), we have also examined the relative activity of these two anaesthetic agents in this model of oxidant-induced cell injury.

Materials and methods

HAEMOLYSIS EXPERIMENTS

Preparation of RBC suspensions

Heparinized blood obtained on the day of experiment from six healthy, non-smoking volunteers was used for these studies (age range 25–35 yr, four males). After separation from plasma and buffy coat by centrifugation for 5 min at 4000 rpm, erythrocytes were washed three times with sterile NaCl 0.15 mmol litre^{-1}. During the last wash the cells were centrifuged for exactly 10 min at 4000 rpm to ensure a constant packed cell volume. The cells were then resuspended in four volumes of phosphate-buffered saline (PBS, NaCl 125 mmol litre^{-1}, Na_2HPO_4 10 mmol litre^{-1}, pH 7.4) to prepare a stock 20% RBC suspension.

Induction of free radical-mediated haemolysis

Free radical-mediated haemolysis of the RBC suspensions was initiated with ABAP (Polysciences). ABAP (R–N=N–R) is a water-soluble azo compound which although stable at 4 °C decomposes at 37 °C to produce organic radicals (R·, reaction 2) at a steady rate:

$$R\text{–}N\text{=}N\text{–}R \rightarrow 2R\cdot + N_2 \qquad (2)$$

These radicals react with molecular oxygen to produce organic peroxyl radicals ($RO_2\cdot$; reaction 3)

$$R\cdot + O_2 \rightarrow RO_2\cdot \qquad (3)$$

which initiate peroxidative damage to membrane proteins and lipids, and thereby induce haemolysis. For example, organic peroxyl radicals react with unsaturated lipid (LH) to produce lipid radicals (L·) and organic hydroperoxides (ROOH):

$$RO_2\cdot + LH \rightarrow ROOH + L\cdot \qquad (4)$$

In our experiments haemolysis was induced by mixing equal volumes of ABAP (200 mmol litre^{-1} dissolved in PBS) and 20% RBC suspensions to produce 10% RBC suspensions in ABAP 100 mmol litre^{-1}. The suspensions were incubated at 37 °C under aerobic conditions and agitated gently throughout. Aliquots were obtained every 30 min for measurement of percentage haemolysis and spectroscopic analysis.

Measurement of haemolysis

The extent of haemolysis in the RBC suspensions was measured spectrophotometrically, by comparing the extracellular haemoglobin content of the aliquots with that of a fully haemolysed reference sample. Thus, 200 µl of RBC suspension was added to 3.8 ml of PBS and centrifuged for 4 min at 4000 rpm. The supernatant was added to an equal volume of Drabkin's reagent (stock solution, potassium ferricyanide 1.21 mmol litre^{-1}, potassium cyanide 1.54 mmol litre^{-1}, potassium dihydrogen phosphate 2.06 mmol litre^{-1}) in order to convert the various species of haemoglobin present to cyanmethaemoglobin, its most stable form. The absorption of this solution was measured at 540 nm. The fully haemolysed reference was prepared in the same way, except that the 200-µl aliquot was added to distilled water rather than PBS. Percentage haemolysis was measured according to the equation

$$\%\ \text{haemolysis} = A/B \times 100$$

where A = absorbance of the sample aliquot and B = absorbance of the fully haemolysed reference. A line plot of percentage haemolysis *vs* time was constructed, from which was estimated the time taken to achieve 50% haemolysis (H_{50}, min).

Experimental design

The effect of propofol (Diprivan, Zeneca) was examined at 2, 6-diisopropylphenol concentrations of 12.5, 25 and 50 µmol litre^{-1}. The Intralipid content of the 12.5- and 25-µmol litre^{-1} flasks was adjusted to equal that of the 50-µmol litre^{-1} flask, as was that of the Intralipid control flask. The effect of thiopentone was examined at 62.5, 125 and 250 µmol litre^{-1}, with the equivalent control containing PBS. In both cases, the agents were added to the 200-mmol litre^{-1} stock solution of ABAP immediately before mixing with the 20% RBC suspension. In order to exclude spontaneous haemolysis during the incubation period, a second (blank) control consisted of a 10% RBC suspension with propofol or thiopentone but without ABAP.

Spectroscopic analysis of RBC suspensions

Different haemoglobin species have different absorption spectra and can therefore be distinguished spectroscopically. We investigated qualitatively and quantitatively the changes in the proportions of various haemoglobin species present during haemolysis. Qualitative assessments were made from absorption scans, measured using a Pye Unicam SP8-500 scanning spectrophotometer (range 500–700 nm, scan speed 2 nm s^{-1}). The proportions of the various haemoglobin species present in the reaction mixtures were made by measuring the absorbance of the suspensions at set wavelengths (560, 577 and 630 nm), correcting for background absorbance measured at 700 nm, and applying the following equations:

$$[\text{oxy-Hb}] = 0.068425A_{577} - 0.001442A_{560} - 0.082173A_{630}$$

$$[\text{met-Hb}] = 0.041828A_{577} - 0.079247A_{560} + 0.318075A_{630}$$

$$[\text{ferryl-Hb}] = 0.095969A_{560} - 0.054490A_{577} - 0.046882A_{630}$$

where A = measured absorbance at each wavelength. These equations are similar to those described elsewhere for analysis of myoglobin [12] and were derived by solving the simultaneous equations for the measured absorbance at the given wavelengths set up using the following millimolar extinction coefficients for haemoglobin [13]: oxyhaemoglobin λ_{560} 8.6, λ_{577} 15.0, λ_{630} 0.17; methaemoglobin, λ_{560} 4.30, λ_{577} 4.45, λ_{630} 3.63; ferrylhaemoglobin, λ_{560} 14.1, λ_{577} 3.9, λ_{630} 3.0.

In further spectroscopic studies, we examined if this model of erythrocyte oxidative injury involved generation of transient intermediate ferrylhaemoglobin species such as $Fe^{4+} = O\text{-protein}\cdot$ and $Fe^{4+} = O$, which are known to be generated during oxidation of methaemoglobin by peroxides. These unstable and reactive species are difficult to detect in cellular systems, particularly in low concentrations. The latter can be "trapped" by Na_2S, which reacts with ferrylhaem species to form stable oxysulpho compounds which absorb strongly at 620 nm [14]. Thus, in these experiments, ABAP-induced haemolysis was carried out in the presence of Na_2S 8 mmol litre^{-1}. The presence of oxysulphohaemoglobin was identified by spectral scanning and quantified by measuring the change in absorption at 620 nm.

HAEMOGLOBIN OXIDATION EXPERIMENTS

Spectroscopic analysis of the red cell suspensions showed that ABAP-induced haemolysis was associated with generation of both met- and ferrylhaemoglobin. Furthermore, there was consistently more methaemoglobin in the flasks containing propofol than those containing Intralipid, saline or thiopentone. In order to test the hypothesis that this latter observation was a result of the reduction of ferrylhaemoglobin (formed during ABAP-induced oxidative stress of the erythrocyte) back to methaemoglobin, we examined the effect of propofol on the peroxidation of methaemoglobin by hydrogen peroxide (H_2O_2).

Human haemoglobin (Sigma), which we found to be more than 80 % methaemoglobin, was prepared as a 23-µmol litre^{-1} solution in PBS. Precipitates were removed by centrifugation and the pH adjusted to 7.4 with NaOH. It was then oxidized with an excess of H_2O_2 (H_2O_2:haem of 20:1), to which was then added either propofol 12.5 or 50 µmol litre^{-1}, Intralipid, saline or thiopentone. All reactions were carried out at room temperature. Using the equations described above, the proportions of oxy-, met- and ferrylhaemoglobin were measured before and after the addition of H_2O_2 and at 10-min intervals for 30 min after the subsequent addition of propofol, thiopentone, Intralipid or saline.

STATISTICAL ANALYSIS

Values are expressed as mean (SEM) and 95 % confidence intervals. The effects of propofol and thiopentone on the rates of haemolysis, as expressed by H_{50} values, were analysed using analysis of variance (ANOVA), using Bartlett's test to determine homogeneity of variances of the groups [15]. Differences between individual groups were compared using a two-tailed unpaired t test, to which a Bonferroni correction was applied, and quantified by confidence interval analysis. The relationship between drug concentration and H_{50} values was explored further by applying a post-test for linear trend to the rank-ordered ANOVA tables [16]. This latter test describes the relationship of the measured variable (in this instance H_{50}) to column number in the ANOVA table, and thereby allows the underlying relationship between concentration of drug and H_{50} to be investigated. The effect of propofol on H_2O_2-induced peroxidation of methaemoglobin was analysed using ANOVA and Bonferroni corrected t tests.

Results

HAEMOLYSIS EXPERIMENTS

The effects of propofol and thiopentone on ABAP-induced haemolysis are shown in figure 1 and table 1. Propofol delayed ABAP-induced haemolysis in a concentration-dependent manner, and while at the concentrations examined here complete haemolysis was eventually achieved, higher concentrations of propofol also suppressed the maximum degree of haemolysis observed (data not shown). Although thiopentone also delayed the onset of haemolysis, comparison of H_{50} values showed that its effect was less than that of propofol (table 1).

Spectroscopic analysis of the red cell suspensions

Spectral scanning of the reaction mixtures suggested a steady shift from oxy- to methaemoglobin during ABAP-induced haemolysis (fig. 2). A feature of this analysis was consistently greater absorption at 630 nm in the propofol-containing flask compared with that containing Intralipid. Quantitative spectroscopic analysis confirmed these findings (fig. 3). Thus there were significantly higher concentrations of methaemoglobin in the propofol flasks in comparison with the Intralipid-containing control. As

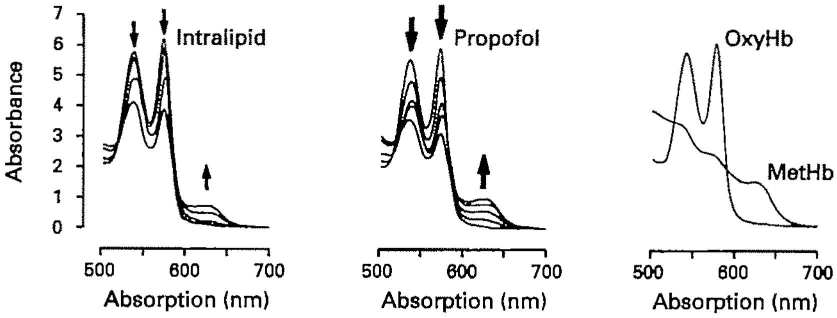

Figure 2 Sequential spectral absorption scans (absorption expressed in arbitrary units) of red cell suspensions containing Intralipid or propofol 50 μmol litre^{-1} during ABAP-induced haemolysis. Scans were performed every 60 min for 240 min and overlaid for ease of analysis. For comparison, the scans of pure oxy- (OxyHb) and methaemoglobin (MetHb) are shown. The direction of the changes in the sequential spectra are shown by the arrows. At time 0 both flasks contained predominantly oxyhaemoglobin. In the Intralipid flask there was little change before 180 min when the increase in absorption at 630 nm and the corresponding reduction in absorption at 540 and 577 nm suggest the formation of methaemoglobin. In comparison with Intralipid, the presence of propofol appeared to accelerate this transition from oxy- to methaemoglobin, with absorption at 630 nm being higher at any given time.

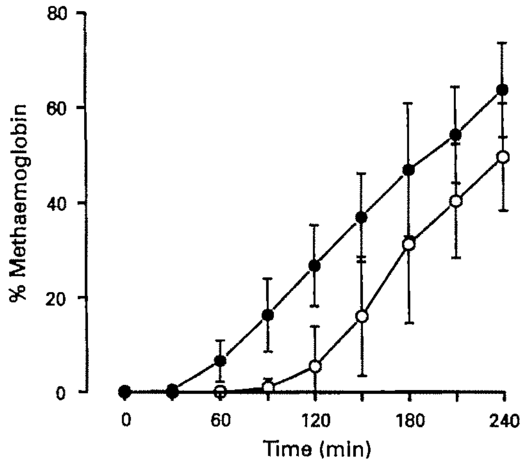

Figure 3 Effect of propofol 50 μmol litre^{-1} (●) and Intralipid (○) on the level of methaemoglobin measured by quantitative spectroscopic analysis during ABAP-induced haemolysis (expressed as percentage of total haem; mean, 95 % confidence intervals, $n = 6$). The effects of propofol 12.5 and 25 μmol litre^{-1} were intermediate between those of propofol 50 μmol litre^{-1} and Intralipid and were omitted for the sake of clarity. There was no difference between Intralipid and saline (the latter data were also omitted).

there was no difference between the concentrations of methaemoglobin in the Intralipid and saline flasks, this appeared to be an effect of propofol rather than Intralipid. Comparison of haemolysis and methaemoglobin data showed that while in the Intralipid-containing flasks methaemoglobin appeared only *after* cell lysis had started, in the propofol-containing flasks the appearance of methaemoglobin *preceded* haemolysis (fig. 4). In contrast with propofol, thiopentone had little effect of the concentrations of methaemoglobin (data not shown).

While confirming that oxidation of oxyhaemoglobin to the met- state had taken place, this quantitative analysis also suggested that in the early stages of haemolysis, 5–10 % of the total haemoglobin content was ferrylhaemoglobin (fig. 5). Furthermore, the proportion of this Fe^{4+} species was consistently lower in the presence of propofol in comparison with Intralipid. As relatively low concentrations of ferrylhaemoglobin were detected, it was felt important to obtain independent evidence for its generation during ABAP-induced haemolysis, using the sulphide-trapping method. Absorption at 620 nm (indicative of the reaction product of ferryl-

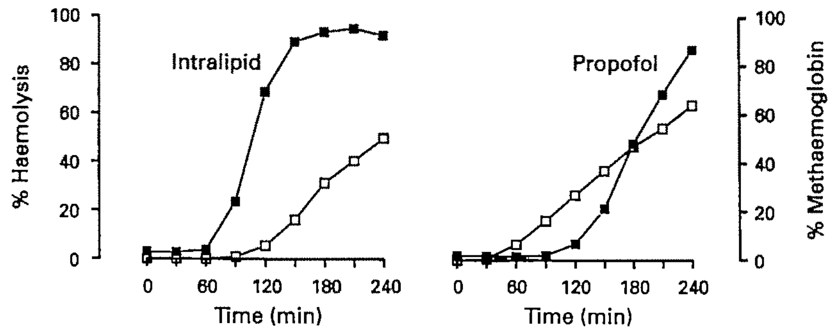

Figure 4 Effect of propofol 50 µmol litre^{-1} and Intralipid on the relationship between haemolysis (■) and increase in methaemoglobin (□) (mean, $n = 6$). In the Intralipid-containing flasks, haemolysis preceded significant methaemoglobin formation. In contrast, the presence of propofol, while delaying haemolysis, promoted the formation of methaemoglobin.

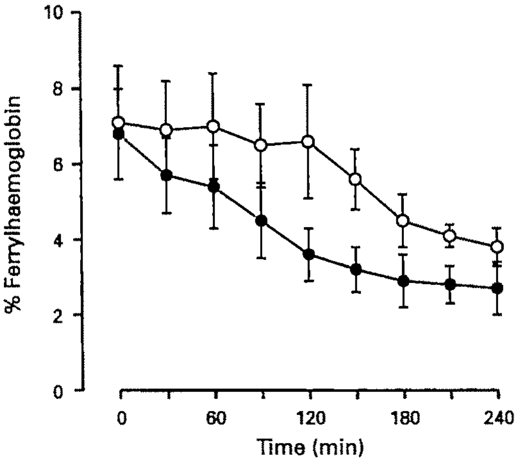

Figure 5 Changes in ferrylhaemoglobin concentrations during ABAP-induced haemolysis (expressed as percentage total haem; mean, 95% confidence intervals, $n = 6$ in each case). The concentrations of ferrylhaemoglobin in flasks containing propofol 50 µmol litre^{-1} (●) and an equivalent quantity of Intralipid (○) are shown. There was no difference in the concentrations of ferrylhaemoglobin between Intralipid- and saline-containing flasks, and the effect of intermediate concentrations of propofol (12.5 and 25 µmol litre^{-1}) was between the effects of propofol 50 µmol litre^{-1} and Intralipid (data not shown for the sake of clarity).

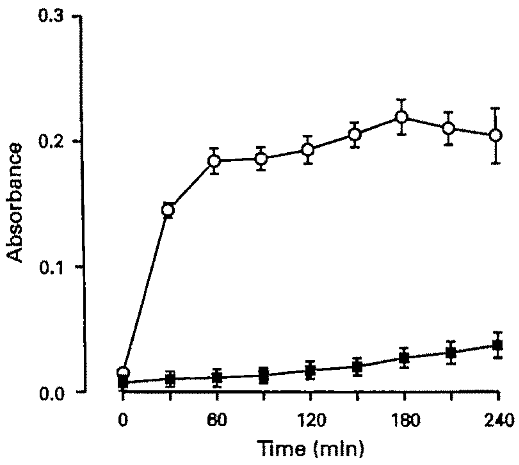

Figure 6 Absorption at 620 nm during ABAP-induced haemolysis in the presence of Na_2S 8 mmol litre^{-1} (mean, 95% confidence intervals) ○ = Saline, ■ = non-haemolysing control ($n = 6$).

haemoglobin and sulphide) increased rapidly in the red cell suspensions to which ABAP had been added, but only very slowly in the blank controls (fig. 6). Thus the formation of ferrylhaemoglobin during the early stages of the process was confirmed.

HAEMOGLOBIN OXIDATION EXPERIMENTS

The results of these experiments are shown in table 2. Oxidation of methaemoglobin with a 20-fold excess of H_2O_2 generated significant quantities of ferrylhaemoglobin, with a corresponding reduction in the proportion of methaemoglobin. Serial spectroscopic analysis over the subsequent 30 min demonstrated a gradual reduction in the concentration of the ferryl species accompanied by a corresponding increase in methaemoglobin concentrations. This transition was accelerated by propofol, but not by saline, Intralipid or thiopentone.

Discussion

Several workers have used models of oxidant-mediated haemolysis to investigate the susceptibility of intact cell membranes to oxidant stress and the efficacy of potential antioxidants, although the relationship between this and antioxidant activity in other tissues has not been well defined. Stocks and Dormandy, while commenting on the poor reproducibility of the assay, have shown that H_2O_2-induced haemolysis is inhibited by butylated hydroxyanisole and α-tocopherol [2], both established antioxidants. Haemolysis induced by azo compounds is much more predictable [4–6]. Using this model, Miki and co-workers have demonstrated in rats that dietary-induced deficiency of α-tocopherol enhances susceptibility to haemolysis induced by the water-soluble azo compound ABAP [6] and that antioxidants such as uric acid, ascorbic acid, cysteine, glutathione and water-soluble analogues of vitamin E confer protection *in vitro* [4]. The biochemical mechanisms underlying ABAP-induced lysis of erythrocytes are not defined, although recent studies suggest that radical-mediated injury to membrane lipids is not an important process in this model, and that damage to non-lipid membrane elements such as ion transport proteins is more likely to be responsible [17].

Table 2 Methaemoglobin oxidation experiments. Concentrations of met- and ferrylhaemoglobin (Hb) (expressed as percentage of total haem, mean (SEM) before and after oxidation of methaemoglobin with H_2O_2, and then 0, 10, 20 and 30 min after the subsequent addition of saline, Intralipid, thiopentone 250 μmol litre^{-1} or propofol 50 μmol litre^{-1}. Concentrations were analysed at each stage by one-way analysis of variance (ANOVA), and groups were compared with the propofol group using a *t* test to which a Bonferroni correction was applied ($*P < 0.05$, $**P < 0.01$). † Little ferrylhaemoglobin would be expected in the native preparation. These low values probably represent the inaccuracy in measuring the absorbance at the particular wavelengths used

In this study we have demonstrated that propofol, and to a lesser degree thiopentone, inhibited ABAP-induced haemolysis. Propofol (P-OH) is a phenol-based antioxidant and a potent inhibitor of lipid peroxidation *in vitro* [8, 9] and *in vivo* [18]. For example, it scavenges lipid peroxyl radicals ($LO_2\cdot$) through a process of hydrogen atom transfer to form a relatively stable propofol phenoxyl radical ($P\text{-}O\cdot$) and a lipid hydroperoxide (LOOH) (reaction 5) [8]:

$$P\text{–}OH + LO_2\cdot \rightarrow P\text{–}O\cdot + LOOH \qquad (5)$$

It is not clear if inhibition of ABAP-induced haemolysis by propofol resulted from scavenging of organic peroxyl radicals generated by ABAP (reaction 3), scavenging of lipid peroxyl radicals subsequently generated by it, or interruption of some other oxidant-mediated process initiated within, or close to, the cell membrane (e.g. generation of ferrylhaemoglobin species which have been shown to induce lipid peroxidation). Thiopentone has also been shown to inhibit lipid peroxidation *in vitro*, although the mechanisms for such an activity have not been defined.

Difficulties in explaining the inhibitory effects of propofol and thiopentone in this model result in part from the lack of information on the mechanisms of ABAP-induced haemolysis. It has been hypothesized that the release of iron from iron-containing proteins in tissues exposed to an oxidative stress may lead to a second wave of radical-mediated injury as a result of the ability of the released iron to catalyse further radical generation via the Haber–Weiss cycle (reactions 6–9) [1]:

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2\cdot^- \qquad (6)$$

$$O_2\cdot^- + O_2\cdot^- + 2H^+ \rightarrow H_2O_2 + O_2 \qquad (7)$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + \cdot OH \qquad (8)$$

$$O_2\cdot^- + Fe^{3+} \rightarrow Fe^{2+} + O_2 \qquad (9)$$

It is possible therefore that the release of haemoglobin during ABAP-induced haemolysis may contribute to subsequent erythrocyte membrane damage. Previous workers have dismissed this hypothesis because they could find no evidence for a change in the redox state of haemoglobin during this process [6]. In contrast, this study has shown that considerable methaemoglobin was formed during this process, although the demonstration that the concentrations were highest in the propofol-containing flasks (that is, the flasks in which haemolysis was delayed) does not ostensibly support the proposition that haem-bound iron contributes to erythrocyte oxidative injury.

The capacity of haem-containing proteins such as haemoglobin and myoglobin to generate radicals is thought to result in part from the ability of haem-bound iron to undergo one-electron transfer (oxidation–reduction) reactions and thereby oscillate between redox states (reaction 1). The absorption spectra of these haemoglobin species are distinct, allowing their relative proportions to be measured in both cellular and non-cellular preparations [13, 14]. How such redox transitions account for radical generation is not however entirely clear. It may result from the formation of the highly reactive hydroxyl radical via the Haber–Weiss cycle ($\cdot OH$, reactions 6–9), although several studies have demonstrated that such processes do not occur with intact haem proteins such as haemoglobin [1]. Other workers have suggested that haemoglobin and myoglobin may generate oxidant stress in tissues which is not mediated by the formation of $\cdot OH$ [13, 19], but which results from radical formation within amino acid residues of the globin element of the molecule (which can be represented by $-XH \rightarrow -X\cdot$). Thus, the oxidation of methaemoglobin ($HX\text{-}HbFe^{3+}$) by H_2O_2 and other hydroperoxides produces, via a two-electron transfer reaction, ferrylhaemoglobin ($\cdot X\text{-}HbFe^{4+}\text{-}OH$) [20] which is an unstable and reactive species in which the haem iron is one oxidizing equivalent above the met-state, with the second oxidizing equivalent present as a radical species on a protein residue within the globin moiety (as a tyrosine-derived phenoxyl radical):

$$\mathrm{HX\text{-}HbFe^{3+} + H_2O_2 \rightarrow \cdot X\text{-}HbFe^{4+}\text{-}OH + H_2O} \qquad (10)$$

Myoglobin behaves in a similar manner [21, 22] and in so doing promotes lipid peroxidation in cell membrane systems, although it is not clear if this is initiated by the protein radical or the ferrylhaem element of the molecule [12]. This injury can be attenuated by thiol-containing compounds such as *N*-acetylcysteine and *N*-(2-mercaptopropionyl)glycine [12]. Generation of ferrylhaemoglobin is also associated with increased concentrations of peroxidation in a ruptured erythrocyte preparation [23].

In order to explain the (higher) concentrations of methaemoglobin generated during ABAP-induced haemolysis in the presence of propofol we hypothesize that the organic hydroperoxide generated by ABAP (ROOH, reaction 4) oxidizes oxyhaemoglobin ($\mathrm{HX\text{-}HbFe^{2+}\text{-}O_2}$) to the ferryl state ($\mathrm{\cdot X\text{-}HbFe^{4+}\text{-}OH}$):

$$\mathrm{ROOH + HX\text{-}HbFe^{2+}\text{-}O_2 \rightarrow ROH + \cdot X\text{-}HbFe^{4+}\text{-}OH + O_2} \qquad (11)$$

in a manner analogous to the peroxidation by *hydrogen* peroxide (*H*OOH) described above (reaction 10). We suggest further that propofol (P–OH) reduces this ferryl species back to methaemoglobin thus:

$$\mathrm{P\text{–}OH + \cdot X\text{-}HbFe^{4+}\text{–}OH \rightarrow HX\text{–}HbFe^{4+} + {}^{-}OH + P\text{–}O\cdot} \qquad (12)$$

$$\mathrm{P\text{–}OH + HX\text{–}HbFe^{4+}\text{–}OH \rightarrow HX\text{–}HbFe^{3+} + P\text{–}O\cdot + H_2O} \qquad (13)$$

The formation of ferrylhaemoglobin during ABAP-induced haemolysis and reduced concentrations of this species in the propofol-containing flasks supports the first part of this hypothesis. The second series of experiments provided more definitive evidence that propofol, but not thiopentone, Intralipid or saline, promoted the reduction of ferrylhaemoglobin to methaemoglobin (reactions 12 and 13). It is not clear if generation of ferrylhaemoglobin is directly responsible for the oxidative stress to which erythrocytes are exposed when incubated with ABAP, although the association between reduced concentrations of ferrylhaemoglobin and lower rates of haemolysis in the propofol-containing flasks would support this contention.

We conclude from this *in vitro* study that propofol is capable of protecting erythrocytes against oxidant stress. Although this effect has been demonstrated at concentrations relevant to anaesthesia (12.5–50 μmol litre^{-1} is equivalent to 2.2–8.8 μg ml^{-1}), further work is required to demonstrate that this is a clinically significant effect. The mechanisms whereby propofol protects against ABAP-induced haemolysis remain to be fully elucidated. In this respect, although propofol inhibits lipid peroxidation, we have shown in these experiments that there is a further aspect to the antioxidant properties of this agent. Thus propofol can interact with high oxidation-state species of haemoglobin, and hence reduce ferrylhaemoglobin to the met-state. The reduction in the concentrations of these damaging high-oxidation state species may contribute to the protection afforded to membrane structures by the presence of this lipid-soluble radical scavenging molecule.

Antinociceptive actions of intrathecal xylazine: interactions with spinal cord opioid pathways

C. S. GOODCHILD, Z. GUO, A. DAVIES AND J. P. GENT

Summary

We have studied rats with chronically implanted subarachnoid catheters. Xylazine, an α_2 adrenoceptor agonist, was injected intrathecally and nociceptive thresholds measured at two skin sites: the tail and the neck. Intrathecal xylazine (dose range 24.3–389 nmol) produced increases in electrical thresholds for nociception in the tail without any change in the neck; this observation suggested that the antinociceptive action of this drug was confined to the caudal part of the spinal cord responsible for tail innervation. The magnitude of this effect was dose-dependent. Tail flick latency also increased in these rats and the antinociceptive effects were antagonized in a dose-dependent manner by the selective α_2 adrenoceptor antagonist idazoxan (dose range 6.7–540 nmol). Intrathecal idazoxan also suppressed the increase in tail flick latency caused by the mu opioid agonist fentanyl (0.74 nmol) given intrathecally. This effect was also dose-dependent. The idazoxan dose–response curve for this suppression of fentanyl antinociception assessed with tail flick latency was the same as that for suppression of xylazine. In contrast, the antinociceptive effects of intrathecal xylazine were not affected by concurrent administration of opioid or $GABA_A$ antagonists. We conclude that intrathecal xylazine produced spinally mediated antinociceptive effects by combination with spinal cord α_2 adrenoceptors and that neither opioid nor GABA-containing propriospinal neurones were involved in the mediation of this effect. However, α_2 adrenoceptors in the spinal cord appear to be involved with antinociception produced by intrathecal fentanyl. (*Br. J. Anaesth.* 1996; **76**: 544–551)

Key words

Sympathetic nervous system, xylazine. Sympathetic nervous system, adrenergic block. Analgesics opioid, fentanyl. Spinal cord. Pain, mechanism.

Drugs selective for α_2 adrenoceptors and even subtypes of α_2 receptors have been shown to produce antinociceptive effects assessed with a variety of tests, such as hot plate, tail flick, paw pressure and visceral nociception [1–4]. Antinociceptive effects are readily demonstrated after intrathecal injection of these drugs. However, rarely is evidence provided that would indicate that the drug was confined in its action to the spinal cord and that it did not produce the antinociceptive effects by spreading to the brain.

It has been shown recently that differential or segmental antinociceptive effects occur after intrathecal injection of a variety of opioid and benzodiazepine agonists [5–9]. In experiments where segmental antinociceptive effects were clearly demonstrated with the electrical current threshold (ECT) test, increases in tail flick latency after some intrathecal drugs have also been shown [9–11]. In such experiments some of the antinociceptive effects of intrathecal 5-HT (increases in tail ECT but *not* tail flick latency) resulted from activation of µ opioid and $GABA_A$ systems within the spinal cord [11, 12]. A similar interaction between opioid and α_2 adrenoceptor spinal cord systems has been suggested, although proof of restriction of drug effects to the spinal cord, as described above, was not provided [13–15]. In this study, we report the segmental antinociceptive effects of an intrathecal α_2 adrenoceptor agonist and characterize these antinociceptive effects using ECT and tail flick latency tests. The combination of the drug with α_2 adrenoceptors was responsible for these effects and the possible involvement of spinal cord opioid or $GABA_A$ receptor systems was investigated.

Materials and methods

This work was carried out with permission from the licensing authorities in the UK (Home Office Licence No. PPL50-00131). In all experiments attention was paid to ethical guidelines for investigation of experimental pain in conscious animals [16]. Experiments were performed on male Wistar rats (weights 150–200 g) with chronically implanted lumbar subarachnoid catheters. Two tests, measurements of electrical current threshold for nociception (ECT) and tail flick latency, were used to demonstrate the antinociceptive effects of intrathecally administered α_2 adrenoceptor agonist (xylazine) and opioid agonists fentanyl (µ selective) and U50488H (κ selective). Dose–response relationships of xylazine

given alone were assessed and then in a separate series of experiments, we investigated the effects of various antagonists on spinally mediated antinociception caused by a standard dose of intrathecal agonist. Dose–response curves for the opioids were determined in previous experiments [9]. Idazoxan (Research Biochemicals International; RBI) was used as the α_2 adrenoceptor antagonist, naloxone (Du Pont) as the opioid antagonist and bicuculline (Sigma, London) as the $GABA_A$ antagonist. All drugs were given intrathecally in a volume of 5 µl made up in physiological saline or 6% glucose solution.

CATHETER IMPLANTATION

Rats were anaesthetized with halothane in oxygen-enriched air ($F\text{I}_{\text{O}_2} = 0.5$) and a mid-lumbar laminectomy performed under aseptic surgical conditions using a 1.5-mm dental drill. The dura mater was exposed and incised. A catheter was manufactured from a 5-cm length of Portex tubing (i.d. 0.25 mm, o.d. 0.75 mm) stretched to a length of 10 cm in hot water (i.d. 0.1 mm approximately). It was introduced 1.0 cm into the subarachnoid space through an incision in the dura to lie next to the most caudal segments of the spinal cord, as described previously [9]. The catheter deadspace volume was measured before implantation; this varied between 4.5 and 7.5 µl. After closure of the surgical wounds with nylon and silk sutures (Ethilon and Mersilk; Ethicon Ltd) the animals were allowed to recover from general anaesthesia; this usually took 5–10 min.

After full recovery from general anaesthesia the animals were observed carefully for normal movement and behaviour. Any animal exhibiting signs of neurological damage was killed immediately (typically 5% of rats). The rest of the animals were subjected to a lignocaine test; we have previously found this to be a reliable test for correct intrathecal positioning of the catheter [8]. This test was performed after each cannulation and after each experiment in which intrathecal drug was administered. Thus intrathecal injection of drugs was confirmed. Any animal exhibiting a negative lignocaine test after cannulation (typically 10%) was excluded.

NOCICEPTIVE TESTS

A series of nociceptive tests was performed on each animal, the first on the day after cannulation. Although this is early after surgery, this preparation has been shown to produce stable baseline readings for the whole of the first week after cannulation [6, 9, 11, 17]. One test was performed each day on each animal up to a maximum of six. The rats were kept in groups of five before intrathecal cannulation and then in single boxes in rooms with a 12-h light–dark cycle. They were allowed free access to food and water throughout. They were placed individually in a proprietary restrainer and experiments were carried out in a quiet, darkened environment to minimize distraction of the animal by extraneous noise and light. Nociceptive thresholds were measured every 5 min using the ECT. In some experiments tail flick latency was also measured.

ELECTRICAL CURRENT THRESHOLD

Needle electrodes were placed 1 cm apart in the skin at the base of the neck. Wire electrodes were applied to the surface of the skin 1 cm and 5 cm from the base of the tail. The electrical current threshold (measured in mA at each skin site) was assessed, as described previously [9], every 5 min by the "up–down" method until three consecutive stable control readings had been obtained. The intrathecal drug or combination of drugs (see below) was then injected down the intrathecal catheter using the catheter swellings (used as markers to determine the catheter deadspace volume before implantation) to determine precisely the injection volume and dose. The electrical current threshold was measured at both skin sites every 5 min for at least another 20 min.

Individual responses were measured in mA. It has been found previously that these values for nociceptive thresholds vary between individuals and in the same individual at different times because of differences in electrode placement. They were therefore standardized by dividing the mean of the three threshold readings obtained 5, 10 and 15 min after intrathecal injection of agonist by the mean of the three corresponding readings taken before injection. This standardized response (denoted r) was a multiple of the control value.

TAIL FLICK LATENCY TEST

Tail flick latency was measured before assessment of ECT in the tail. The heat from a 150-W projector bulb was focused on to the tip of the tail painted black. Tail flick latency (measured in seconds) was assessed every 5 min until three stable control (pre-drug administration) measurements had been achieved (typically four trials), and then every 5 min after intrathecal drug administration. The increase in tail flick latency was standardized as a percentage of maximum possible effect (%MPE) calculated as follows:

$$\%\text{MPE} = \frac{\text{tail flick latency (post-drug)} - \text{tail flick latency (predrug)}}{\text{cut-off time} - \text{tail flick latency (pre-drug)}} \times 100$$

The cut-off time was the maximum time allowed for the animal to flick its tail away from the heat source before the lamp was automatically switched off. This was set at 10 s to avoid burning the tail.

ANTINOCICEPTIVE EFFECTS OF XYLAZINE

ECT was measured in the tail and neck in 48 experiments on 24 rats. In 30 of these experiments (11 rats) tail flick latency was also measured. Xylazine was injected intrathecally (24.3–389 nmol dissolved in 6% glucose 5 μl) over a period of 30 s with the animal tilted 45° head up to restrict distribution of the drug to the lumbar spinal cord. The standardized responses in both the neck and the tail were grouped for each dose of xylazine and the mean (SEM) calculated.

In nine of the above experiments xylazine 195 nmol was given intrathecally. The responses (ECT and tail flick latency) were standardized differently from those above to produce average time–response curves. The three control readings taken before intrathecal injection were averaged for ECT in the tail and neck. All values of current threshold (mA) at each 5-min period (whether before or after drug administration) were then divided by the corresponding average pre-injection value for that pair of electrodes. For tail flick latency each reading was standardized as %MPE using the equation above. The values thus obtained in different experiments for tail flick latency and ECT (tail and neck) were combined for each time of testing to produce means that were plotted on time–response curves. Thus the timing of onset of segmental antinociceptive effects (increases in tail ECT without any change in the neck threshold) could be compared with the onset of antinociceptive effect demonstrated by the tail flick latency test.

EXPERIMENTS USING IDAZOXAN

Xylazine

We performed 42 experiments in nine rats using tail flick latency and ECT tests. Intrathecal xylazine was given alone (195 nmol dissolved in 6% glucose 5 μl) at the beginning and after a series of once daily experiments with idazoxan in each rat. In intervening experiments (maximum of four) the same dose of xylazine was given intrathecally 5 min after a range of doses of idazoxan (6.7–540 nmol). The response of idazoxan was calculated as percentage suppression of the response to agonist given alone for both the ECT and tail flick latency tests. This was done by calculating the mean (R) of all tail responses to xylazine 195 nmol given alone for each test. Percentage suppression of control agonist response was calculated from the following equation:

$$\% \text{ suppression} = \frac{\text{R}-\text{r}}{\text{R}-1} \times 100\,\%$$

where R = response (either ECT (tail × control) or increase in tail flick latency, %MPE) in each individual experiment with antagonist. For the results of tail flick latency a value of 0, not 1, was used in the denominator. The results for percentage suppression by each dose of antagonist in individual experiments were grouped and the mean (SEM) calculated. These results were used to plot idazoxan dose–response curves.

Fentanyl

The experimental design in these experiments was the same as that for xylazine. Both nociceptive tests were used to assess the effect of intrathecal fentanyl 0.74 nmol dissolved in 6% glucose 5 μl. This dose was chosen from the dose–response relationship determined in previous experiments [9]. This dose caused segmental antinociceptive effects similar to those of xylazine. Sixty-five experiments were performed in 18 rats in which responses to agonist alone were assessed before and after an intervening series of experiments in which fentanyl 0.74 nmol was injected intrathecally 5 min after idazoxan (dose range 6.7–540 nmol), also injected intrathecally. We plotted percentage suppression of the antinociceptive effects of fentanyl by idazoxan, derived as above, and idazoxan dose–response curves.

Controls

Tail flick latency and ECT (tail) were measured every 5 min for 15 min before and 20 min after intrathecal injections of either idazoxan 180 or 540 nmol dissolved in 6% glucose 5 μl, or 6% glucose 5 μl alone in 13 rats. We searched for evidence of residual drug effects or progressive neurological damage at each time of testing by comparing the absolute values of ECT in the tail obtained at each time of testing with the first measurements obtained in that animal.

EXPERIMENTS USING NALOXONE

Xylazine

Sixteen experiments were performed in 11 rats. Both nociceptive tests were used to assess the effect of naloxone 2 mg kg^{-1} dissolved in saline 1 ml given i.p. on the antinociceptive effects of intrathecal xylazine 195 nmol dissolved in 6% glucose 5 μl. One experiment was performed on each animal per day. First the animal received intrathecal xylazine alone. On the following day, after three stable pre-injection readings had been obtained with both tests, naloxone was given i.p. 5 min before intrathecal injection of xylazine. Both nociceptive tests were carried out every 5 min for another 20 min. The results from each experiment were combined to produce mean (SEM) values for the responses in both tests to agonist alone and to agonist after i.p. injection of naloxone.

U-50488H

Larger doses of naloxone are required to suppress the effects of κ-selective compared with μ-selective opioids. U-50488H, a selective κ opioid agonist, was used to assess the effectiveness of the dose of naloxone to suppress all opioid responses in the xylazine experiments. The same design was used in these experiments as in those described above for fentanyl, xylazine and naloxone. We performed four experiments in four rats. Measurement of ECT (tail and neck) was used to assess the effects of intrathecal U-50488H on its own (210 nmol dissolved in saline 10 μl) and after i.p. naloxone 2 mg kg^{-1}. Tail flick latency was not used because the drug does not alter this measure of antinociception [7, 18, 19]. Results were expressed as mean (SEM) for U-50488H given alone and in the presence of naloxone.

STATISTICAL ANALYSIS

Comparisons of responses to xylazine, fentanyl and U-50488H were made with an unpaired *t* test to confirm that the doses used were equipotent. The effect of naloxone on the antinociceptive responses of xylazine and U-50488H was assessed using paired *t* tests.

EXPERIMENTS WITH BICUCULLINE

Eight experiments were performed on four rats in which measurements of both ECT and tail flick latency were used to assess the effects of the GABA$_A$ antagonist bicuculline on the antinociceptive action of intrathecal xylazine 195 nmol dissolved in 6% glucose 5 µl. A dose of 50 pmol of bicuculline was chosen from previous studies [6, 12]. In addition, intrathecal bicuculline 50 pmol given alone had no effect on the ECT in the tail [6]; these control experiments were therefore not repeated.

In another four rats the antinociceptive effects of intrathecal xylazine given alone and injected 5 min after administration of intrathecal bicuculline 50 pmol were assessed using both nociceptive tests. The responses in each group were combined to produce mean (SEM) values and compared using a paired *t* test.

Results

ANTINOCICEPTIVE EFFECTS OF INTRATHECAL XYLAZINE

Figure 1 shows the dose–response curve for the antinociceptive effects of intrathecal xylazine assessed with both nociceptive tests. Doses up to 389 nmol produced highly significant increases in the electrical current threshold in the tail (mean 2.67 (SEM 0.16) × control; $n = 8$; $P < 0.01$ paired Student's *t* test) with no significant increase in the electrical current threshold measured in the neck (1.1 (0.07); $n = 8$). At the same time intrathecal xylazine caused significant increases in tail flick latency (76 (10) %MPE; $n = 8$; $P < 0.01$ paired Student's *t* test).

Figure 2 shows time–response curves for tail flick latency and ECT responses in nine rats that received intrathecal xylazine 195 nmol. Intrathecal xylazine caused simultaneous significant increases in tail flick latency and ECT in the tail. These effects lasted for the duration of the experiment and were accompanied by no significant changes in electrical threshold in the neck. The time to offset of the responses could not be measured in this preparation because licensing restrictions only allowed restraint for this time. However, examination of control (predrug injection) and subsequent electrical current thresholds in the tail revealed no evidence for drug effects lasting until the next day or the occurrence of neurological damage; thresholds did not increase in any of the experimental series' as they progressed.

ANTAGONISM WITH INTRATHECAL IDAZOXAN

Xylazine

Doses of intrathecal idazoxan (6.7–540 nmol) given intrathecally 5 min before intrathecal xylazine 195 nmol caused dose-dependent suppression of the antinociceptive effects of xylazine assessed by both tests (fig. 3). There were no significant differences (paired Student's *t* test; $P > 0.5$) between the responses to xylazine given alone at the beginning of the series of experiments (ECT 2.05 (0.06) × control; tail flick latency 90.2 (5.5) %MPE) and those

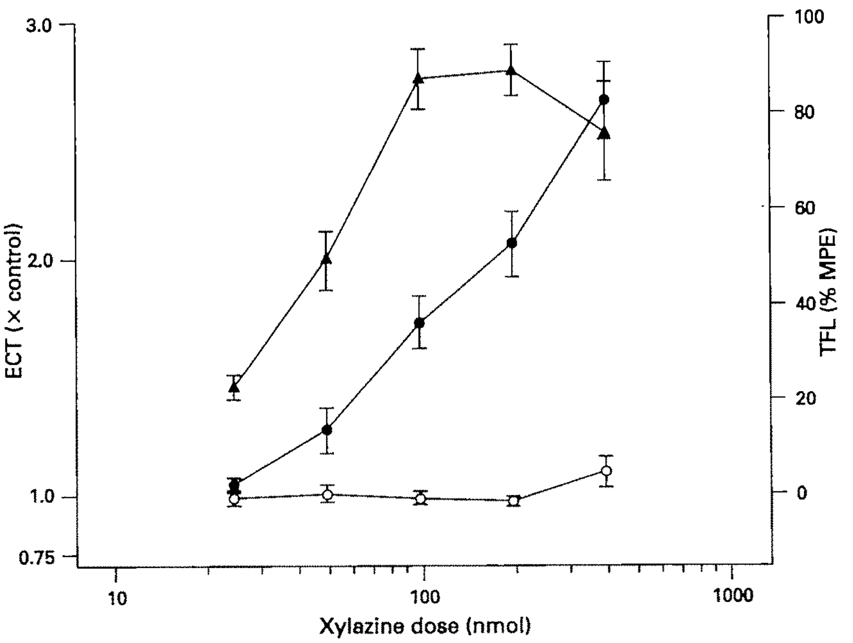

Figure 1 Intrathecal xylazine dose–response curves. Intrathecal xylazine caused dose-related antinociceptive effects demonstrated by an increase in tail flick latency (TFL (▲)) and increase in the electrical current threshold (ECT) in the tail (●) with no change in the neck (○) thresholds (mean, SEM). %MPE = percentage of maximum possible effect.

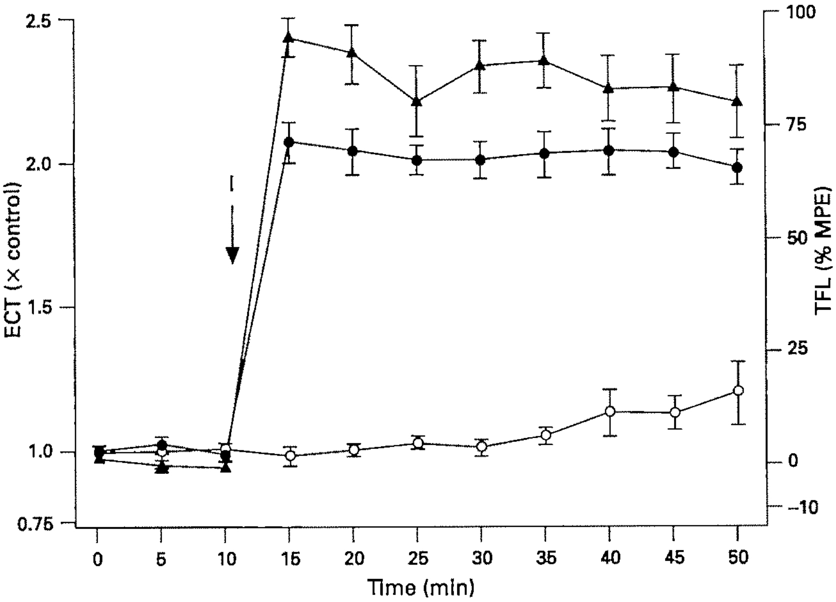

Figure 2 Time–response curves for intrathecal xylazine 195 nmol with the electrical current threshold test ((ECT) tail (●) and neck (○) electrodes) and tail flick latency (TFL) (▲) (mean, SEM) ($n = 9$). %MPE = percentage of maximum possible effect.

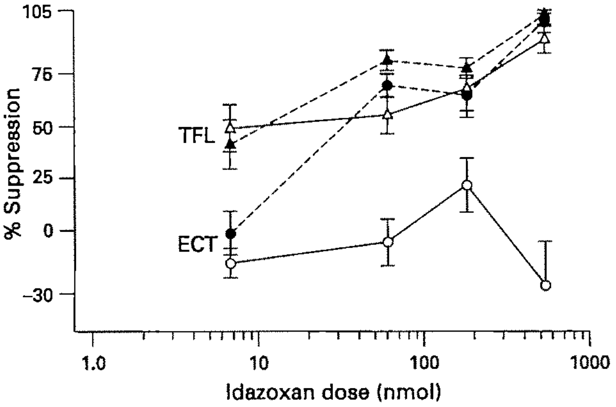

Figure 3 Idazoxan dose–response curves for suppression of the antinociceptive effects of xylazine (——) and fentanyl (——). Idazoxan suppressed the antinociceptive effects of xylazine in both nociceptive tests (tail flick latency (TFL) and electrical current threshold test (ECT)) but only suppressed the TFL effect of fentanyl.

obtained after the series of experiments (ECT 2.2 (0.11) × control; tail flick latency 94.8 (4.9) %MPE).

Fentanyl

The antinociceptive effects of fentanyl assessed with the tail flick latency test were suppressed by idazoxan, with the same dose–response relationship as that for suppression of the antinociceptive effects of xylazine assessed by both nociceptive tests (fig. 3). However, the effects of fentanyl assessed by the ECT test were not suppressed by idazoxan. There were no significant differences between the antinociceptive responses to intrathecal fentanyl given alone at the beginning of the series of experiments (ECT 1.93 (0.1) × control; tail flick latency 73.2 (5.9) %MPE) or after the series of experiments (ECT 2.18 (0.12) × control; tail flick latency 79.9 (4.7) %MPE). There were no significant increases in neck ECT (1.08 (0.11) × control). These responses also did not differ significantly from the corresponding responses to intrathecal xylazine given alone. The doses of the two drugs were therefore equieffective in the production of antinociceptive effects assessed by both tests, and the actions of both and interactions with idazoxan were restricted to the spinal cord. Control (pre-injection) and subsequent responses indicated that there was no drug accumulation or progressive neurological deficit as the experimental series progressed.

Both doses of idazoxan and 6% glucose did not cause significant changes in thresholds assessed by either nociceptive test (table 1).

EXPERIMENTS WITH NALOXONE

The dose of naloxone used (2 mg kg^{-1} i.p.) was sufficient to suppress totally the segmental antinociceptive effects produced by U-50488H, confirming previous studies with κ selective opioids [7, 17]. This high dose of naloxone did not produce any significant suppression of the antinociceptive effects caused by intrathecal xylazine (table 2). There were no significant differences between the responses to intrathecal xylazine and U-50488H given alone. All the responses to intrathecal U-50488H were segmental; no significant increases in neck ECT occurred (0.95 (0.11) × control).

EXPERIMENTS WITH BICUCULLINE

Intrathecal xylazine alone (195 nmol) produced significant segmental antinociceptive effects in the ECT test (1.96 (0.1) in the tail and 0.99 (0.01) in the neck; $n = 4$) and significant increases in tail flick latency (83 (17) %MPE; $n = 4$). Concurrent intrathecal administration of bicuculline 50 pmol did not significantly suppress either the ECT response (2.17 (0.1) in the tail and 1.0 (0.02) in the neck; $n = 4$) or tail flick latency (82.5 (13) %MPE; $n = 4$).

Table 1 Antinociceptive effects of idazoxan and 6% glucose (mean (SEM) (*n*)), as assessed by the electrical current threshold for nociception (ECT) and tail flick latency (TFL). %MPE = percentage of maximum possible effect

	ECT (× control)		
Controls	Tail electrodes	Neck electrodes	TFL (%MPE)
6% Glucose 10 μl	0.99 (0.03) (10)	1.01 (0.02) (10)	0.8 (1.0) (4)

Discussion

Intrathecal injections of xylazine produced segmental antinociceptive effects in the ECT test and simultaneously caused increases in tail flick latency. These effects occurred without any signs of sedation. The antinociceptive effects of xylazine assessed by both tests exhibited the same pattern of onset and were maintained for the entire experiment. Xylazine antinociception was maintained for much longer periods than any of the opioids or benzodiazepines in this preparation [7, 9]. The drug effects had disappeared 24 h later because there was no increase in control (pre-drug) tail electrical thresholds in subsequent experiments. These experiments have confirmed the antinociceptive effects of spinal α_2 adrenoceptor agonists reported by many others [1–4, 20–23]. Although most of those studies did not perform any of the manoeuvres mentioned above to prove a spinal cord action of the drug administered, the weight of evidence indicates a spinal site is responsible for the antinociception in a wide variety of tests. Waterman, Livingston and Bouchenafa showed segmental antinociceptive effects (five dermatomes around the catheter site) after spinal administration of xylazine in conscious sheep [22]; this effect was reversed completely by idazoxan. Our experiments allowed precise measurements of electrical thresholds and comparisons of dose–response curves to analyse drug interactions at the level of the spinal cord.

The dose–response curve for the tail flick latency response lies significantly to the left of that for the electrical current threshold response. Similar observations were made by Skingle, Hayes and Tyers [24] using clonidine, although they did not show differential responses in skin areas innervated by caudal compared with rostral spinal cord segments (a segmental effect). We have reported such differences in the dose–response curves for the two tests after intrathecal 5-HT [11].

Differences in the mechanisms responsible for the antinociception caused by 5-HT in tail flick latency compared with the ECT have also been demonstrated. The antinociceptive effects of 5-HT assessed by ECT could be suppressed by naloxone and bicuculline. However, the antinociceptive effects of 5-HT assessed by tail flick latency were not affected by either antagonist [11, 12]. Therefore, these results indicated involvement of propriospinal systems using GABA_A and μ opioid receptors in the pathways excited by ECT.

In the present study we have demonstrated that the antinociceptive effects of intrathecal xylazine are mediated by a combination of the agonist with spinal cord α_2 adrenoceptors because both the tail flick latency response and ECT were suppressed selectively by intrathecal idazoxan. This confirms the findings of Waterman, Livingston and Bouchenafa, although they did not perform a detailed dose–response analysis of the antagonism [22]. The same dose of idazoxan produced similar suppression of both responses. In contrast with the results obtained previously for intrathecal 5-HT [11, 12] it was not possible to demonstrate involvement of either an opioid or GABA_A receptor-mediated intermediate stage in the antinociception produced by xylazine; neither naloxone nor bicuculline suppressed increases in tail flick latency or ECT caused by intrathecal xylazine. The dose of naloxone used was sufficient to block all spinal opioid receptors as it was capable of completely suppressing the antinociceptive effects of the κ selective opioid against U-50488H in this series of experiments and has previously been shown to be capable of suppressing spinal antinociception caused by a variety of opioids and benzodiazepines [7, 17]. The dose of bicuculline used was also sufficient to block spinal GABA_A receptors as it has been shown previously to be effective in the suppression of spinally mediated antinociceptive effects of midazolam and 5-HT [12].

As segmental effects were demonstrated in all of our experiments for all intrathecal agonists it must be concluded that the actions of the agonists and their interactions with the antagonists must have occurred at the spinal cord level. We conclude therefore that the antinociceptive effects of xylazine result from an action on spinal α_2 adrenoceptors;

neither opioid nor GABA–benzodiazepine systems are involved as neither naloxone nor bicuculline suppressed these effects of xylazine.

Moreover, some of the spinally mediated antinociceptive effects of intrathecal fentanyl (ECT effects) result from actions at native μ opioid receptors and do not involve any other propriospinal system. In contrast, for increases in tail flick latency caused by intrathecal fentanyl there seems to be an interaction between the native μ opioid pathway and those pathways activated by α_2 adrenoceptor agonists, as the selective α_2 adrenoceptor antagonist idazoxan suppressed the effects of intrathecal fentanyl on tail flick latency. The results of these experiments with fentanyl and idazoxan indicate that the μ selective opioid binds with opioid receptors leading to activation of a spinal cord pathway that involves a native α_2 adrenoceptor; this is an essential part in the production of an increase in tail flick latency.

Interactions between μ opioid and α_2 adrenoceptor systems have been reported by several authors. For example, potentiation of the antinociceptive effects of intrathecal morphine by oxymetazoline has been reported [14]. Paw pressure and tail flick latency measurements were used but no proof of confinement of drug actions to the spinal cord was given. The potentiation (not simply the addition of effects) might therefore have been because of the actions of either or both drugs at supraspinal and spinal sites. The results presented in this study indicate that some potentiation is possible because the pathways activated by fentanyl and xylazine were not totally convergent. A similar relationship between the adrenoceptor and opioid systems has been reported from cross tolerance studies [13, 15, 25]. In one of these studies [25] it was shown that rats tolerant to ST-91 (an α_2 adrenoceptor agonist) showed no cross tolerance to morphine but morphine-tolerant rats demonstrated cross tolerance to ST-91. This might be predicted by the results of this study; induction of tolerance at the α_2 adrenoceptor by ST-91 also reduces the effect of morphine which acts via the adrenoceptor after binding with the opioid receptor. The nociceptive test used in this latter study was the tail flick latency test, the test which revealed convergence of the two spinal cord systems in the experiments reported here. Both of the other studies also used tail flick latency [13, 15] although one [13] also used paw pressure; neither study provided proof of confinement of the drugs to the spinal cord. Both of these latter studies seem to be at variance with the results reported here. The first [15] reported that chronic administration of clonidine (α_2 adrenoceptor agonist) decreased the antinociceptive effect of intrathecal morphine as tolerance to morphine developed, a result that would be predicted by the present study. However, they [15], in common with the second group of investigators [13], showed that chronic administration of morphine to cause morphine tolerance also decreased the effect of intrathecal α_2 adrenoceptor agonist. It is likely that morphine acted at sites in the brain leading to continuous activity in descending systems releasing noradrenaline onto spinal cord α_2 adrenoceptors [21, 26, 27]. This might have induced down-regulation of these receptors thereby inducing cross tolerance with the α_2 adrenoceptor agonists.

REVIEW ARTICLE

Postoperative sleep disturbances: mechanisms and clinical implications

S. ROSENBERG-ADAMSEN, H. KEHLET, C. DODDS AND J. ROSENBERG

Major surgery is beset by complications such as pulmonary, cardiac, thromboembolic and cerebral dysfunction, which cannot be attributed solely to inadequate surgical and anaesthetic techniques, but rather to increased organ demands caused by the endocrine metabolic response to surgical trauma [33]. Postoperative cerebral dysfunction comprises delirium, confusion and milder degrees of mental dysfunction [1, 48, 53, 62], and disturbances in the normal sleep pattern [4, 7, 9, 13, 17, 34, 39, 42, 65]. Changes in early postoperative sleep [4, 7, 8, 13, 17, 34, 39, 42, 65] and sleep after non-surgical stress [10, 20, 24, 26, 27, 29, 60] are characterized by a decrease in total sleep time, elimination of rapid eye movement (REM) sleep, a marked reduction in the amount of slow wave sleep (SWS) and increased amounts of non-REM (N-REM) sleep stage 2. Recent data have suggested that postoperative sleep disturbances may be involved in the development of altered mental function [27], postoperative episodic hypoxaemia [38, 65] and haemodynamic instability [40]. The aim of this article, therefore, is to review the incidence and duration of postoperative sleep disturbances, and to evaluate possible mechanisms and potential implications for postoperative outcome.

The normal sleep pattern

Using standardized polysomnographic recordings, which include simultaneous electroencephalographic (EEG), electro-oculographic (EOG) and electromyographic (EMG) recordings, sleep can be divided into different sleep stages (see below). By questionnaire, subjective sleep quality, which has been shown to be related to total sleep duration and number of awakenings [3], may be assessed.

Sleep is not homogeneous, but is divided into two discrete forms, REM and N-REM, by their electrophysiological characteristics [58], and each has been subdivided further. There are striking differences between these two sleep patterns. For example, arousal to effective awareness depends on the magnitude of the stimulating input and the "depth" of the sleep stage. Wakening from REM and stage 4 N-REM requires the greatest input, and this is as true for external stimuli, such as noise and light, as for internal autonomic signals, such as hypoxia or pulmonary stretch receptor reflexes. This clearly has an important influence on the hazards that may accompany deep sleep after surgery (see below).

N-REM sleep is subdivided into four stages of increasing depth or resistance to arousal, with stage 1 N-REM being light sleep and stage 4 N-REM very deep sleep (fig. 1). The physiology of N-REM sleep is based entirely on the autonomic medullary and brain stem control systems. There is a reduction in basal metabolic rate and this is associated with a progressive decrease in oxygen requirement, heart rate, arterial pressure, temperature and ventilation. The decrease in arterial pressure is largely because of peripheral vasodilatation, with cardiac output remaining relatively unchanged. Other physiological variables are generally unchanged during N-REM sleep. The tone of the anti-gravity muscles decreases with increasing depth of N-REM sleep, but the tonic drive to the diaphragm is maintained at all levels and types of sleep. There is a reduction in hypoxic and hypercapnic ventilatory responses and the response to increasing respiratory resistive loads. The maximum decrease occurs in stages 3 and 4 N-REM (also called slow wave sleep (SWS)), where for example the hypoxic drive decreases by 40%.

REM sleep is the phase most closely associated with dreaming. It is more akin to full awareness than sleep, in the variability and rapidity of changes in physiological state. There are marked variations in arterial pressure and heart rate, rate and depth of breathing, and metabolic rate. It appears that we act out our dreams physiologically. Major differences from N-REM sleep are also evident in respiratory control during REM sleep. The α-motor neurones are hyperpolarized during REM, with the exception of the facial muscle supply and that of the diaphragm. The hypoxic ventilatory response is reduced by up to 60% and carbon dioxide responses to between 27%

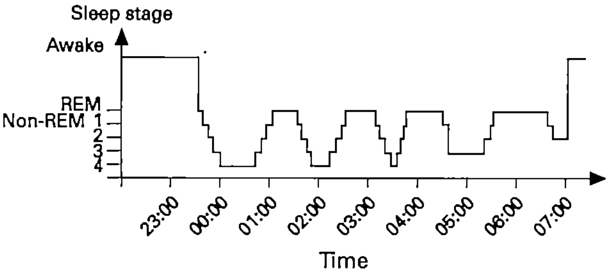

Figure 1 The normal sleep pattern (hypnogram).

and 0% [15] of the awake response. The arousal response to hypoxia requires a decrease in Sp_{O_2} to less than 70% for activation.

Sleep is essential and any alteration or suppression of specific sleep stages results in a rebound response when the inhibition is removed. The harmful effects of prolonged REM sleep in the postoperative period have been well documented. The time scale for these changes has not been described fully but they are thought to last for 1 or more weeks after surgery.

The mechanisms underlying the initiation and maintenance of sleep and its stages are still speculative, but there are some important features related to the effects of surgery and anaesthesia on sleep. N-REM sleep is linked closely with the central action of serotonin (5-HT) and, to a lesser degree, the monoamine noradrenaline. There are marked reductions in the amount of deep N-REM sleep in patients given benzodiazepines and opioids. REM sleep can be initiated by acetylcholine agonists in animal studies and neostigmine in human volunteers. Atropine markedly reduces REM sleep. Also α_2 agonists such as clonidine, or dopamine (D_2) agonists such as apomorphine, reduce REM sleep, and the monoamine oxidase inhibitors (MAOI) can almost abolish REM. Prazosin, an α_1 antagonist, increases the incidence of cataplexy, a REM-related component of narcolepsy. It is tempting to try to isolate key drugs as causal agents, for instance opioids, but the same pattern is seen after regional anaesthesia alone (see below).

Airway control during sleep

During wakefulness, the airway is maintained patent by the action of the paired strap muscles surrounding the oropharynx and pharyngopharynx. This prevents the collapse of this part of the airway by the subatmospheric pressures generated by the chest and diaphragmatic action. On initiation of sleep there is a progressive decrease in upper airway muscle tone and maintenance of the normal action of the chest and diaphragm. In the light stages of N-REM sleep this disproportionate decrease in tone makes collapse more likely. As the airway becomes progressively narrow, airflow becomes suddenly turbulent. This produces vibration of the upper airway or snoring. Thus snoring is partial airway obstruction. If there is a greater load on the airway muscles because of fatty deposits (obesity) or increased inspiratory resistance (such as the macroglossia of Down's syndrome), further collapse is likely and may culminate in complete airway obstruction.

In REM sleep, atonia of the anti-gravity muscles predisposes to instability of the airway, and most obstructive apnoea episodes occur in this stage of sleep. When the airway has become obstructed, further inspiratory effort is futile because of the lack of muscle tone during deep sleep. Vigorous paradoxical ventilatory movements are easily visible but ineffective. The only route to recovery of the airway is arousal from sleep which is usually very brief (< 5 s) and not associated with recall. The cycle of sleep–obstruction / hypoxia–arousal–sleep–obstruction/hypoxia may occur more than 100 times each hour. The consequences of these episodes of obstruction are two-fold: physiological effects of the progressive hypoxia and hypercapnia, and daytime sleepiness from repeated life-saving arousals. These patients are described as suffering from obstructive sleep apnoea (OSA) syndrome [46].

The consequences of airway obstruction during sleep may be profound and include progressive hypoxia, bradycardia and hypercapnia. Pulmonary artery pressure increases by hypoxic pulmonary vasoconstriction, and there is a generalized increase in systemic peripheral resistance. During REM sleep this causes increased oxygen demands at a time when hypoxia and hypertension are marked and ischaemic injury becomes likely, particularly of the heart. If apnoeas occur during N-REM, the association of hypotension and hypoxia may lead to cerebral hypoperfusion and stroke.

Function of sleep

The function of sleep is largely unknown, although several theories have been proposed. The most widely held theory is that sleep serves as a period of restoration, either total body or neurological restoration [66]. Total or selective sleep deprivation affects particularly the brain, with psychological and neurological dysfunction [30], impairment in behavioural and psychological performance [8, 23, 30] and sleepiness [8], and impaired concentration [30] and performance on psychometric tests [8, 23, 30]. Finally, mood is affected, with increased sadness and irritability, and decreased vigour [30]. Selective REM sleep deprivation produces a state of pronounced irritability and lability, and signs of confusion, anxiety and suspicion [2]. Deprivation of REM sleep is followed by a significant increase (rebound) in a recovery night [2]. SWS deprivation produces a feeling of physical discomfort [2], characterized by a depressive and hypochondrial reaction [2]. Selective deprivation of SWS also produces a rebound in SWS during a recovery night [2, 23].

The postoperative sleep pattern

Only six studies have been performed with EEG recording of sleep in postoperative patients after non-cardiac surgery, including a total of 35 patients after major abdominal surgery [4, 17, 39, 65], 18 patients after herniorrhaphy [17, 34] and 46 patients after minor undefined surgery [42] (table 1).

Table 1 Summary of clinical studies with EEG measured sleep after non-cardiac surgery. ↑ = Increased, ↓ = decreased, → = unchanged, 0 = not measured

	Type of surgery	Postoperative nights	Total sleep time	Duration of REM sleep	Duration of SWS	Duration of stage 2	No. of arousals	Rhythmicity	No. of patients

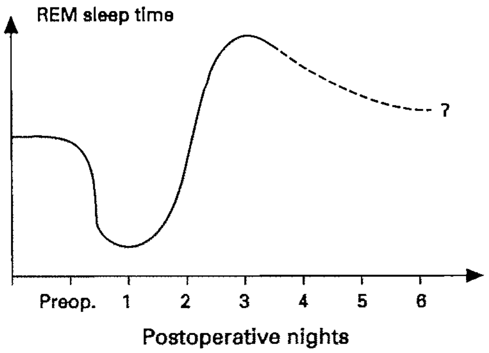

Figure 2 Changes in total REM sleep on pre- and postoperative nights (based on [4, 17, 34, 39, 42, 65]).

After abdominal surgery all patients were sleep deprived, as shown by total sleep time, proportion of REM sleep and SWS on the first and second postoperative nights in the ICU [4] and on the ward [17, 34, 38, 39, 65]. Total sleep time was reduced by up to 80% on at least 1 of the first postoperative nights [4, 7, 13, 17, 34], with considerable inter-individual variation. Throughout the operative night and the subsequent 1 or 2 nights, sleep was highly fragmented with numerous movement arousals and spontaneous awakenings with long wake periods [17, 34, 39], preventing the inherent rhythmicity of sleep and the normal distribution of sleep stages [17, 39].

REM sleep is usually absent on the first and sometimes the second and third postoperative nights [4, 17, 34, 38, 39, 42, 65]. During the following 2–4 nights, when other sleep abnormalities recover, REM sleep reappears with increased density and duration (rebound) in most patients [34, 38, 39, 65] (fig. 2). In patients undergoing cholecystectomy and gastroplasty, Knill and colleagues showed that increments in REM sleep during rebound were primarily a result of lengthening of individual REM sleep periods rather than to an increased number of periods [31]. Thus, increased total REM sleep time, combined with increased REM density, results in a substantial rebound in total REM activity [39]. The increase in REM activity is associated with frequent reports of distressing and vivid nightmares [39]. Nightmares have been shown to be frequent (about 20%) during the first week after major non-cardiac surgery [7, 9], with the highest incidence on the fourth postoperative night [9], corresponding to the period of rebound REM sleep.

On postoperative nights 1–4 there was a marked reduction in the amount of SWS [4, 17, 34, 39, 42, 65]. In one study SWS was absent in all 10 patients studied on the first and second nights after major abdominal surgery [65]. An increased duration of SWS (rebound) in the middle of the first post-operative week may occur after initial deprivation of SWS [65].

The duration of the abnormal postoperative sleep pattern has been described only poorly. No studies with EEG monitoring have been performed later than the sixth night after abdominal surgery. Total sleep time is gradually normalized to the pre-operative level within the first postoperative week [34]. REM sleep was still increased in nine of 12

Table 2 Summary of studies of postoperative sleep quality (measured by questionnaire). ↑ = Increased, ↓ = decreased, → = unchanged, 0 = not measured. *Patients were asked retrospectively about the whole postoperative period up to 2 yr after the surgical procedure

	Type of surgery	Postoperative nights	Total sleep time	No. of arousals/awakenings	Subjective sleep quality	Nightmares	No. of patients
Ellis & Dudley [17]	Inguinal hernia repair	1, 2	↓(in all)	↑(in all)	↓(in all)	0	8
	Upper abdominal surgery	1, 2	↓(in all)	↑(in all)	↓(in all)	0	4

	Minor orthopaedic surgery	Retrospective*	0	0	0	↑(in 7 %)	57

patients on the sixth night after cholecystectomy or on the fifth night after gastroplasty [39]. In most patients SWS gradually returned towards normal during the third and fourth postoperative night [34, 39, 65].

Studies based on observations by staff have shown that during the first night in the intensive care unit (ICU), the majority of subjects (56 %) were sleep-deprived with respect to total sleep time [27]. Similarly, the subjective feeling of sleep quality in postoperative patients has been shown to be decreased markedly during the first 1 or 2 nights followed by recovery of sleep quality, for most patients before discharge [7, 13, 17, 34] (table 2). A questionnaire study showed that approximately 23 % of patients after elective orthopaedic, vascular or abdominal surgery had decreased sleep quality at the time of discharge from hospital, and about 25 % of these patients showed changes for more than 2 weeks after discharge [7].

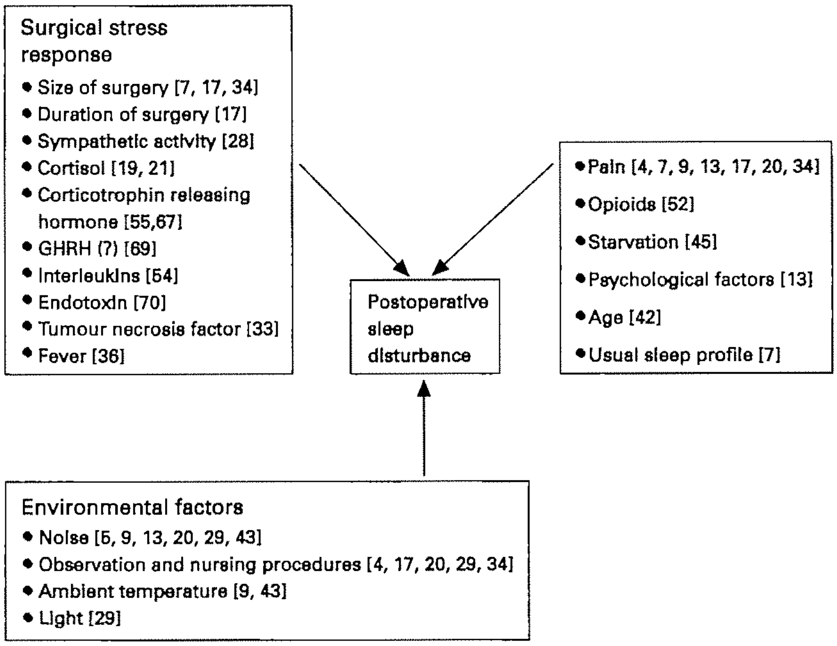
In summary, profound alterations in sleep pattern occur during the first 1–6 nights after major abdominal surgery. As previous studies have concluded that sleep duration and the frequency and periodicity of sleep disruption are the most important determinants for the restorative capability of sleep [3, 8, 23], such sleep changes may be expected to influence restoration of body organ dysfunction and in particular cerebral function.

Pathogenesis of postoperative sleep disturbance

Several factors may contribute to the disturbed sleep pattern in the surgical patient (fig. 3). The magnitude of surgery is important, as the reduction in REM sleep, SWS and the lack of inherent rhythmicity are more pronounced after major (gastrectomy or vagotomy) than minor (hernia repair) surgery [17]. In questionnaire studies, the greatest incidence of sleep disturbances was also found after the more major surgical procedures [13, 17, 27]. The duration of the operative procedure was related to the duration of postoperative sleep disturbance [17], probably as a result of more extensive surgical trauma.

In studies of patients receiving general or regional anaesthesia for herniorrhaphy [34], minor orthopaedic procedures [9] or minor undefined surgery [42], a similar degree of sleep disturbance was found, regardless of anaesthetic technique, suggesting that general anaesthesia *per se* is not an important pathogenic factor. Furthermore, general anaesthesia of 3 h duration in non-surgical volunteers produced only a modest reduction in SWS for 1 night and no changes in REM sleep [51]. Furthermore, similar changes in sleep pattern as are seen in postoperative patients have been found in non-surgical patients with acute ischaemic stroke [24], acute myocardial infarction [10], congestive heart failure [26] and medical and trauma ICU patients [20, 29, 60]. Thus general anaesthesia *per se* must be of minor importance in the pathogenesis of postoperative sleep disturbance, compared with the physical stress response caused by the surgical trauma.

The injury of surgery is followed by a complex



Surgical stress response
• Size of surgery [7, 17, 34]
• Duration of surgery [17]
• Sympathetic activity [28]
• Cortisol [19, 21]
• Corticotrophin releasing hormone [55,67]
• GHRH (?) [69]
• Interleukins [54]
• Endotoxin [70]
• Tumour necrosis factor [33]
• Fever [36]
Postoperative sleep disturbance
•Pain [4, 7, 9, 13, 17, 20, 34]
•Opioids [52]
•Starvation [45]
•Psychological factors [13]
•Age [42]
•Usual sleep profile [7]
Environmental factors
• Noise [5, 9, 13, 20, 29, 43]
• Observation and nursing procedures [4, 17, 20, 29, 34]
• Ambient temperature [9, 43]
• Light [29]

Figure 3 Factors which may contribute to postoperative sleep disturbances.

stress response involving hormones and humoral mediators of the endocrine–metabolic system, immunosuppression and an inflammatory response [6, 35]. The inflammatory reaction constitutes the local response, whereas endocrine–metabolic activation with increased plasma concentrations of catabolic hormones and reduced concentrations of anabolic hormones, leads to hypermetabolism with acceleration of most biochemical reactions, including muscle protein breakdown, resulting in a negative nitrogen balance [35]. The response may last for a few days or even weeks, depending on the magnitude of the surgical insult and occurrence of complications.

The increased postoperative sympathetic activity with increased catecholamines may contribute to postoperative sleep disturbances, as high levels of noradrenergic activity maintain wakefulness [28]. The postoperative influence of surgical trauma on insulin is biphasic, with an impaired insulin response to glucose during the initial phase followed by an increased insulin response but with concomitant increased peripheral insulin resistance (post-receptor defect) [35]. Cortisol, another of the key mediators in the endocrine response to surgery, causes reduction in REM sleep and increases non-REM sleep when administered to healthy volunteers [19, 21]. Furthermore, corticotrophin-releasing hormone, which is increased in surgical stress, decreases non-REM sleep and increases wakefulness in a dose-dependent manner in rabbits and rats [55, 67]. In contrast, growth hormone releasing hormone (GHRH) may have a sleep inducing effect [69], and is probably increased during the postoperative period.

Administration of one of the key mediators of injury, interleukin-1, into the lateral ventricle of rabbits results in hyperthermia and increased non-REM sleep, with suppression of REM sleep, thus resembling the postoperative situation [54]. Pretreatment with an interleukin-1 receptor antagonist prevented interleukin-1-induced sleep disturbances [54]. Endotoxin administration to healthy volunteers [70] and intracerebroventricular injection of tumour necrosis factor in rabbits [33] also caused deprivation of REM sleep and an increase in non-REM sleep, with no changes in SWS. As REM sleep is controlled by many regions in the brain and there is a dynamic interaction between cortex and other subcortical systems [32], the postoperative REM sleep disturbance may represent a global excitatory effect of the entire surgical stress response on the brain, rather than being caused by specific mediators of the surgical stress response.

Fever, which is seen commonly in postoperative patients, is associated with decreased REM sleep and increased SWS in rats with fungal infections [36]. It is not known if the fever-induced sleep disturbance is mediated by cytokines only or if it is induced by the increased temperature *per se*.

Morphine 0.1 and 0.2 mg kg^{-1} i.m., administered to healthy volunteers without pain, disrupted sleep in a dose-dependent manner [52]. After a dose of 0.1 mg kg^{-1}, only SWS was reduced, whereas a larger dose of 0.2 mg kg^{-1} produced a marked reduction in both REM sleep and SWS with an increase in nocturnal awakenings [52]. There are no data on the effect of systemic or extradural morphine on sleep in postoperative patients.

After operation, pain is the most commonly reported cause of night-time awakenings [13], and based on questionnaires, provision of analgesia is the most helpful intervention to improve sleep [13]. No comparisons have been made between opioid and non-opioid drugs. In patients with pain from active rheumatoid arthritis, sleep disturbances similar to the postoperative period have been demonstrated [49]. The role of pain *per se*, that is nociceptive stimulation *vs* concomitant release of inflammatory mediators (cytokines) and stress hormones, has not been evaluated.

The noise level in an ICU is usually greater than is internationally recommended at all times of the day and night [5]. Acoustically disturbed sleep has a decreased subjective quality, with less SWS than undisturbed sleep [23]. Patients have reported noise as one of the most disturbing factors of sleep in the postoperative period on the ward [7, 13] and in the ICU [29]. In addition, other "external" factors such as frequent observations and therapeutic procedures [29] and a high room temperature [43] may have a negative effect on sleep pattern in the surgical patient. An i.v. catheter did not affect sleep in volunteers [37], but starvation, as seen in most patients after major procedures, may be associated with decreased REM sleep and increased SWS, as shown in volunteers [45].

Obstructive sleep apnoea (OSA) syndrome

Special mention should be made of patients with the sleep apnoea syndrome. Sleep apnoea is defined as a pause of more than 10 s in breathing during sleep, and OSA is defined as at least five apnoeas per hour [48]. OSA is a common finding in non-surgical patients, with an incidence of 1–9% [48], although the more severe forms are less common. It has several major implications for anaesthesia and surgery throughout the operative period. These patients have repetitive episodes of often severe hypoxia and may have pulmonary hypertension. They may have impaired reflex responses to hypoxia, hypercapnia and inspiratory loads, and may also have altered autonomic cardiovascular reflexes [14, 71]. The treatment of OSA with nasal continuous positive airway pressure (CPAP) is highly effective at preserving the airway during sleep and over several weeks can improve the diminished reflex responses to hypoxia and hypercapnia [44]. However, it is more prudent to assume that they do not respond normally to any of these challenges during anaesthesia and in the postoperative period. They may be vulnerable to depressant medication such as benzodiazepines and opioids [12], and respiratory arrest can occur if these are given. All common anaesthetic induction agents, volatile and i.v., reduce upper airway tone in an identical manner to deep sleep. Some of the predisposing causes of sleep apnoea, such as a large tongue and recessive mandible, are also associated with difficulty in tracheal intubation and maintenance of a patent airway. Recovery from surgery and anaesthesia, while the normal protective reflexes are returning, may be a hazardous time, and obstruction of the airway can be difficult to overcome. This must be borne in mind after return to the ward if sedation or opioid analgesia is given. Regional methods of pain relief are believed to be safer than systemic opioid analgesia [18]. If patients are treated with CPAP, it is important that they bring their machines into hospital as they can be used in the recovery unit to preserve the airway until full recovery occurs and on the ward while their sleep returns to normal.

No data are available about postoperative sleep in patients with sleep apnoea syndrome, but extreme episodic oxygen desaturation in the late postoperative period has been described in a patient with the sleep apnoea syndrome [61], which may therefore be a potential surgical risk factor.

Clinical implications of postoperative sleep disturbances

The clinical consequences of suppression of REM sleep and SWS with subsequent rebound in the postoperative period remain unknown, although there are several potentially important implications.

The postoperative rebound of REM sleep in the middle of the first postoperative week may contribute to the development of sleep-disordered breathing and nocturnal hypoxaemia [38, 65]. Episodic hypoxaemia is more frequent during periods of REM rebound than during other sleep stages in the postoperative period [65].

REM sleep is associated with profound sympathetic activation on nights with postoperative rebound [41] and in normal subjects [46, 68]. REM sleep in normal subjects is associated with haemodynamic instability [40, 47, 68], and increased mean arterial pressure [47, 68]. In the postoperative period these haemodynamic changes may occur with the hypoxaemic episodes [38, 65], and following uncomplicated abdominal surgery, episodic hypoxaemia was associated with cardiac ischaemia [22, 59, 64]. Sleep apnoea and episodic oxygen desaturation may induce life-threatening cardiac arrhythmias in non-surgical patients [25]. As the amount of REM sleep and the intensity of its phasic events increase in the postoperative period with simultaneous episodic hypoxaemia and haemodynamic instability, postoperative REM sleep rebound may be particularly dangerous and lead to postoperative myocardial ischaemia, infarction and eventually to unexpected postoperative death. This hypothesis warrants further study, but is supported by the finding that the majority of unexpected postoperative deaths occurred at night [63].

Postoperative impairment of mental function is a common complication in the elderly, with an incidence of 7–77% after major surgery and a peak incidence in the middle of the first week after operation [1, 48, 53, 62]. The pathogenic mechanisms are not completely understood [1, 48, 53, 62], but factors such as hypoxaemia [1, 62] and sleep disturbances [27] may be important. After sleep deprivation in non-surgical volunteers, impaired mental performance has been demonstrated on a simple reaction time test [8, 23], as decreased ability for creative thinking [31], and by impaired ability to perform other cognitive functions [31]. The performance deficit is related to age [30] and to loss of sleep *per se* rather than to changes in the composition of sleep [8, 23]. Mood is affected also by sleep deprivation with decreased vigour and an increase in the subjective feelings of sleepiness [2, 23, 30] and fatigue [30]. As the postoperative sleep disturbances are pronounced and of the same magnitude as in the above-mentioned studies in volunteers, postoperative sleep disturbance may be an important contributing factor in the development of postoperative cerebral dysfunction. Furthermore, postoperative sleep disturbance could be a contributing factor in the phenomenon of postoperative fatigue [11], although a direct relationship between postoperative fatigue and sleep abnormalities remains to be demonstrated.

Prevention and treatment of postoperative sleep disturbances

As the magnitude and duration of the surgical procedure determines the degree of postoperative sleep disturbance [9, 17], a reduction in the surgical stress response by minimally invasive surgery may be effective. So far, there are no comparative studies between sleep patterns after the same operation performed either as a traditional open procedure or by minimally invasive surgical techniques. Stress reduction by neural block with local anaesthetics [35] may be expected to improve postoperative sleep also, but no data are available from studies using continuous nerve block techniques. As previous studies have suggested that pain [13, 49] and morphine [52] disturb postoperative sleep, continuous analgesic techniques with neural block using local anaesthetics without morphine should be evaluated, and the effect of NSAID because of their well-documented opioid-sparing effects. Preliminary studies with ketorolac after lower abdominal surgery have shown decreased opioid requirements and increased quality of sleep on the first postoperative night [56].

Noise [7, 13, 20], nocturnal nursing procedures [29], starvation [45] and increased room temperature [43] are sleep disturbing factors that could be eliminated in the postoperative period.

It has been reported that about 30% of medical and 88% of surgical patients receive sedative drugs during hospitalization [57]. Some of the most commonly used drugs are benzodiazepines, which have an important influence on sleep architecture with attenuated REM sleep and SWS, and increased stage 2 sleep [16]. Recent studies have suggested that the newer hypnotics zopiclone and zolpidem are less likely to alter sleep architecture [16] and that they may increase REM sleep and SWS to a normal level in non-surgical patients with disturbed sleep (insomnia) [16, 50]. The effect of these drugs on the postoperative sleep pattern is unknown and should be evaluated in future clinical trials.

As previously mentioned, patients with sleep apnoea syndrome are more susceptible to respiratory depression after sedative and narcotic administration [12] and the significance of the sleep apnoea syndrome as a surgical risk factor [61] should therefore be explored in future studies.

In summary, postoperative sleep disturbances represent an important research field, as they may have a significant negative impact on postoperative outcome.

SHORT COMMUNICATIONS

Effect of apparatus on functional residual capacity

G. B. DRUMMOND

Summary

As the route of breathing and use of airway apparatus such as mask, mouthpiece and noseclip can alter breathing pattern, this study has used the helium dilution method to estimate the effects of mouthpiece and mask breathing on functional residual capacity (FRC) in the supine position, and the change in FRC that occurs between the sitting and supine positions while breathing by mouthpiece. In 13 normal subjects, breathing by mouthpiece, FRC was smaller, by a median of 1.07 litre (interquartile values 0.73–1.43 litre) in the supine compared with the sitting position ($P < 0.01$), but residual volume (RV) did not change significantly. FRC measured in the supine position was significantly greater when breathing by mask than by mouthpiece (0.25, 0.04–0.38 litre) and RV was greater by similar amounts (0.20, −0.02 to 0.49 litre). This difference may result from increased inspiratory activity while breathing via the mask. (*Br. J. Anaesth.* 1996; **76**: 560–562)

Key words

Lung, volume. Lung, functional residual capacity. Equipment, masks anaesthesia. Equipment, breathing systems.

Although functional residual capacity (FRC) in adults is commonly thought to be determined passively by the opposing elastic forces of the lung and chest wall, evidence has accumulated that muscle action influences FRC. Reduction of muscle action, by sleep [1], small doses of neuromuscular blockers or induction of anaesthesia may reduce FRC [2]. Consequently, factors that affect the amount and pattern of respiratory muscle activity may affect FRC. Devices such as masks, noseclips and mouthpieces which alter the route of breathing also affect the pattern of breathing [3], and the activity of upper airway muscles is altered by changes in the route of respiration and by posture [4].

The relationship between airway apparatus and FRC has not been studied well, although interventions in patients such as nasal packing or jaw wiring can alter FRC [5]. Previous studies have used a variety of apparatus which may have affected the reported observations and hence the experimental conclusions. This study was designed to investigate the influence of breathing either via a mask or a mouthpiece on FRC in normal subjects. The influence of body position was included to allow comparison with a manoeuvre that is known to affect lung volume.

Methods and results

I recruited 13 healthy, non-smokers, with no respiratory disease, who were not obese. The study was approved by the local Ethics Committee. All patients were familiar with the respiratory apparatus and none had eaten recently. They were not told of the aim of the study, only that their lung volumes would be measured under three conditions.

FRC was measured using helium dilution, with a 10-litre, water-sealed, valveless spirometer (Godart, C. F. Palmer) and a katharometer (Cambridge Instruments). The linearity of the katharometer was checked by serial dilution. This procedure was used also to estimate the volume of the spirometer on each occasion. The spirometer was checked for leaks and brought to a steady temperature by running the system for 4 h before the studies started. The speed of the circulation fan was adjusted carefully so that the pressure at the subject connection was exactly atmospheric. The spirometer was filled with air, and helium and oxygen were added in a 4:1 ratio to obtain approximately 10% helium at the start of the measurements. The katharometer output was displayed on a digital voltmeter to obtain a resolution of at least 0.5% of the initial helium concentration. Subjects breathed air via a three-way tap attached to the spirometer, and were switched to the spirometer as close to FRC as possible. If this was not achieved, the appropriate correction was made by reading the error from the spirometer trace. Oxygen was added to maintain the volume of the spirometer constant. Equilibration was assumed when the concentration of helium had not changed for more than 30 s. Duplicate FRC measurements were made in six subjects in the sitting position to estimate the reproducibility of the measurements. The values differed by a median of 0.13 litre (interquartile values −0.11 to 0.34 litre). Because the precision of measurement of FRC is limited, values are given to the nearest 10 ml. An approximate estimate of oxygen consumption was made from the rate of addition of oxygen over the second half of the measurement period.

Three conditions were applied in random order (random number table): sitting upright with the arms supported at the sides, breathing from a flanged

mouthpiece and with a noseclip attached; lying supine on a soft trolley with the arms supported at the sides and the head in a neutral position on a pillow, breathing from a mouthpiece with a noseclip attached; and supine in the same position but breathing from a mask (Respironics CPAP mask) with a pneumatic rim which covered the mouth and nose, and held in place with a four-strap harness. A leak-free seal was ensured with water-soluble lubricating jelly (KY, Johnson and Johnson). This was tested at the start and end of each measurement by asking the subject to attempt to breathe when the tap outlet was occluded. On each occasion extreme care was taken to adjust the position of the spirometer connection so that there was no tension on the mouth or head of the subject and the subject was comfortable. Before each measurement, subjects breathed room air for at least 10 min until the respiratory pattern had become stable. Subjects were not allowed to sleep or doze during the measurements. At the end of each measurement period, expiratory reserve volume (ERV) was measured in triplicate. This was read from the spirometer chart to the nearest 30 ml. At least 15 min was allowed between FRC measurements for helium washout from the lungs.

The volume of the mask and mouthpiece were estimated by water displacement. For the mask, this was done by holding the mask over the face of three volunteers while in the supine position, with the nostrils sealed with tape and the mouth shut. The mouthpiece had a volume of 37 ml and the mask volumes were 129, 121 and 155 ml in three different subjects. A mean value of 135 ml was taken. These values were subtracted from the FRC values before statistical analysis.

Data were analysed using a spreadsheet (Microsoft Excel, version 5.0) and a statistics package (Minitab version 8.2), run with MS DOS version 6, on a GA-486US computer. Lung volumes (BTPS) are expressed as medians and interquartile values. The following primary paired *a priori* comparisons of FRC and residual volume (RV) were made using the Wilcoxon test: supine *vs* sitting, breathing via the mouthpiece; and breathing either via the mouthpiece or via the mask in the supine position. We expected patient position to have an effect on FRC and oxygen consumption, but not on RV and the null hypothesis was that there would be no difference between measurements made with the mask and mouthpiece. Oxygen consumption was also compared in the same manner.

As expected, there was a significant difference between FRC in the sitting and supine positions (median 1.07, interquartile values 0.73–1.43 litre) ($P < 0.01$) (table 1). RV did not differ significantly (-0.08, -0.30 to 0.37 litre), but oxygen consumption was greater in the sitting position by 77 (12–97) ml min^{-1} ($P < 0.05$).

FRC with the mask was greater than with the mouthpiece in 10 subjects, and less, by a value smaller than 50 ml, in three. The median difference was 0.25 (0.04–0.38) litre ($P < 0.01$). However, ERV was not affected by the route of measurement (median difference 0, -0.07 to 0.04 litre) so that RV was also significantly greater when breathing with the mask (0.20, -0.02 to 0.45) ($P < 0.05$). There was a positive correlation between the difference of FRC and RV between mask and mouthpiece in each subject ($r = 0.83$) and the relationship was close to 1:1.

Oxygen consumption was not different when measured with the mask or mouthpiece (median difference 20, -18 to 46 ml min^{-1}).

Comment

My results suggest that the use of a mouthpiece, and hence the obligatory use of the mouth for the route of respiration, is associated with a consistently smaller FRC and RV than when a mask is used. Both values were less by approximately 0.2 litre. However, the clear relationship between the differences in both FRC and RV suggests that the changes are related and the possibility that there is a common error has to be examined. A leak of helium during measurements with the mask would cause the second measured concentration to be smaller and hence the calculated FRC would be greater. In view of the care taken to ensure a leak-free contact with the face and repeated tests of the mask seal, this possibility is unlikely, although it cannot be discounted. Mask measurements of FRC in the sitting position were not performed because of the problem of ensuring a good seal in this position.

Repeated measurements of FRC in awake and sleeping subjects using a mask and the helium dilution technique have shown similar reproducibility to that found in this study [1]. A decrease of approximately 0.3 litre with REM sleep was found compared with the awake state.

The use of different types of airway apparatus such as noseclips, mouthpieces and masks alters the pattern of breathing, in comparison with measurements made using non-invasive methods, such as inductance bands.

Both body posture and route of breathing affect the activity of the muscles of the upper airway [4]. It is not clear if the route of breathing, or the apparatus used to measure breathing, also affects respiratory muscles that influence FRC. Although it is widely appreciated that body posture affects FRC, the predominant explanation offered for this effect is a mechanical one, attributing the greater FRC in the upright posture to the inspiratory effect of the abdominal contents. However, in the upright position abdominal muscles are active and thus FRC is not determined only by passive elastic forces. FRC is reduced by interventions that reduce muscle activity such as partial neuromuscular block [2]. Breathing through the nose, which is the usual route when both are available, is associated with activation of upper airway muscles [6]. In patients, nasal packing causes a decrease in FRC, and jaw wiring causes an increase in FRC [5]. To fully elucidate the possibility that there is activation of inspiratory muscles during mask breathing it would have been of interest to measure inspiratory reserve volume and ERV. However, when the study was designed it was the subdivisions of FRC that were considered of interest and the study did not include a vital capacity manoeuvre during the FRC measurements.

Measurements of oxygen consumption were not directly relevant, but showed that the sitting position was associated with significantly greater oxygen consumption, which is presumably caused by greater postural muscle activity. Previous studies of FRC have not always reported the type of apparatus used. The effect noted in this study is comparable with the changes in FRC found by some investigators and clearly could affect the magnitude of the observations of previous studies, and perhaps explain some of the discrepancies found in earlier investigations.

Measurement technique and variation in intramucosal pH

P. R. WOOD AND P. G. P. LAWLER

Summary

We have calculated gastric intramucosal pH (pH_i) from Trip catheter saline tonometered samples in two patients undergoing ventilation using four different sampling techniques, each repeated five times. pH_i was calculated from measurement of $P\text{CO}_2$ in tonometered saline ($T\text{CO}_2$). $T\text{CO}_2$ was measured immediately, and then at 6-min intervals for 30 min. Variation in measurement was greatest for capped syringes stored at room temperature, and least when stored uncapped on ice. $T\text{CO}_2$ always decreased significantly within 12 min. The mean difference in pH_i (all sampling techniques) over 30 min was 0.1005 pH units. The results indicate that the calculated pH_i was subject to variation as a result of both the method of sample storage and delay in measurement. An error of ±0.1 pH units may have clinically important implications if pH_i is used to monitor either severity of illness or efficiency of resuscitation. (*Br. J. Anaesth.* 1996; **76**: 563–564)

Key words

Gastrointestinal tract, pH. Monitoring, pH oesophageal.

The use of a Trip tonometer (Tonometrics, Inc., Bethesda, MD, USA) to measure gastric intramucosal pH (pH_i) is a recent innovation in intensive care medicine. A Trip nasogastric catheter incorporates a saline-filled balloon, which lies in contact with the gastric mucosa. Diffusion of carbon dioxide from gastric mucosa, into saline, allows for its subsequent measurement ($T\text{CO}_2$) using a conventional blood-gas analyser. An arterial blood-gas sample is obtained concurrently, and the measured bicarbonate (HCO_3) used to determine pH_i indirectly using a slide rule nomogram, supplied with the tonometer. pH_i is said to be an indicator of organ-specific oxygen and substrate delivery and may reveal splanchnic hypoperfusion, a situation of potential critical importance in clinical shock [1, 2].

Priming with saline, and subsequent sampling of the Trip catheter (deadspace = 1.5 ml, sample volume = 2.5 ml), may produce error if air is introduced into the system. Any delay between sampling and measurement may also affect the derived result, a situation well recognized with arterial blood-gas analysis [3]. We tested this possibility by calculating pH_i using different sample conditions and measurement times.

Methods and results

Local Ethics Committee approval was obtained before the study. Measurements were made in two stable patients undergoing ventilation who received i.v. H_2 receptor antagonists (ranitidine) throughout the period of investigation. Nasogastric feeding was suspended for 2 h before sampling. The Trip saline prime was allowed to equilibrate *in vivo* for 90 min before analysis.

Arterial blood-gas and tonometered saline samples were obtained and processed by one investigator using an IL 1312 blood-gas analyser, located within the intensive care unit (ITU). The Trip catheter was re-primed immediately after sample withdrawal.

$T\text{CO}_2$ was measured within 30 s of sampling (0 min), and arterial blood-gas 3 min later, between which the analyser self-calibrated automatically. The measurements were then repeated on the same sample pair, every 6 min for a total of 30 min, during which each individual sample was stored under one of four conditions (all collected in a 2-ml disposable plastic syringe): (1) capped, room temperature; (2) capped, on ice; (3) uncapped, room temperature; and (4) uncapped, on ice.

Accuracy of timing between sampling was ensured by the use of a stop clock and verified by the results print-out from the automatic blood-gas analyser. Each condition was studied exclusively five times during a single 24-h period, producing a total study period of 4 days. Before each series of measurements the blood-gas analyser was subject to a two-point calibration. Under these conditions the reproducibility of recurrent $P\text{CO}_2$ measurement (equivalent to electrode re-calibration drift) was less than 0.01 kPa.

All measurements within each condition were averaged and mean values at time = 0 min and time = 30 min were compared using a paired t test. $P < 0.05$ was considered significant.

The influence of time on $T\text{CO}_2$, pH_i and arterial HCO_3 is shown for each condition in table 1. The mean value of $T\text{CO}_2$ at $t = 0$ varied by as much as 1 kPa depending on the sampling condition, but the subsequent downward trend over 30 min was seen with each technique, reaching significance at 12 min

Table 1 Variation in bicarbonate, tonometered carbon dioxide and pH_i at $t = 0$ and $t = 30$ with sample technique (mean (SD))

Sample technique	HCO_3 (mmol litre^{-1})			T_{CO_2} (kPa)			pH_i		
	$t = 0$	$t = 30$	P	$t = 0$	$t = 30$	P	$t = 0$	$t = 30$	P
Capped, room temperature	27.820 (1.201)	27.360 (1.861)	0.315	5.678 (0.765)	4.172 (0.393) (26.521 %)	0.001	7.396 (0.043)	7.518 (0.013) (1.649 %)	0.000
Capped, ice	26.660 (1.137)	26.200 (1.153)	0.004	6.334 (1.312)	4.992 (1.288) (21.190 %)	0.003	7.328 (0.107)	7.434 (0.129) (1.447 %)	0.007
Uncapped, room temperature	24.300 (0.644)	23.940 (0.594)	0.266	5.318 (0.609)	4.288 (0.442) (19.364 %)	0.012	7.364 (0.062)	7.452 (0.035) (1.195 %)	0.022
Uncapped, ice	24.940 (0.270)	24.760 (0.358)	0.195	5.168 (0.217)	4.336 (0.291) (16.099 %)	0.005	7.372 (0.038)	7.458 (0.028) (1.166 %)	0.005

($P < 0.05$). pH_i increased under all conditions, with highly significant and clinically important increases at 30 min ($P < 0.02$).

The initial calculated pH_i of 7.365 (mean of all values) increased by a mean of 0.1005 pH units at 30 min (minimum increase 0.086, uncapped ice; maximum 0.122, capped, room temperature), as a result of changes in measured T_{CO_2}. The increases were significant at 12 min in all but one condition (uncapped ice), which became significant at 18 min. There was no statistically significant change in measured arterial bicarbonate over 30 min, with the exception of capped ice samples ($P = 0.004$).

Comment

We have demonstrated that T_{CO_2} measurement and subsequent pH_i calculation is subject to variation, depending on the sampling technique. The variation in mean T_{CO_2} at $t = 0$ is explained, we believe, by our methodology which studied each individual sampling technique on a different day, and was therefore subject to patient variation. However, a subsequent drift in measured T_{CO_2} occurred with all four conditions. This corresponded to a change in calculated hydrogen ion concentration over 30 min of 24.6 %, 21.7 %, 18.5 % and 18.1 % for conditions 1 to 4, respectively (mean of all four sample types = 20.72 %), the change in acidity being disguised by the unit of measurement (pH).

In practice, measurements of arterial blood gases are often delayed. Our results demonstrated that delays in measurement, particularly of T_{CO_2}, and hence calculated pH_i, may have significant implications for the diagnosis and monitoring of resuscitation.

A pH change of 0.1005 units (mean increase in all samples over 30 min) would at a pH value of approximately 7.35, produce alternative values of 7.25 or 7.45. As a pH_i value of less than 7.35 is considered pathological [4] errors of this nature and magnitude are worrying. Our patients were stable and never clinically shocked and therefore we do not know if the measurement changes that we have documented become more or less significant when pH_i is pathologically low.

In this study a significant problem with drift in arterial bicarbonate measurement occurred only with the capped ice samples, but as pH_i is calculated from the HCO_3/T_{CO_2} ratio, any drift in this variable is yet another potential source of concern. The accuracy of measurement of T_{CO_2} can be improved by using a phosphate buffered solution [5] but prompt analysis would still be advised. An additional acknowledged difficulty is the error attributable to the choice of blood-gas analyser [6].

We suggest that strict standardization of the conditions of measurement for both arterial blood gases and the tonometered sample is necessary before results gained from Trip analysis may be usefully applied in, and between, different intensive care patient groups.

Magnesium sulphate enhances residual neuromuscular block induced by vecuronium

T. FUCHS-BUDER AND E. TASSONYI

Summary

Magnesium sulphate ($MgSO_4$) is currently used for haemodynamic control during anaesthesia and the early postoperative period. We have investigated the effect of this treatment on residual neuromuscular block after administration of vecuronium. Twenty adult patients were allocated randomly to one of two groups to receive $MgSO_4$ 60 mg kg^{-1} either at recovery from vecuronium block to a train-of-four (TOF) ratio of 0.7, or 1 h after recovery to a TOF ratio of 0.7. Neuromuscular transmission was monitored using electromyography and TOF stimulation. $MgSO_4$ caused rapid and profound recurarization in all 20 patients. $MgSO_4$ decreased the amount of acetylcholine released at the motor nerve terminal and thus may lead to recurarization in patients previously exposed to neuromuscular blocking agents. (*Br. J. Anaesth.* 1996; **76**: 565–566)

Key words

Neuromuscular block, vecuronium. Neuromuscular block, recovery. Ions, magnesium. Measurement techniques, electromyography.

Magnesium sulphate ($MgSO_4$) may be given during anaesthesia and the early postoperative period for its antihypertensive and anti-arrhythmic properties [1, 2]. While the effect of $MgSO_4$ pretreatment on the pharmacodynamics of neuromuscular blocking agents has been reported [3], less is known about its effects when given after neuromuscular block has recovered clinically (i.e. TOF ratio $\geqslant 0.7$). This question may be of clinical relevance as $MgSO_4$ decreases the amount of acetylcholine (ACh) released at the motor nerve terminal, thus reducing the safety margin of neuromuscular transmission. We therefore hypothesized that $MgSO_4$ may enhance residual neuromuscular block. The aim of the present study was to determine if $MgSO_4$ administration at different times after recovery to a TOF ratio of 0.7 is safe.

Methods and results

After obtaining institutional Ethics Committee approval and written informed consent, we studied 20 patients, ASA I or II, undergoing elective surgery. We excluded patients with known neuromuscular disease or receiving medications influencing neuromuscular function. After premedication with midazolam 7.5 mg, patients were anaesthetized with fentanyl 2–3 μg kg^{-1}, thiopentone 4–5 mg kg^{-1} and 1% isoflurane with 60% nitrous oxide in oxygen. Patients' lungs were ventilated to normocapnia and skin temperature over the adductor pollicis was maintained greater than 34 °C. Neuromuscular function was assessed by supramaximal stimulation of the ulnar nerve with TOF stimuli at 2 Hz every 20 s and recording the electromyographic response (twitch height, TOF ratio) of the adductor pollicis muscle (Relaxograph, Datex Instrumentarium Corporation, Finland). When the end-tidal isoflurane concentration had stabilized, the Relaxograph was recalibrated, the control twitch height (first response of TOF) determined, and vecuronium 100 μg kg^{-1} administered. Patients were allocated randomly to one of two groups of 10 each to receive $MgSO_4$ 60 mg kg^{-1} in saline 100 ml as a short infusion either at recovery to a TOF ratio of 0.7 or 1 h after recovery to a TOF ratio of 0.7. The onset of recurarization (time from end of perfusion of $MgSO_4$ to minimum twitch height), minimum twitch height, number of TOF responses at minimum twitch height, and time to recovery of the TOF ratio to 0.7 again, were recorded.

The typical time course of vecuronium neuromuscular block and subsequent effect of $MgSO_4$ are shown in figure 1. In the group that received $MgSO_4$ at a TOF ratio of 0.7, the following values were recorded before administration of $MgSO_4$: mean twitch height 78 (SD 3)% and TOF ratio 0.71 (0.02). Onset of maximal block was 328 (79) s, minimum twitch height was 23.5 (11)%, median number of TOF responses at minimum twitch height was 2 (range 0–4) and time to recovery to a TOF ratio of 0.7 was 28.8 (10.5) min. In patients who received $MgSO_4$ 1 h after recovery to a TOF ratio of 0.7 the following values were obtained: twitch height 88 (6)%, TOF ratio 0.87 (0.14), onset of maximal block 480 (120) s, minimum twitch height 34 (20)%, median number of TOF responses at minimum twitch height 3 (range 2–4) and time to recovery to TOF 0.7 22 (7.6) min.

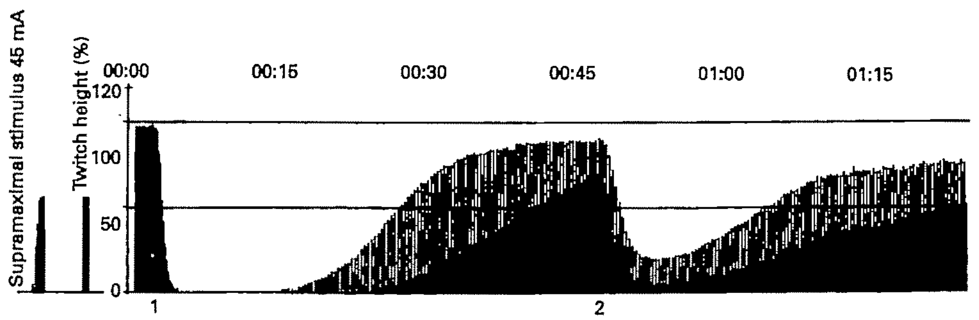

Figure 1 Time course of vecuronium neuromuscular block and $MgSO_4$-induced recurarization: 1 = administration of vecuronium 100 μg kg^{-1}; 2 = recovery of TOF ratio to 0.7 and infusion of $MgSO_4$ 60 mg kg^{-1}.

Comment

This study has demonstrated that administration of $MgSO_4$ after return of neuromuscular function to a TOF ratio of 0.7 leads to recurarization. The risk of muscle paralysis persists, at least during the first hour after recovery to a TOF ratio of 0.7. Recurarization is rapid in onset and profound enough to compromise respiration.

We chose $MgSO_4$ 60 mg kg^{-1} as this dose is used currently in anaesthetic practice [2]. However, at these concentrations, $MgSO_4$ without neuromuscular blockers does not induce measurable block [4].

Decreased ACh release at the motor nerve terminal by $MgSO_4$ is the most likely explanation for the observed recurarization. According to the concept of the margin of safety of neuromuscular transmission [5], the twitch response may be normal with 70–80 % of the ACh receptors at the neuromuscular junction still blocked by a non-depolarizing neuromuscular blocking agent. However, in this situation, any decrease in ACh release may enhance neuromuscular block with subsequent clinical consequences such as recurarization. Patients in the early postoperative period, with a large percentage of ACh receptors still occupied, are particularly vulnerable to drug interaction at the neuromuscular junction.

In summary, $MgSO_4$ in clinically relevant doses caused profound recurarization when given to patients recovered from neuromuscular block. We conclude that when $MgSO_4$ is given in the postoperative period, respiration and neuromuscular function have to be monitored carefully to avoid complications caused by muscle weakness.

Comparison of the effect of two dose schedules of oral omeprazole with oral ranitidine on gastric aspirate pH and volume in patients undergoing elective surgery

I. D. LEVACK, R. A. BOWIE, D. P. BRAID, A. J. ASBURY, R. L. MARSHALL, K. B. SLAWSON, H. BIRRELL AND K. R. W. GILLON

Summary

We have compared gastric aspirate pH and volume at induction of anaesthesia in 222 patients who had received either omeprazole or ranitidine before elective operations. Omeprazole was given orally either as 40 mg on the evening before and 40 mg on the morning of surgery or as 80 mg on the morning of surgery. Ranitidine 150 mg was given orally on the evening before surgery and 2 h before anaesthesia. Treatment success was defined as aspirate pH $\geqslant 2.5$ and volume < 25 ml at induction of anaesthesia. Treatment was successful in 84% (95% confidence interval (CI) 73–91%) of patients in the omeprazole 40+40 mg group, 84% (95% CI 73–91%) in the ranitidine group and 73% (95% CI 61–83%) in the omeprazole 80 mg group. There were no statistically significant differences between the groups. Twelve patients in the omeprazole 80 mg group had gastric pH < 2.5 and four had volume > 25 ml. Only three patients had a gastric pH < 2.5 in the omeprazole 40+40 mg group and none had volume > 25 ml, which compared well with the ranitidine group. Omeprazole, given as 40 mg in the evening and 40 mg on the morning of operation, has a potential role for use in patients at risk for aspiration during general anaesthesia. (*Br. J. Anaesth.* 1996; **76**: 567–569)

Key words

Antacids, omeprazole. Antacids, ranitidine. Gastrointestinal tract, antacids. Gastrointestinal tract, pH. Gastrointestinal tract, volume.

Acid aspiration, particularly during general or obstetric emergency surgery, is associated with morbidity and mortality [1]. It is generally agreed that patients with gastric contents of pH < 2.5 and volume $\geqslant 25$ ml are at risk of pulmonary damage should aspiration occur. Various pharmacological agents such as H_2 receptor antagonists, antacids and anticholinergics have been used to reduce the risk of aspiration or the risk of pulmonary damage should aspiration occur [2]. Omeprazole is a potent inhibitor of gastric acid secretion, binding irreversibly to the parietal cell proton pump (H^+K^+-ATPase) which is the end-point in the pathway to gastric acid secretion, thus producing long lasting acid inhibition. The use of omeprazole in both its i.v. and oral formulations has been investigated extensively [3].

In this large, multicentre study in patients undergoing elective operations, we have compared the effects of omeprazole in single and divided dose regimens with the H_2 receptor antagonist, ranitidine, on pH and volume of gastric contents.

Methods and results

The study was approved by the Ethics Committees of the five participating hospitals and informed written consent was obtained from all patients.

We studied patients of both sexes, aged 18–70 yr, undergoing elective surgery, in a double-blind, double-dummy, parallel group study. Patients with active oesophageal or peptic ulcer disease, pyloric stenosis and those receiving antisecretory drugs were excluded from the study. Patients were allocated randomly to one of three treatment regimens according to a computer-generated randomized list: omeprazole 80 mg at 06:00 (or 10:00 if surgery was scheduled for after 13:00) on the morning of surgery; omeprazole 40 mg at 20:00 on the evening before surgery and 40 mg at 06:00 (or 10:00 if surgery was scheduled for after 13:00) on the morning of surgery; ranitidine 150 mg at 10:00 on the evening before surgery and ranitidine 150 mg 2 h before anaesthesia. In addition, patients were premedicated in accordance with hospital practice (temazepam, diazepam, lorazepam or morphine). Anaesthesia and tracheal

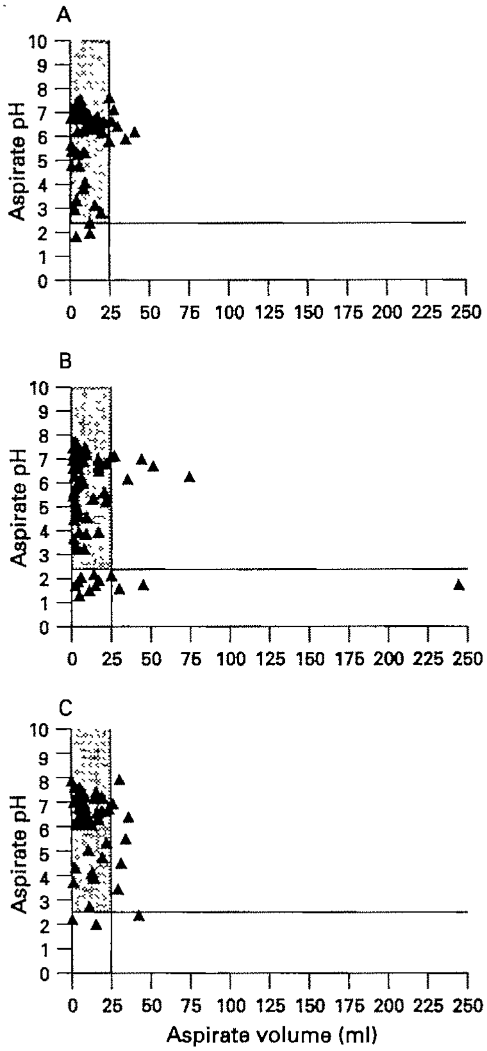

Figure 1 Aspirate pH and volume at induction of anaesthesia. A: Omeprazole 40+40 mg (26 patients with zero volume were not included); B: omeprazole 80 mg (14 patients with zero volume were not included); C: ranitidine 150+150 mg (19 patients with zero volume were not included).

intubation were performed according to normal practice.

Immediately after induction of anaesthesia and insertion of the tracheal tube, a nasogastric tube was inserted into the stomach and its position confirmed by auscultation during insufflation of a small quantity of air down the tube. Gastric contents were aspirated, the time noted and the volume collected was measured. pH was measured in an aliquot of gastric fluid.

The nasogastric tube was removed before recovery from anaesthesia. It was hoped that, by using this method, residual gastric volume would be measured accurately in the majority of patients, although there is a possibility of error in obtaining all of the gastric juice in cases where the volume is small.

Patients were asked if they had been aware of any unusual symptoms in the postoperative period.

Treatment was considered to be successful if the following criteria were achieved: gastric contents of pH $\geqslant 2.5$ and volume < 25 ml at induction of anaesthesia. Results are presented as percentage of patients with a successful treatment, with 95% confidence intervals (CI) in each group.

We recruited 222 patients (74 male). The three treatment groups were well matched for age (mean 43.9 (range 18–70) yr) and weight (67.3 (45.5–110) kg). Randomization was successful, with 74 patients in each omeprazole group and 73 in the ranitidine group. The proportion of females to males was similar in all groups. All patients who received treatment were included in the analysis, except for one case, where surgery was cancelled.

The percentages of patients achieving the success criteria in the treatment groups were 73% (95% CI 61–83%) in the omeprazole 80 mg group, 84% (73–91%) in the omeprazole 40+40 mg group and 84% (73–91%) in the ranitidine group. As the 95% CI for all three groups overlapped, there was no significant difference in success proportions between the treatment groups.

Intragastric pH values relative to intragastric volumes are shown in figure 1. Patients with zero gastric volume were counted as treatment successes in the analysis. Treatment was successful in those patients depicted in the top left quadrants of the graphs, that is with pH $\geqslant 2.5$ and volume < 25 ml. Treatment was successful in the majority of patients in each treatment group. No patient in the omeprazole 40 mg+40 mg group (fig. 1A), four patients in the omeprazole 80 mg group (fig. 1B) and one patient in the ranitidine group (fig. 1C) were considered to be at increased risk from aspiration because of a combination of pH < 2.5 and volume $\geqslant 25$ ml (lower right quadrants of fig. 1).

There were no serious adverse events. Minor adverse events observed or reported by the patients all resolved.

Comment

The majority of patients in each of the treatment groups studied were treated successfully. The percentage success rate was greater in the divided dose omeprazole group and in the ranitidine group compared with the single dose omeprazole group at induction of anaesthesia, but this difference was not statistically significant. These results are similar to those reported from other groups [4, 5]. Although the anaesthetic technique was standardized, there was some variability in anaesthetic agents used between centres and, in particular, premedication, including the use of morphine, which is known to inhibit gastric emptying. However, only three patients received morphine before anaesthesia and all three were treated successfully. It is also possible that patients in the ranitidine group who had operations in the afternoon could have had a failed treatment because of the long interval between the evening and pre-anaesthesia dose. This was not the case as more patients on the morning surgical list had a failed treatment in this group.

This is the first large multicentre study comparing directly omeprazole with ranitidine when given as premedication. Ewart and colleagues reported a single centre study where 70 patients received the same dose regimens of omeprazole and ranitidine as in this study except that the evening dose of omeprazole was given 2 h later at 22:00 [4]. This group also reported high success rates of 100% in the omeprazole group and 94% in the ranitidine group when similar success criteria were applied.

Twelve patients who received a single dose of omeprazole 80 mg had a gastric pH < 2.5 and four also had volume > 25 ml. This suggests that this dose regimen is not sufficiently effective to be recommended for use. Only three patients had pH < 2.5 in the omeprazole divided dose group and none had a volume > 25 ml. These results compare well with the ranitidine group.

There are concerns about what value can be regarded as a safe pH. Crawford [6] has advocated a minimum pH value of at least 3.0, as pH 3.5 has been shown to cause serious pneumonitis. However, calculation of the data from this study using a higher pH value of 3.5 does not substantially affect the results (omeprazole 40 + 40 mg = 80%, omeprazole 80 mg = 71%, ranitidine 150 + 150 mg = 84%).

In conclusion, we have shown that omeprazole 40 mg in the evening and 40 mg on the morning of operation has a potential role for use in patients considered to be at risk of aspiration during general anaesthesia and is well tolerated in this group of patients.

CASE REPORTS

Unilateral convulsion after induction of anaesthesia with propofol

D. COCHRAN, W. PRICE AND C. L. GWINNUTT

Summary

We report a case in which a 42-yr-old man suffered a unilateral convulsion immediately after i.v. injection of propofol, and was discovered subsequently to have an old contralateral cerebral infarct. This complication and the current information on the relationship between propofol and abnormal neurological activity are discussed. (*Br. J. Anaesth.* 1996; **76**: 570–572)

Key words

Anaesthetics i.v., propofol. Complications, spontaneous excitatory movement.

Since its introduction, propofol has been linked with both pro- and anticonvulsant activity. We describe a case in which a convulsion, limited to the left side of the body, occurred immediately after administration of propofol in a patient who was subsequently shown to have an undiagnosed cerebral infarct. We could not find a previous report of this type of abnormal neurological activity after propofol.

Case report

A 42-yr-old man presented for surgical correction of a Dupuytren's contracture of his right hand during general anaesthesia. The preoperative anaesthetic assessment was unremarkable and he declined any premedication. On arrival in the anaesthetic room, monitoring by pulse oximetry and ECG was commenced, and an i.v. cannula was inserted, after which his lungs were preoxygenated via a Bain coaxial system for approximately 2 min. Anaesthesia was induced with propofol 200 mg. As the injection finished the patient developed irregular jerking movements on his left arm and leg which gradually became more violent and similar to the clonic phase of a grand mal convulsion. This lasted approximately 1 min and resolved spontaneously. Ventilation was unaffected, oxygen was administered continuously and peripheral oxygen saturation remained greater than 95 % throughout. As the episode was brief and resolved spontaneously, it was decided to continue, and anaesthesia was maintained with isoflurane and 65 % nitrous oxide in oxygen. An axillary block of the left arm was performed using 0.25 % bupivacaine 40 ml without adrenaline for postoperative pain relief. During operation he received fentanyl 100 µg when a skin graft was taken from his thigh. There were no further episodes of seizure activity during anaesthesia or recovery.

Because of the unilateral nature of the seizure, a CT scan was performed after operation. This revealed a wedge-shaped, low-density area in the right posterior parietal lobe, consistent with an infarct in the vascular watershed between the territories of the middle and posterior cerebral arteries (fig. 1). On direct questioning, the patient revealed that he had suffered from meningitis at 16 yr of age which had left him with a mild bilateral hearing loss and a slight weakness in his left leg, which had recently resulted in him having to give up playing football. A more detailed neurological examination after these results showed some slight muscle wasting in the left lower leg and an up-going plantar on the left. He suffered no further seizures in hospital and was discharged home.

Discussion

Since 1987 there have been a variety of reports linking propofol with the occurrence of abnormal neurological sequelae, ranging from minor involuntary movements to opisthotonos and grand mal convulsions, both in previously healthy patients and those known to suffer from epilepsy. Excitatory events have been reported on induction of anaesthesia with propofol [1], but appear to be more common during recovery [2–7], in two patients after intervals of 21 h and 5 days between administration of propofol and the convulsions [7, 8]. Although most cases describe single convulsions, status epilepticus and repeated attacks of opisthotonos for 23 days have been reported after anaesthesia, of which propofol was a component [4, 9].

A criticism of these reports is that on many occasions combinations of drugs were administered, making the implication of propofol impossible, as many of the commonly used anaesthetic agents have been reported as being capable of causing clinically evident seizure activity [10]. Propofol has been administered uneventfully to a patient on two occasions but associated with a grand mal convulsion when given with alfentanil on a third occasion [11]. However, in the case reported by Shearer of grand mal convulsions lasting for 3 h, propofol was clearly implicated as it was the only agent administered [12].

The abnormal movements reported after propofol have been labelled as seizures, grand mal convulsions

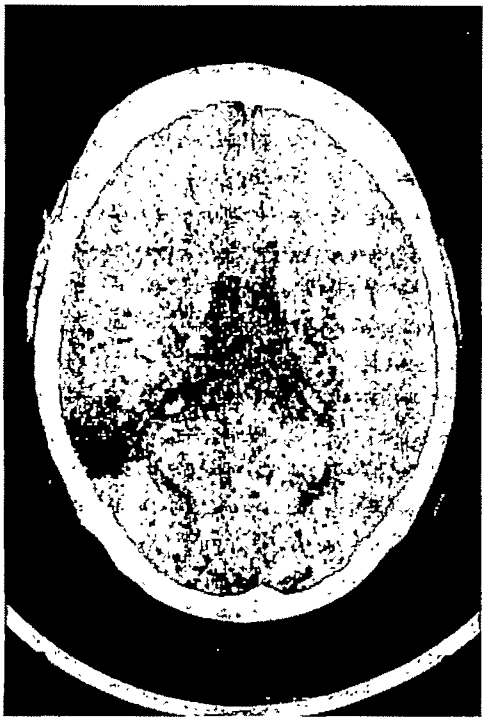

Figure 1 Axial CT scan showing an area of low density in the right posterior parietal lobe.

and status epilepticus, all of which imply an epileptic aetiology. Electroencephalographic (EEG) evidence to support such claims is variable; in cases where the EEG has been monitored during administration of propofol, evidence of epileptiform activity has not been accompanied by motor manifestations [13, 14], while EEG recordings after the events have been reported as normal [5, 12]. By late 1992, the Committee of Safety of Medicines had received 170 reports describing convulsions after the use of propofol with only a small minority of patients (14%) receiving anticonvulsants or with a past history of epilepsy. The convulsions occurred soon after administration of propofol in 69% of all patients and after a delay ranging from 1 h to 6 days in the remainder [15].

Despite the claims that propofol may have proconvulsant activity, there is a significant amount of evidence to the contrary. Propofol infusions have been shown to be effective controlling status epilepticus assessed neurophysiologically when standard treatments have failed [16–19] and are capable of inducing burst suppression in both adults and children during cardiopulmonary bypass [20, 21]. In patients undergoing surgery for intractable epilepsy, EEG recording from chronically implanted electrodes revealed no increase in seizure activity, but profound burst suppression after boluses of propofol [22], and similarly, propofol infusion did not cause increased seizure activity in patients with intractable partial epilepsy [23]. Recently, Borgeat and colleagues have shown that the excitatory movements are not accompanied by EEG changes suggestive of seizure activity [24]. Animal studies in mice [25] and rabbits [26] demonstrated that propofol was effective against both electrical and drug-induced seizures, and when used to induce anaesthesia for electroconvulsive therapy there was a significant shortening of the duration of the seizure, as assessed clinically [27–30].

A true seizure is an alteration in the CNS resulting from an electrical discharge from neurones in either cortical or subcortical tissues, evidence of which is lacking in the majority of patients described as having seizures after propofol. It has been suggested that the explanation for the origin of the seizures and opisthotonos is depression of inhibitory subcortical structures in the CNS resulting in excitatory dystonic movements and opisthotonos, characteristic of midbrain and spinal excitatory activity, respectively [31]. Subcortical centres are thought to be affected by lower concentrations of propofol for longer periods than cortical ones, which are responsible for hypnosis, as demonstrated by the observation that low doses of propofol have a direct antiemetic action [32] and reduce pruritis associated with extradural and intrathecal administration of morphine [33]. This possibly explains the greater incidence of excitatory events during the recovery phase.

A similar mechanism can be invoked in patients known to suffer from epilepsy. If a cortical focus is inhibited normally by subcortical activity, administration of propofol may result in the "release" of epileptic seizure activity in susceptible patients [34]. This is possibly the explanation for the events seen in our patient. Cerebral infarcts are a well recognized cause of seizure activity [35]. If this area was inhibited normally by subcortical activity, the seizure may have occurred as a result of depression of the inhibitory neurones before the full dose of propofol had reached the central circulation. As plasma and brain concentrations of propofol increased, the seizure abated as a result of an anticonvulsant effect. Interestingly, no convulsion was seen subsequently as propofol concentrations decreased, but this may have been masked by the concurrent use of other anaesthetic agents.

It is possible that there are two groups of patients who suffer a period of "seizure" activity after administration of propofol. The majority exhibit the motor manifestations of subcortical inhibition, without abnormal electrical discharge from any group of neurones. In these patients, the terms convulsion, seizure or epileptiform activity should be avoided, as misinterpretation could lead to the patient being labelled "epileptic" with all the attendant social and economic consequences. Perhaps dystonic or myoclonic movement would be a more accurate and less worrying description of the patient. The remainder are a small group of epileptic patients in whom a true seizure may be precipitated by administration of propofol. However, it is well known that these patients are also more susceptible to drug-induced decerebrate rigidity [36] and therefore definitive identification of the cause of such an event in a known epileptic may not be clear-cut.

Therefore, it would seem sensible to avoid the use of propofol in patients who are known to be at risk of developing seizures and in those with epilepsy if their control is poor, where anticonvulsant medication has been omitted or if they are to be discharged early after receiving propofol. However, as the present case demonstrates, the former circumstances are not always clear to either the patient or the anaesthetist, despite preoperative assessment.

Airway management for patients with a tracheal bronchus

S. IKENO, H. MITSUHATA, K. SAITO, Y. HIRABAYASHI, S. AKAZAWA, H. KASUDA AND R. SHIMIZU

Summary

A tracheal bronchus is an aberrant, accessory or ectopic bronchus arising almost invariably from the right lateral wall of the trachea, causing hypoxaemia, atelectasis, or both, during anaesthesia. We describe two patients with a tracheal bronchus found before anaesthesia. One tracheal bronchus was found by tracheobronchoscopy and the other by chest x-ray. Because of recognition of the anomaly before operation, anaesthesia was uneventful in each patient. (*Br. J. Anaesth.* 1996; **76**: 573–575)

Key words

Complications, tracheal bronchus. Intubation tracheal.

Tracheal bronchus is an aberrant or accessory bronchus arising almost invariably from the right lateral wall of the trachea [1]. The incidence is reported to be approximately 0.1–3% [1–3] and is usually asymptomatic [4]. A tracheal tube can obstruct [5–7, 14] or migrate into a tracheal bronchus [7, 8], causing pulmonary atelectasis, hypoxaemia, or both. We report two patients with an ectopic tracheal bronchus that was found before operation by tracheobronchoscopy or chest x-ray.

Case reports

PATIENT NO. 1

A 55-yr-old woman was referred to our hospital for surgical treatment of carcinoma of the right middle lobe. She had undergone appendicectomy and abdominal total hysterectomy under spinal anaesthesia, but had never received general anaesthesia. Routine laboratory tests, arterial blood-gas analysis and ECG were normal. Spirometry suggested minor airway obstruction.

Bronchoscopy was performed and revealed an ectopic tracheal bronchus arising 3 cm above the carina. Chest x-ray was normal except for the tumour capacity. Tracheobronchography confirmed that the ectopic tracheal bronchus arose directly from the trachea and supplied the apical and anterior segment of the right upper lobe. The bronchus arising 4.6 cm below the carina supplied the posterior segment of the right upper lobe (fig. 1).

Lobectomy of the right middle lobe was scheduled under one-lung anesthesia with a left-sided, double-lumen endobronchial tube (BronchoCath 35Fr. Mallinckrodt Medical, St Louis, USA). Because the tracheal cuff of the tube could obstruct the tracheal bronchus when the bronchial cuff was in the left main bronchus, we examined accurately the relationship between the position of the tracheal bronchus and the tracheal cuff. The length from the peripheral edge of the tracheal cuff to the proximal edge of the bronchial cuff was 4.5 cm. The distance from the carina to the orifice of the tracheal bronchus was 3.5 cm. Therefore, when the bronchial cuff was positioned correctly, the orifice of the tracheal bronchus was located 1 cm below the tracheal cuff ensuring the patency of the tracheal bronchus.

Before induction of anaesthesia, an extradural catheter was inserted at T6–T7. After induction with thiopentone and suxamethonium, the tracheobronchus was intubated. The position of the bronchial cuff was confirmed by bronchoscopy. Anaesthesia was maintained with nitrous oxide–oxygen–sevoflurane and continuous extradural block. The operation was uneventful. The tracheobronchus was extubated after atelectasis in all lobes was excluded by chest x-ray. Her postoperative course was uneventful.

PATIENT NO. 2

A 2-yr-old girl was referred for anaesthetic assessment before burr hole irrigation for subdural empyema. She had been suffering from recurrent subdural haemorrhages from the age of 9 months, and had undergone burr hole irrigation on five occasions in another hospital.

Preoperative laboratory tests and ECG were unremarkable. Chest x-ray showed an ectopic tracheal bronchus arising about 1 cm above the carina (fig. 2). This had not been diagnosed previously. Burr hole irrigation was scheduled under general anaesthesia. Because the tracheal bronchus was identified clearly on chest x-ray, bronchoscopy was not performed before induction of anaesthesia with

nitrous oxide–oxygen–sevoflurane. After administration of suxamethonium, a tracheal tube was advanced 14 cm from the right corner of the mouth. After bilateral respiratory sounds were confirmed, tracheobronchoscopy was performed, showing that the ectopic tracheal bronchus was not obstructed. Respiratory sounds were monitored throughout and surgery was uneventfully. After chest x-ray excluded atelectasis in all lobes, the trachea was extubated. Her postoperative course was uneventful.

Discussion

In patient No. 1, we were able to perform one-lung anaesthesia safely, because we had confirmed before operation that the orifice of the tracheal bronchus was not obstructed by the double-lumen tube. In patient No. 2, the orifice of the tracheal bronchus was not obstructed with the tracheal tube, because the orifice was located near the carina.

Tracheal bronchi are associated occasionally with other congenital anomalies, including cyanotic heart disease [1], but our patients had no other anomalies. Bronchial anomalies may be reported as an incidental finding on bronchoscopy, as in patient No. 1 [1].

There are two types of tracheal bronchi: supernumerary and displaced [9]. The former, which is comparatively rare, is an accessory bronchus. A displaced bronchus arises from an abnormal position and supplies one or more segments of the upper lobe, most commonly the apical segment [4]. Although tracheal bronchi are usually reported to be asymptomatic, they may cause stridor in children. They may also be related to inflammatory conditions affecting the lung on that side, including recurrent pneumonia [4, 10], non-obstructive bronchiectasis [4, 11] and postobstructive pneumonia distal to an adenoma arising in the tracheal bronchus [4, 12]. A tracheal bronchus has been reported as high as 6 cm above the carina [4, 13]. In such patients, a tracheal tube could obstruct an ectopic tracheal bronchus [5–7, 14] or an ectopic tracheal bronchus could be intubated [7, 8], causing atelectasis, hypoxaemia, or both. Recognition of a tracheal bronchus before anaesthesia can guide airway management. In three patients reported previously, however, tracheal bronchi were found during general anaesthesia [6, 7, 14, 15], and some were identified on chest x-ray retrospectively [6]. In patient No. 2, we diagnosed a tracheal bronchus before anaesthesia on chest x-ray alone, because we were alert to the possibility.

One-lung anaesthesia in these patients may be difficult [5, 15]. In patient No. 1, we were able to perform one-lung anaesthesia safely because we had confirmed the relationship between the tracheal

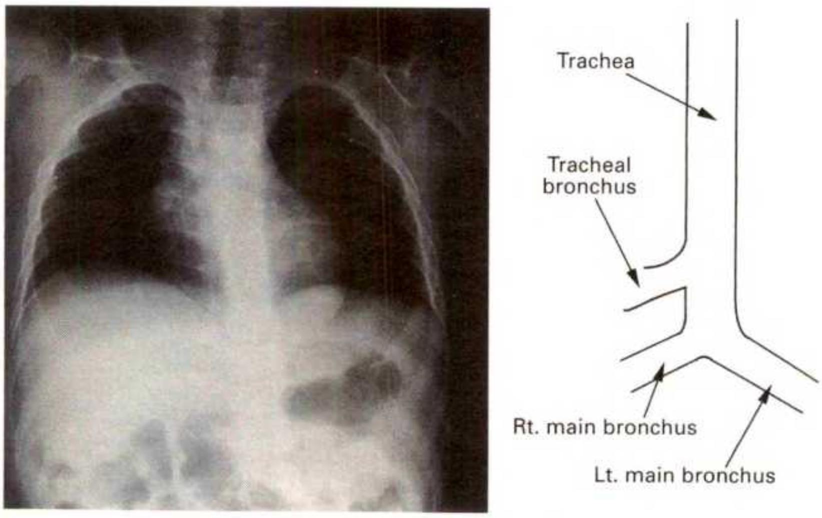

Figure 2 Chest x-ray (patient No. 2) showing an ectopic tracheal bronchus arising approximately 1 cm above the carina.

bronchus and the bronchial cuff. Bronchial blockers may be useful in some situations. In particular, for left lung surgery, a blocker in the left main bronchus enables the right lung to be ventilated effectively with a short tracheal tube.

In conclusion, chest x-ray should be observed carefully to exclude ectopic tracheal bronchus. Tracheal bronchi should be included in the differential diagnoses of airway problems, including hypoxaemia, atelectasis, or both, during anaesthesia.

Observations on patient-controlled administration of propofol

S. J. Thorpe*, V. R. Balakrishnan* and L. B. Cook
Department of Anaesthesia, Royal Oldham Hospital

We have investigated the safety of a previously described method of patient-administered propofol [1]. This used 0.33-ml boluses of propofol 10 mg ml^{-1} infused over 6 s with no lockout. We studied 100 healthy patients (32 women, 68 men) aged 18–45 yr presenting for elective surgery.

Observations were made each min during the study. These included oxygen saturation, heart rate and an anaesthetist's assessment of the airway patency. An independent observer scored the patient's sedation using the scale in table 1 [1]. After baseline observations, patients attempted to put themselves to sleep by pressing a button on the hand-held device. The patient was deemed to have stopped pressing the button when no demands for propofol had been made for 30 s. After a set of observations had been noted, the anaesthetist took over the handset and continued to press the button until a sedation score of 6 was reached, when the study ended.

Sedation was established quickly. Only five patients were still anxious after 2 min. After 3 min no patient was still anxious and more than 70 patients had slurred speech. Men pressed the button for 312 (SD 95) s and women pressed for 247 (SD 70) s. The proportion of the total sleep dose self-administered and the dose self-administered adjusted for weight were similar in both sexes.

When they stopped pressing the button, the majority of patients were not over-sedated (table 1). However, two patients were unresponsive and nine others were over-sedated. During self-sedation there was a minor decrease in mean saturation from 97.8% to 96% ($P < 0.0001$, ANOVA). One patient desaturated to 84% transiently: no other patient's saturation fell below 90%. There were no other significant changes.

We concluded that the system studied worked well but carried too high a risk of over-sedation for unsupervised use.

Key words
Sedation, patient-controlled. Complications, overdose.

Airway pressure signals during high frequency jet ventilation

E. S. Lin
Department of Anaesthesia, Glenfield Hospital Trust, Leicester

Monitoring central airway pressure (*Paw*) during high frequency jet ventilation (HFJV) is essential because of the risk of barotrauma [1]. *Paw* is monitored in practice in the central airway. However, the point at which *Paw* is sampled requires consideration because the morphology of the *Paw* waveform and its peak, mean and trough values vary with position relative to the jet [2]. Monitoring *Paw* proximal to the jet does not yield values which reflect distal airway pressures. *Paw* signals sampled 5–10 cm in front of the jet are readily accessible and lie within the tracheal or tracheostomy tube. However this region is influenced by the hydrodynamics of the injected gas. *Paw* signals recorded here have a complex waveform (fig. 1D) and their interpretation is uncertain.

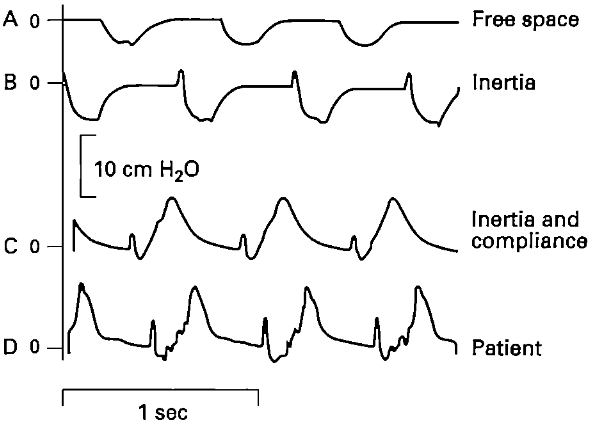

Figure 1 P5 signals during high frequency jet ventilation.

An investigation of the nearfield *Paw* signal, sampled at 5 cm (P5 signal) has been performed using a Penlon-Bromsgrove jet ventilator to inject into different load configurations. Pressure signals have been recorded with a calibrated piezoresistive transducer (Motorola MPX10DP) and signal conditioning amplifier (Analog Devices 1B131AN), using a digital storage oscilloscope (Gould 1604). Figure 1 shows P5 signals obtained during high frequency jet ventilation at 1.67 Hz (100 min^{-1}) applied to (A) free space (B) an inertia (C) an inertia and compliance in series. These results suggest that P5 signal morphology was not only related to the injected gas flow but also to the compliance and inertia of the injected load. Use of the P5 signal for monitoring airway pressure during HFJV is practical and non-invasive, and may also reflect changes in compliance and inertia of the respiratory system.

Patient-controlled propofol: randomized, double-blind dose refinement

A. F. Smith*, S. J. Thorpe* and L. B. Cook
Department of Anaesthesia, Royal Oldham Hospital

Over-sedation is a danger of patient-controlled sedation [1]. We have reduced the rate of drug administration by diluting propofol to half or three quarter strength. The dose was 0.33 ml with no lockout and an infusion rate of 3.3 ml min^{-1}. These dilutions result in maximum infusion rates of 16 and 25 mg min^{-1}.

We have studied 25 healthy patients aged between 18 and 45 yr, scheduled to undergo elective operations lasting less than 30 min. Patients were allocated randomly to receive 0.5 or 0.75 % propofol in a double-blind manner. Routine non-invasive monitoring was attached, and patients were asked to try to put themselves to sleep by pressing the handset. We recorded sedation score, airway quality, heart rate and arterial oxygen saturation at 1-min intervals.

Patients were asked to say when they first noticed any sedative effect. The time of onset of slurred speech was noted. In addition, patients were shown three objects—before starting, at 2.5 and at 4.5 min. When the patient became sedated enough so as not to press the button for 30 s, we took over the handset and continued giving propofol using the pump until the patient was unresponsive. Postoperatively, recall of the objects shown was tested. The data were analysed using the unpaired two tailed *t*-test or chi-square test as appropriate. Table 2 shows the results.

Table 2 Mean (SD) values for sedation times and amnesia for the two groups

	0.5 % Propofol group ($n = 9$)	0.75 % Propofol group ($n = 16$)	*P* value
Notices effect (min)	2.8 (2.1)	1.7 (0.8)	NS
Slurred speech (min)	5.7 (1.9)	3.9 (1.3)	< 0.05
Time to sedation (min)	6.7 (1.8)	4.5 (1.4)	< 0.01
Amnesia at 2.5 min	0 %	17 %	NS
Amnesia at 4.5 min	0 %	43 %	< 0.05
Over-sedated	0	0	—

We concluded that propofol at 16 mg min^{-1} takes too long to produce amnesia and sedation to be useful in clinical practice. A maximum infusion rate of 25 mg min^{-1} may represent an acceptable compromise between speed of onset and risk of over-sedation.

Key words
Sedation, patient-controlled. Anaesthetics i.v., propofol. Complications, overdose.

Auditory evoked responses, median frequency and 95 % spectral edge during anaesthesia with desflurane and nitrous oxide

S. K. Pal*, R. Sharpe*, D. Nathwani* and D. E. F. Newton
Academic Department of Anaesthesia, St Mary's Hospital Medical School, Northwick Park Hospital, Harrow

Desflurane has rapid onset and emergence from anaesthesia. In paralysed patients a reliable means of monitoring light anaesthesia is, therefore, more important than with other volatile agents. We compared auditory evoked responses (AER) with EEG power spectral analysis in 12 patients. The study was approved by the Harrow Research Ethics Committee. Premedication was with morphine 10 mg and atropine 0.4 mg and anaesthesia was induced by inhalation of desflurane in 67 % nitrous oxide in oxygen. Tracheal intubation was followed by vecuronium 0.1 mg kg^{-1} given by infusion to produce two train-of-four responses. In four 10-min periods, the patients received 1.5, 3 or 6 % desflurane in random order. In the fourth period the previous concentration was repeated, ensuring that every dose followed every other dose including itself equally often. This eliminates carryover effects while retaining the advantage of a within-patient study.

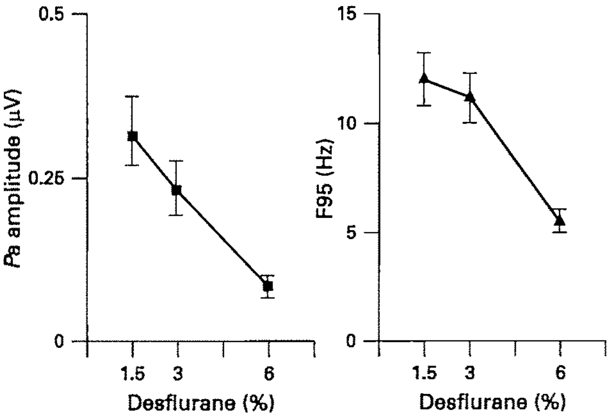

Figure 2 *Pa* amplitude of the AER and the F95 (95 % confidence limits of between-patient data).

A calibrated Datex Ultima measured end-expiratory gas concentrations, and the $P\mathrm{E}'_{CO_2}$ was maintained at 4.5–5 kPa. The AER, median frequency (F50) and 95 % spectral edge (F95) of the EEG were recorded for the last 2.5 min of each period, using specially designed equipment [1].

ANOVA was performed on the log of *Pa* and Nb amplitudes and latencies and on the F50 and F95 of the within-patient data. There was a highly significant effect of dose for all variables (fig. 2) (*Pa* and Nb amplitude $P < 0.001$; *Pa* and Nb latencies $P \leqslant 0.002$; F59 and F95 $P < 0.001$). Burst suppression was not observed.

Rampil [2] investigated desflurane in nitrous oxide at a higher range of doses (6 %–15 %), and although at 6 % his values for F50 and F95 (4.2 Hz and 17.1 Hz) were greater, this can be accounted for by premedication. At low concentrations the AER showed a greater linearity with dose than the EEG variables, and may be better at monitoring light anaesthesia in the paralysed patient.

Evaluation of bispectral index as an objective sedation score in the intensive care unit

A. J. Pearson, C. J. D. Pomfrett, B. R. H. Doran and B. J. Pollard
University Department of Anaesthesia, Manchester Royal Infirmary

Bispectral analysis is an advanced EEG signal processing technique which tracks both linear and non-linear changes in signals to enable subtle changes in electrical brain activity to be quantified. The bispectral index (bsi) is a numerical display of the overall bispectral properties (power, frequency and phase) generated by a sophisticated algorithm. Previous work has shown a correlation between bispectral analysis and patient movement at skin incision during anaesthesia [1, 2], but as yet little work has been published to show the reliability of bispectral analysis for objectively measuring depth of sedation in the intensive care unit (ICU).

Five intensive care patients, aged 30–77 yr, were studied. All patients were receiving sedation to ensure compliance with mechanical ventilation. A modified Ramsey score was used by the ICU nursing staff to assess the level of sedation for each patient before EEG recording. The bsi was recorded (using the Aspect A1000) at 15-min intervals on each patient for a 1-h period, two or three times a day. During EEG recording normal ICU routine was allowed to continue in order to have a true reflection of the effects on the indices. The data were examined for any correlation between sedation scores and bsi.

The overall range of the bsi was 17–96. The mean bsi for patients with a sedation score of 4 was 66.8, for a score of 5 was 63.5 and for a score of 6 was 34.6. Using the Wilcoxon signed rank test there was no significant difference in bsi in patients with a sedation score of 4 and 5 ($P = 0.12$) but there was a significant difference between the patients with scores of 4 and 5 and those with a score of 6 ($P = 0.02$ and $P = 0.02$).

Increases in bsi were observed when patients were disturbed either for nursing intervention or physiotherapy, but in all cases no alteration in the patients sedation score was evident.

Evoked EMG response during inhalation of a sub-anaesthetic concentration of isoflurane

S. L. Polhill* and D. C. Smith
Department of Anaesthesia, Southampton General Hospital, Southampton

Failure to maintain the pre-block control response is the major limit to the usefulness of the evoked EMG for monitoring neuromuscular transmission during anaesthesia. The EMG response does not decrease in awake volunteers [1]. Sub-anaesthetic concentrations of isoflurane have been given to volunteers [2] and used for long-term sedation in the intensive therapy unit [3], but the effect on neuromuscular transmission has not been studied.

We studied 15 volunteers who were free of neuromuscular disease and who were not taking drugs known to modify neuromuscular transmission. Neuromuscular transmission was measured with a Relaxograph and Medicotest Blue Sensor P-00-S electrodes. Supramaximal stimulation of the ulnar nerve at the wrist produced a response recorded over the belly of the first dorsal interosseous muscle, with the indifferent electrode on the proximal phalanx of the first finger. The ground electrode was placed over the median nerve at the distal wrist crease. The arm was abducted to 45°, supinated and placed on an armboard with 30° flexion at the elbow. The fingers were strapped flat onto the board with adhesive tape. The subjects were asked to relax completely before the study started. The Relaxograph was calibrated to the 100 % transmission reference with the volunteers breathing room air, and the EMG response was recorded every 20 s for 25 min. After 2 min with a stable T1 response, the volunteers started to breathe 0.2 % isoflurane in oxygen, from a calibrated vaporizer, via a Mapleson A breathing system with a fresh gas flow of 8 litre min^{-1}. After 25 min the study was stopped and the Relaxograph was recalibrated.

Verbal contact was maintained with the volunteers at all times; although most felt light-headed, none lost consciousness. The T1 response of the EMG remained at 100 (5)% in 10 of the 15 subjects. Of the other five subjects, in three cases the T1 response decreased below 95 % of the control response, while in two cases the response increased to greater than 105 % of control. However, in no subject did the T1 response deviate more than ±10 % from the control value. The supramaximal stimulus current at recalibration was identical to that at initial calibration in all subjects.

The changes in the control response of the evoked EMG in this study were not clinically significant, and were similar to those seen in awake volunteers [1].

Magnetic resonance imaging of the superior vena cava during spontaneous respiration with continuous positive airway pressure via a facemask in normal subjects

A. H. Mayor*, P. Hughes*, I. Ryder* and J. R. Sneyd
Departments of Anaesthesia and Imaging, Derriford Hospital, Plymouth

Although there are beneficial effects of continuous positive airway pressure (CPAP) in respiratory failure and upper airway obstruction, the increase in intrathoracic pressure may reduce cardiac output, by increasing resistance to venous return and/or impairing ventricular function. Previous studies with magnetic resonance imaging (MRI) have looked at the effect of positive end expiratory pressure (PEEP) on atrial and ventricular cardiac volumes in ventilated subjects [1]. The purpose of the present study was to determine the effect of facemask CPAP on superior vena cava (SVC) cross-sectional area and left and right ventricular size and shape, in an attempt to clarify the mechanism of decreased cardiac output.

Five healthy male volunteers were studied breathing spontaneously for four 30-min periods with 0, 7.5, 15 and 0 cm H_2O CPAP via a tight fitting facemask. MRI imaging consisted of cardiac gated T2-weighted axial images of the SVC and short axis images of the ventricles. Short axis imaging planes were prescribed separately for each different CPAP level to avoid errors as a result of cardiac rotation and lifting. Measurements on SVC and left and right ventricular cross-sectional area were obtained by manually tracing the regions of interest on sequential scans using a pre-program data package averaging two independent estimations at each level. Heart rate and non-invasive blood measurements were made during each study. So far SVC diameter data have undergone analysis. Statistical analysis was by ANOVA.

SVC cross-section was significantly reduced throughout the cardiac cycle by 15, but not by 7.5 cm H_2O CPAP, $P < 0.005$ ANOVA (fig. 3).

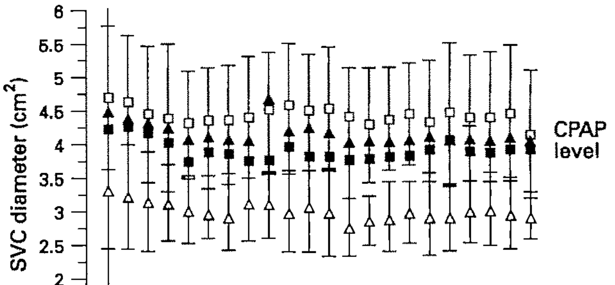

Figure 3 The effect of continuous positive airway pressure (CPAP) on superior vena cava (SVC) diameter during spontaneous respiration, $n = 5$, data are means (SD). Some error bars have been omitted for clarity. (□) 0 cm H_2O, (■) 7.5 cm H_2O, (△) 15 cm H_2O, (▲) 0′ cm H_2O.

Post-tetanic constant stimulus train patterns during neuromuscular block with atracurium and vecuronium

A. Bryan, B. J. Pollard, M. A. Keegan* and I. T. Campbell
University Department Anaesthesia, Manchester Royal Infirmary, Manchester

The response to varying frequency (de-crescendo) trains of stimuli given 1 s after tetanic stimulation of 50 Hz for 5 s has been previously reported [1]. This study examined the response to constant frequency post-tetanic trains of stimuli.

The electromyographic data acquisition system was custom built using a 386 PC, an analogue to digital converter, isolated pre-amplifier and programmable stimulator [2]. The stimulator was programmed to deliver trains of constant current, supramaximal stimulus pulses of width 0.2 ms according to a predefined suite of patterns. The pulse train patterns each consisted of a single twitch, a 15-s delay, a tetanic stimulus of 50 Hz for 5 s, a 1-s delay and a constant frequency train. The constant frequency trains were CT1 (2 Hz), CT2 (4 Hz), CT3 (6 Hz), CT4 (8 Hz) and CT5 (10 Hz). The electromyographic response of the adductor pollicis to ulnar stimulation was recorded using surface electrodes to monitor neuromuscular block and the data were stored for off-line analysis.

Anaesthesia was induced using thiopentone and maintained using nitrous oxide–oxygen–enflurane with fentanyl as required. The data acquisition system was calibrated and either atracurium 0.4 mg kg^{-1} ($n = 5$) or vecuronium 0.07 mg kg^{-1} ($n = 5$) was given. The trachea was intubated and ventilation controlled. End-tidal CO_2 was maintained at 35–40 mm Hg. Trains of stimuli were administered at 5-min intervals and neuromuscular block maintained using increments of the same agent as for intubation. At the end of the procedure residual block was antagonized using neostigmine and glycopyrronium.

The ratio of the evoked compound action potential peak-to-peak response of the single twitch (To) and of each response (Tn) of the constant series for train CT1 is shown in figure 4.

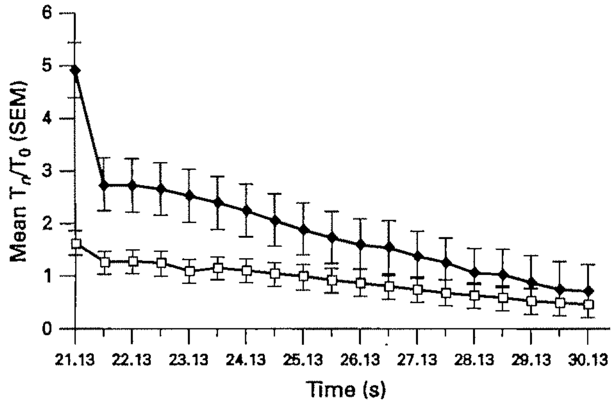

Figure 4 Mean response to train CT1.

There was a significant difference in the area under the curve for the atracurium group compared with the vecuronium group for train CT1 ($P < 0.05$, two sample t-test) and for the mean value of the observations for trains CT2 and CT5. This pattern of response is similar to the standard post-tetanic count response to 1.0-Hz stimulation with the inherent effect of fade from atracurium and vecuronium and differs from that seen with varying frequency pulse trains.

Key words
Measurement techniques, electromyography. Neuromuscular block, vecuronium. Neuromuscular block, atracurium.

Effect of stimulation rate on force of contraction in partially paralysed rat phrenic nerve hemidiaphragm preparations

K. Richards*, A. J. England and A. Feldman
The Magill Department of Anaesthesia, Chelsea and Westminster Hospital, London and The John Hammond Department of Anaesthesia, East Surrey Hospital, Redhill

Bowman [1] has postulated that presynaptic receptors augment acetylcholine release at the neuromuscular junction during high rates of stimulation. We have attempted to quantify the effect of drug activity on the putative pre- and post-synaptic receptors by using fast and slow rates of indirect stimulation.

Wistar rat phrenic nerve hemidiaphragm preparations were suspended in Kreb's solution maintained at 37 °C. They were pretensioned to 8 *g* and, after stabilization, indirect supramaximal square wave stimuli were applied. A series of experiments was performed using α-bungarotoxin, an agent believed to bind preferentially to the post-synaptic receptor [2], hexamethonium, an agent suspected of having marked presynaptic receptor activity [1, 3], vecuronium and rocuronium. A dose of drug previously demonstrated to give about 10% twitch height depression (THD) during 0.1-Hz rates of stimulation was added to the tissue bath and the THD allowed to stabilize. Without washing out the neuromuscular blocking agent the preparation was then stimulated at rates of 0.2 Hz, 0.5 Hz, 1 Hz and 2 Hz and the response recorded. The mean percentage THD after 200 twitches was calculated for each agent and at each rate of stimulation. The relationship between percentage THD and rate of stimulation (and the standard deviation of the residuals from the line) for each agent was calculated by linear regression and comparison between the groups at each rate of stimulation was by analysis of variance.

Twenty-two rats were used during this series of experiments giving 35 data points for α-bungarotoxin, 52 for hexamethonium, 52 for vecuronium and 38 for rocuronium. The results are displayed in figure 5.

The slopes of the regression lines were −6.9% Hz^{-1} (8.0) for α-bungarotoxin, 28.4% Hz^{-1} (15.9) for hexamethonium, 15.5% Hz^{-1} (9.1) for vecuronium and 31.9% Hz^{-1} (13.0) for rocuronium.

There was no significant difference between any groups at 0.2-Hz stimulation rates ($P > 0.05$ for all comparisons).

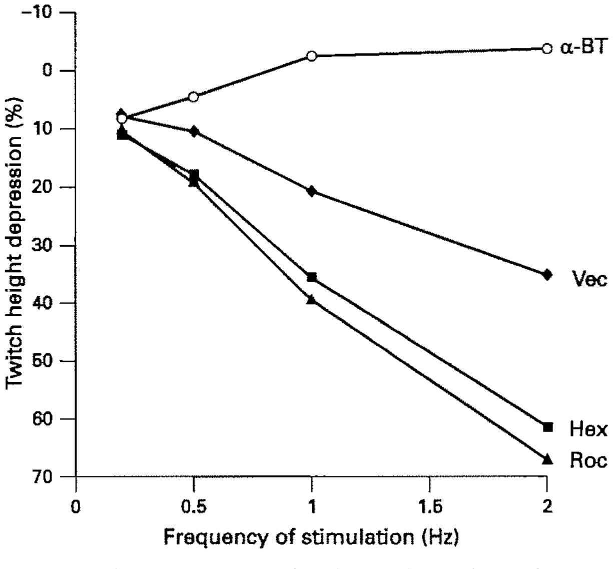

Figure 5 Mean percentage twitch height depression and frequency of stimulation for four neuromuscular blocking agents.

There was no significant difference between hexamethonium and rocuronium at any frequency of stimulation ($P > 0.05$ for all comparisons).

At 0.5 Hz hexamethonium and rocuronium produced more THD than α-bungarotoxin ($P < 0.001$ and $P < 0.001$); and rocuronium produced more THD than vecuronium ($P < 0.05$).

At 1 Hz hexamethonium and rocuronium produced more THD than α-bungarotoxin ($P < 0.001$ and $P < 0.001$) and vecuronium ($P < 0.05$ and $P < 0.05$). Vecuronium produced more THD than α-bungarotoxin ($P < 0.01$).

At 2 Hz hexamethonium and rocuronium produced more THD than α-bungarotoxin ($P < 0.001$ and $P < 0.001$) and vecuronium ($P < 0.01$ and $P < 0.01$). Vecuronium produced more THD than α-bungarotoxin ($P < 0.01$).

The mechanisms underlying α-bungarotoxin and hexamethonium neuromuscular block can be readily differentiated using a small dose of drug by the degree of THD after 200 twitches at frequencies of 1 or 2 Hz. Rocuronium had a similar response to hexamethonium suggesting a presynaptic site of action, but vecuronium lies between hexamethonium and α-bungarotoxin, suggesting a mixed pre- and post-synaptic effect.

Onset time of neuromuscular block is determined by the pharmacokinetics of the blocking drug

A. M. Beaufort*, V. Nigrovic, J. H. Proost*
and J. M. K. H. Wierda

Research Group for Experimental Anesthesiology and Clinical Pharmacology, University of Groningen, Groningen, the Netherlands, Department of Anesthesiology, Medical College of Ohio, Toledo, USA, and Department of Pharmacokinetics and Drug Delivery, University Centre for Pharmacy, Groningen, the Netherlands

Previous reports document that a neuromuscular blocking agent of low potency has a short onset time of submaximal neuromuscular block [1, 2]. The ED_{50}, the i.v. bolus dose of a neuromuscular blocking drug that produces a half-maximal neuromuscular block, is determined by the drug's EC_{50}, the concentration at the site of action that produces a half-maximal neuromuscular block and by its pharmacokinetics. The question we asked was whether the onset time is determined by the agent's EC_{50} or by its pharmacokinetics.

Assuming that inhibition of the enzymic degradation of a neuromuscular blocking agent in plasma does not alter the drug's EC_{50} but only decreases the rate of disappearance of the agent from plasma, its potency—reflected in a lower equi-effective dose—will be increased. It follows that, after inhibition of the enzymic degradation, the onset time will be unaltered were it dependent on EC_{50} and prolonged were it dependent on pharmacokinetics.

Twenty-one pigs were anaesthetized and prepared for measuring the indirectly elicited contractions of the tibialis anterior muscle (supramaximal, single twitch, 0.1 Hz). In 20 pigs the ED_{70} and the onset time (time to peak submaximal neuromuscular block) were determined for either suxamethonium ($n = 10$) or mivacurium ($n = 10$). Thereafter, in 10 of the pigs an inhibitor of plasma cholinesterase (TIPPA) 2.6 mg kg^{-1} was injected i.v. and the ED_{70} and onset time were reassessed. In each pig, inhibition of plasma cholinesterase was documented by measuring its activity in plasma. To assess any influence of the inhibitor on junctional acetylcholinesterase, a continuous infusion of vecuronium maintained, in a separate pig, a 50% neuromuscular block during which the inhibitor was administered.

The inhibitor reduced the activity of plasma cholinesterase by 92.7 (SD 4.1)% (suxamethonium) and by 89.9 (2.2)% (mivacurium). Inhibition of plasma cholinesterase reduced the ED_{70} of suxamethonium from 900 (400–1000) (median (range)) to 150 (135–150) μg kg^{-1} and prolonged the onset time from 40 (20–45) to 131 (114–166) s. Similarly, inhibition of plasma cholinesterase reduced the ED_{70} of mivacurium from 100 (80–150) to 35 (20–50 μg kg^{-1} and prolonged the onset time from 52 (40–59) to 105 (90–125) s. Inhibition of plasma cholinesterase did not alter the vecuronium-induced 50% neuromuscular block, whereas neostigmine decreased the block.

Inhibition of the enzymic degradation of suxamethonium and mivacurium in plasma prolonged the onset time of submaximal neuromuscular block. Since inhibition of the enzymic degradation has no influence on a vecuronium-induced 50% neuromuscular block, we concluded that the onset time of submaximal neuromuscular block is determined by the pharmacokinetics of the blocking agent.

Modelling the interaction of two neuromuscular blocking agents: generation of an additive or a supra-additive neuromuscular block

V. Nigrovic, H. Mellinghoff* and W. Buzello
Anaesthesiology Clinic, University of Cologne, Germany

It has been repeatedly shown that two non-depolarizing neuromuscular blocking agents administered in equi-effective doses produce either a neuromuscular block of a size expected from the sum of the doses (additive effect) or a larger neuromuscular block (supra-additive effect). Generation of an additive or a supra-additive neuromuscular block by two neuromuscular blocking agents has not been modelled previously.

The nicotinic receptor at the end plate has two binding sites for acetylcholine or the neuromuscular blocking agents. Some neuromuscular blocking agents bind preferably to the one site while others bind to the other. For a given site, the ratio of the rate constant for dissociation, k_{dissoc}, to the rate constant for binding, k_{assoc}, defines the equilibrium dissociation constant, K_D, of that neuromuscular blocking agent for that site. A low value for K_D defines a high affinity (strong binding). We postulated that if the first neuromuscular blocking agent forms a strong complex with the first site, a weak one with the second, and a third by binding to both sites, then the second neuromuscular blocking agent might form either similar complexes or a weak complex with the first site, a strong one with the second site, and a third by binding to both sites. We labelled the latter pattern the inverse pattern of affinities. When two neuromuscular blocking agents are present together, eight types of complexes are formed. If the neuromuscular blocking agents display an inverse pattern of affinities then the two additional complexes contain the neuromuscular blocking agents bound either both strongly or both weakly. We equated the concentrations of the neuromuscular blocking agents in the synaptic clefts with their concentrations in the interstitial space of muscle and assumed that only the free neuromuscular blocking agent is available for back-diffusion into the plasma and for binding to the receptors. The rate of change of the concentration for each of the eight complexes was expressed as a difference between the corresponding rates of formation and dissociation. The concentration of the free receptors was defined as the difference between the total receptor concentration ($[R]_{tot} = 4.10^{-9}$ mol $litre^{-1}$, two binding sites per receptor) and the sum of the concentrations of all the complexes. For all neuromuscular blocking agents k_{assoc} was assigned an identical value (4×10^8 min^{-1} mol $litre^{-1}$). We considered two conditions: (i) the neuromuscular blocking agents bind with high affinity to the same receptor site, or (ii) neuromuscular blocking agents show an inverse pattern of affinities, i.e. one neuromuscular blocking agent binds strongly to the first and the other to the second site.

The simulations demonstrated that when the two neuromuscular blocking agents bind to the same site with high affinity, the resulting neuromuscular block is additive. When the neuromuscular blocking agents were assigned an inverse pattern of affinities, the neuromuscular block was enhanced, i.e. supra-additive. The supra-additive neuromuscular block was less pronounced for two neuromuscular blocking agents with vastly different pharmacokinetic properties and could be simulated with neuromuscular blocking agents administered simultaneously or in sequence (the second neuromuscular blocking agent after a partial recovery of the neuromuscular block produced by the first neuromuscular blocking agent). The supra-additive effect was larger proportional to the ratio of affinities of the neuromuscular blocking agents for the two sites.

The proposed model simulated the clinical results. We propose that neuromuscular blocking agents belonging to different chemical groups (isoquinoline or aminosteroid) displayed an inverse pattern of affinities for the two binding sites and, when present together, produced a supra-additive neuromuscular block with a preponderance of the strong complexes (both neuromuscular blocking agents bound to their sites of high affinity).

Infertility among female hospital doctors in the UK

N. J. MARAN*, R. P. KNILL-JONES AND A. A. SPENCE*
University Department of Anaesthetics, Royal Infirmary, Edinburgh and Department of Public Health, University of Glasgow

An increased incidence of involuntary infertility has been noted in studies of female anaesthetists [1, 2]. A more recent study has shown decreased fertility in female dental surgical assistants exposed to nitrous oxide [3].

A prospective postal survey of the health of all female doctors in the UK was carried out between 1977 and 1985. Annual mailings requested details of occupation, work practice, lifestyle, medical and obstetric history as well as some personal details. The principal method of contraception used in each quarter was recorded and any woman recording 8 or more consecutive quarters of no contraception was regarded as having 2 yr or more of infertility. Further details were requested from this group in a follow-up questionnaire.

Infertility was classified as primary or secondary and where infertility was confirmed (including those who had been investigated and no problem found), infertility was termed "pure". A further restricted analysis for the years after 1979 was carried out as more details were made available by a second questionnaire.

Each variable was analysed independently (chi-square) and thereafter all significant variables and all occupational variables were analysed using logistic regression to eliminate the effect of confounding variables.

A total of 913 women recorded 2 yr or more of apparent infertility. Thirty-two stated that their infertility was "not a problem" and were therefore excluded from analysis. In 138 cases, there was doubt as to the accuracy of coding, this group being significantly younger than other women who reported infertility ($P < 0.0001$). Data were analysed both with and without this group. The overall incidence of 2-yr infertility among the female doctors was 6.7–8.3%.

After logistic regression, the only significant variable to affect all groups was increasing maternal age and ethnicity (non-white women reporting more infertility). In the pre-1979 analysis, the only significant occupational variables were that those who worked a rota less arduous than a 1 in 6 reported more infertility. In infertility reported after 1979, however, there appeared to be a small increase in reporting with increasing number of sessions worked each week.

We found no evidence that female anaesthetists have any increased risk of infertility.

Patient attitudes to perioperative suppository administration for postoperative analgesia

M. CARROLL*, F. DAY*, A. HENNESSY* AND C. COONEY*
Department of Anaesthesia, Neath Hospital, Dublin

Diclofenac is effective for postoperative analgesia when administered orally, rectally or by i.m. injection. I.m. injection may be painful [1], yet recent controversy surrounding the use of suppositories has led to concern regarding its rectal administration without informed consent [2].

Four hundred surgical patients were asked to express their preference for i.m. or rectal diclofenac for postoperative pain relief; 82% of patients chose an i.m. injection (85.6% males, 77.5% females, $P < 0.05$). The mean age of men who chose an i.m. injection was 45.2 yr, compared with 49.5 yr for those who chose a suppository. This was not statistically significant. The mean age of females choosing an i.m. injection was 47.8 yr compared with 51.5 yr for those choosing a suppository ($P = 0.13$). Males choosing a suppository were more likely to belong to a higher socioeconomic group ($P < 0.005$). No such difference in socioeconomic profile was observed for females. Females choosing a suppository were more likely to be married and have children ($P < 0.01$). When the possibility of discomfort at the injection site was explained, 22.6% of patients chose a suppository instead (24.7% males, 19.6% females, $P > 0.05$). Females who changed their mind were more likely to belong to a higher socioeconomic group and to be married ($P < 0.05$): 27% of patients choosing an i.m. injection expressed concern that a suppository might be inserted without consent; 11% of patients who chose a suppository expressed similar concern.

A novel fibreoptic pressure transducer system for the upper airway

C. SECKER*, C. D. HANNING, P. GOODYER*, J. FOTHERGILL* AND N. B. JONES*
Departments of Anaesthesia and Engineering, University of Leicester

A novel fibreoptic pressure transducer system (FPTS) has been developed for investigation of the upper airway after anaesthesia and during sleep.

The FPTS comprises a flexible catheter, od 3 mm, containing seven fibreoptic pressure transducers [1]. One is placed at the tip and the others spaced at 20-mm intervals 200–300 mm from the tip. The catheter is covered with a flexible latex membrane which is sealed between transducers to form a "balloon" at each measurement site. The FPTS was calibrated before use by placing it in an airtight chamber and subjecting it to pressures of ±10 cm H_2O measured with an aneroid gauge. Analogue signals from the FPTS were collected using an IMS2000 Cardio Respiratory Sleep System with CARDAS software on a notebook computer (Acer 486) and subsequently exported as ASCII files to a spreadsheet

(Microsoft Excel). The FPTS was passed nasally in eight anaesthetized patients undergoing peripheral surgery and guided into the oesophagus. It was placed so that the distal transducer was mid-oesophagus and the remainder arrayed from posterior nasopharynx to hypopharynx with the second transducer immediately posterior to the soft palate. Position was confirmed by laryngoscopy. After at least 10 min for equilibration, recordings were begun from discontinuation of anaesthesia and return of spontaneous breathing until recovery of full consciousness when the FPTS was removed. Patients were under the care of a trained recovery nurse and were monitored clinically and with pulse oximetry. She was instructed to manage the cases according to usual practice, supporting the airway as she felt necessary.

Satisfactory recordings were obtained in all patients. Several patterns of pressure waveforms were seen. During unobstructed normal breathing, synchronous pressure changes were seen at all sites, the pressure change increasing from proximal to distal. During complete obstruction, increased inspiratory pressure changes were seen distal to the presumed level of obstruction, with no pressure changes above that level. At the presumed level of obstruction, several patterns were seen. The most usual was an inverted pressure waveform with pressure increasing during inspiration. The same pattern was seen during partial obstruction and was usually associated with a waveform suggestive of flow limitation in the distal transducers. This latter waveform was also associated with a reduced, in-phase pressure waveform at the presumed site of obstruction. Snoring was seen as a high frequency pattern superimposed on the pressure waveform.

We hypothesized that the differing pressure changes at the site of obstruction may be explained by pressure on the "balloon" of each transducer. The subatmospheric collapsing force during inspiration was countered by an increase in airway dilator muscle activity. In the awake state this resulted in an increased airway calibre and the transducer reflected intraluminal pressure. In the presence of anaesthetic agents the dilator activity was reduced and airway calibre reduced with inspiration, applying wall pressure to the "balloon". As airway calibre reduced, the wall pressure initially balanced and then exceeded intraluminal pressure giving the reduced amplitude and out-of-phase pressure changes.

The results suggested that airway narrowing may be progressive and is not always associated with snoring. The FPTS may be of value in future investigations of the upper airway.

Key words

Airway, complications. Airway, calibre.

Economy during induction of anaesthesia: a comparison of desflurane with isoflurane via a circle system

S. K. PAL*, Z. ZYCH*, R. RAJENDRAM* AND D. C. WHITE
Department of Anaesthetics, Princess Alexandra Hospital, Harlow, Essex

The use of isoflurane and recently introduced desflurane has increased anaesthetic cost. Renewed interest in low-flow anaesthesia with carbon dioxide absorption has made possible considerable cost savings during maintenance of anaesthesia. However, no attempt has been made to reduce the cost during induction and early stages of anaesthesia because it is generally believed that it is difficult to close the circuit from the start of the anaesthetic. So far the cost of both has been calculated theoretically [1]. We studied 50 patients using a closed system and determined the cost of administering desflurane compared with isoflurane.

Fifty unpremedicated healthy patients (aged 9–78 yr) scheduled for minor orthopaedic procedures in the day-surgery unit were allocated randomly to one of two groups. All patients were induced with propofol 2.5 mg kg^{-1} and fentanyl 1.5 μg kg^{-1} followed by introduction of laryngeal mask airway. Patients in group I received oxygen 500 ml min^{-1}, nitrous oxide 1000 ml min^{-1} and desflurane up to 12% and group II received isoflurane up to 5%, thus delivering up to 180 ml of desflurane vapour/min or up to 75 ml of isoflurane vapour/min, respectively. Breathing was assisted initially to maintain the end-tidal carbon dioxide between 5% and 6%. The fresh gas flows and the vaporizer settings were recorded at 1-min intervals throughout the procedure.

The main findings are shown in figure 6. The calculation is based on the current cost of isoflurane (£0.48/ml) and desflurane (£0.18/ml). The cost of desflurane and isoflurane is essentially the same if used in the manner described above.

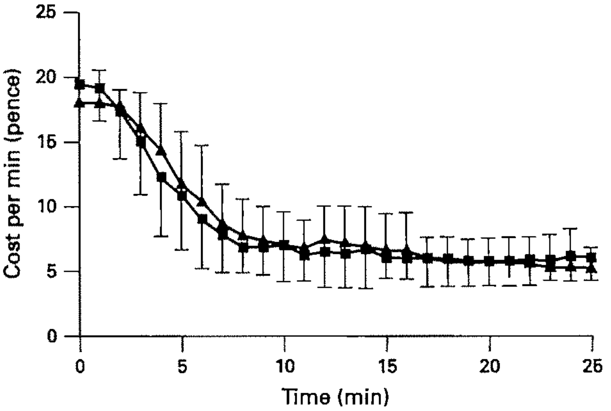

Figure 6 Comparison of costs. (▲) Desflurane; (■) isoflurane.

Induction of inhalation anaesthesia through breathing systems using carbon dioxide absorber can be achieved with fresh gas flows of 1500 ml thus further reducing the cost of anaesthetics. The cost of administering inhalation anaesthetics can be calculated by using simple arithmetic without going into complicated formulae [1–3]. It appeared that there was no significant difference between the cost of desflurane and isoflurane anaesthetic although 1 ml of isoflurane liquid was 2.6 times more expensive than 1 ml of liquid desflurane.

These findings can be explained by consideration of the relative uptake of the two agents.

Key words

Anaesthetics volatile, desflurane. Anaesthesia, audit.

Performance of vaporizers in circle systems (II)

B. ROYSTON, G. MARKEY* AND D. WHITE
Academic Department of Anaesthesia, Northwick Park Hospital, Harrow, Middlesex

In a previous communication [1] we showed that when an in-circle vaporizer (VIC) was used with a spontaneously breathing patient a degree of self-regulation of the inspired anaesthetic concentration occurred. The patient imposed a limit on the amount of anaesthetic received and this was related to the intensity of surgical stimulus. Believing this to be beneficial we have investigated the mechanism of this effect.

The increase in inspired anaesthetic concentration with increased pulmonary ventilation could be attributed to the flow characteristics of the vaporizer—increased gas flow causing higher concentration in the output of the vaporizer. Alternatively, increased recirculation of gas through the vaporizer could be responsible.

We studied isoflurane output from the Goldman, Oxford Miniature (OMV) and Komisaroff vaporizers. A gas mixture of 33% oxygen and 66% nitrous oxide was passed through the vaporizers at a series of known flow rates between 1 and

8 litre min^{-1}. The isoflurane output concentration was measured using a calibrated Datex Capnomac Ultima. The output of the OMV showed little flow dependence whereas the Goldman and the closely similar Komisaroff vaporizers showed considerable variation with flow (fig. 7A).

Steady-state flow measurement of this type do not represent performance under clinical conditions because of the fluctuating nature of respiratory gas flow. We therefore simulated respiration using a Manley ventilator to drive gas through the vaporizer. The output of the ventilator was constricted to resemble normal respiratory flow rates. We studied the isoflurane output at varying tidal volumes and the results are shown in figure 7B. We found that with intermittent gas flow resembling normal breathing the vaporizer output was not affected by tidal volume. Peak flow and respiratory rates were also varied and found not to affect the output of the vaporizer.

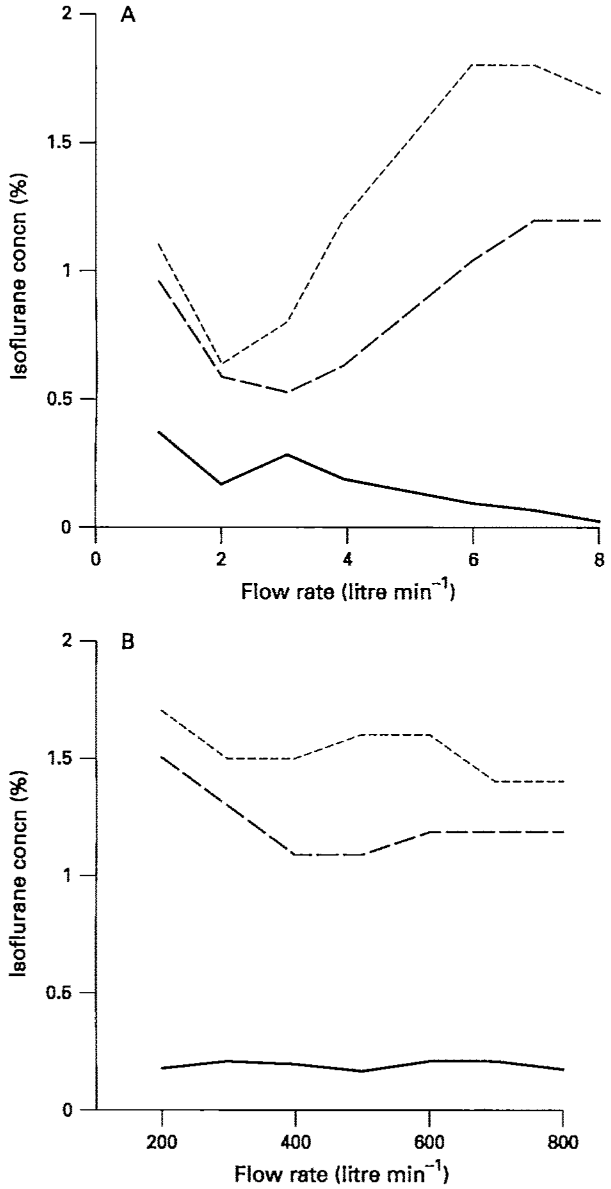

Figure 7 Results. (—) Setting 1; (— — —) setting 2; (- - -) setting 3.

We concluded that the autoregulation was not due to the flow characteristics of the vaporizer but must be attributable to recirculation. We did not exclude the possibility that pressure fluctuations in the system may contribute to autoregulation by producing a form of "pumping effect" [2].

Extradural clonidine provides adjunctive pain relief without sedation for women in labour

M. R. TREMLETT*, J. PARKINS*, D. HUGHES* AND N. REDFERN
Department of Anaesthesia, Royal Victoria Infirmary, Newcastle-upon-Tyne

The short acting α_2 agonist, clonidine, administered at low dosage, enhances pregnancy-related analgesia to visceral but not somatic stimuli in an animal model [1]. In women in labour, a single extradural bolus of 120 µg clonidine, added to 0.125 % bupivacaine, increased the duration of pain relief but caused sedation [2]. The aim of the study was to test the hypothesis that a small initial extradural bolus of clonidine and subsequent infusion could provide adjunctive analgesia without sedation.

Women in early, established, uncomplicated labour were studied. A lumbar extradural catheter was introduced at L2–3 or L3–4, and after a test dose of 3 ml 0.5 % bupivacaine, pain relief was established with 10 ml 0.125 % bupivacaine. Once pain free, informed consent was obtained, and patients were randomized to one of two groups. The control group received a bolus of 10 ml saline, followed by an infusion of 0.03 % bupivacaine at 12.5 ml/h. The treatment group, in addition, received a bolus of 25 µg clonidine followed by 1.5 µg ml^{-1} clonidine added to the bupivacaine infusion. When pain relief was inadequate, boluses of 10 ml 0.125 % bupivacaine were given on the first two requests, and 0.25 % thereafter. Infusions were continued until delivery or obstetric intervention. Sedation was assessed on a 5-point scale from awake (= 1) to awakening only when roused (= 5).

Women in whom labour had been induced for post-maturity predominated in both groups. The addition of clonidine to 0.03 % bupivacaine resulted in a longer time to first request for additional pain relief and a smaller number of additional boluses of local anaesthetic (table 3). A difference in the degree of maternal and fetal sedation was not detected. No mother became bradycardic or hypotensive.

Table 3 Results

	Bupivacaine 0.03 % ($n = 15$) Median (range)	Bupivacaine 0.03 % + clonidine ($n = 15$) Median (range)	Mann-Whitney *U* test
First request for additional pain relief/min	97 (30–295)	195 (58–450)	$P = 0.01$
Number of additional local anaesthetic boluses requested	3 (1–6)	1 (0–3)	$P = 0.0001$
Duration of infusion/min	391 (215–873)	335 (185–735)	$P = 0.26$
Maximum level of sedation seen	1 (1–5)	1 (1–3)	$P = 0.61$

This study demonstrated that clonidine by small initial bolus and subsequent infusion can provide adjunctive analgesia without sedation for women in labour.

Is tramadol is better than ketorolac after day-case laparoscopy?

M. A. Sabar*, A. J. Gosling and A. S. Laurence
Department of Anaesthetics, Royal Preston Hospital

Analgesia after day-case laparoscopy is still unsatisfactory [1, 2], although improved analgesia has been obtained by aggressive use of non-steroidal agents [3]. We have compared the analgesia provided by ketorolac and tramadol after laparoscopy.

Day-case gynaecological laparoscopy patients gave signed, informed consent and had the verbal rating scale (VRS) explained whereby pain was to be assessed by a number between 0 and 10. All were anaesthetized as in previous studies using a standard propofol-fentanyl-atracurium-isoflurane anaesthetic and droperidol 0.5 mg for antiemesis.

Patients were randomized to two groups by sealed envelope. The ketorolac group were additionally given ketorolac 10 mg i.v. at induction, and discharged with six 10-mg tablets of ketorolac to take home. The tramadol group were given 1 mg kg^{-1} tramadol i.v. on induction and discharged with six 50-mg tablets of tramadol to take at home.

All patients were assessed in the recovery room for pain (VRS 0–10), nausea and vomiting (0–3) and the need for analgesia before discharge home was noted. Discharge followed the routine procedure of the unit. At about midday on the first postoperative day, all patients were contacted by telephone. An assessment of pain (0–10), nausea and vomiting (0–3), activity (0–3) and tablets consumed was made by semistructured interview. This was repeated on the second day.

We present data for the first 21 completed patients in each group (table 4). Both groups were comparable for age, weight, and duration of procedure.

There was less pre-discharge analgesia needed (not significant) in the tramadol group, despite similar recovery pain scores. Pain after discharge was, however, significantly less in the tramadol group, although by day 2 tablet consumption in both groups was similar. Nausea and vomiting were similar at all times in both groups. Activity scores in both groups were also similar. The analgesia in the ketorolac group might have been improved by increased dosage but the doses chosen were the maximum currently permitted on the product licence. The tramadol dosage was chosen to provide adequate analgesia, with minimum side effects, which we felt had been achieved.

Table 4 Postoperative indices; mean values (range) $^{*}P < 0.02$ (between groups, chi-square) $^{**}P < 0.01$ (day 1 to day 2, Wilcox) $^{***}P < 0.001$ (between groups, Mann-Whitmey) ††† $P = 0.001$ (day 1 to day 2, Wilcox)

Changes in pineal and pituitary hormone secretion under general anaesthesia

A. Reber, P. R. Huber, W. Ummenhofer, C. Gürtler, C. Zurschmiede, Z. Khan and M. Schneider
Department of Anaesthesia and Hormone Laboratory, University of Basel/Kantonsspital, Basel and Academic Department of Anaesthesia, King's College Hospital, London

It is known that there is an association between sleep disorders and plasma melatonin concentrations [1]. There is evidence that there is a relationship between pineal and pituitary hormone secretion [2]. The secretion of the pineal hormone melatonin is stimulated by darkness and partially suppressed by benzodiazepines [3]. The effect of inhalation anaesthetics and propofol on melatonin secretion has not been reported. We investigated the influence of general anaesthesia and surgery on plasma levels of melatonin and prolactin.

Thirty-two female patients (ASA I or II) scheduled for elective gynaecological surgery (60–90-min duration) were randomized to one of two groups. Premedication consisted of 3.0 mg bromazepam orally at 07.00. General anaesthesia was performed at 08.00 with either isoflurane-nitrous oxide-oxygen-fentanyl or propofol-nitrous oxide-oxygen-fentanyl. During general anaesthesia the patients' eyes were covered allowing no light penetration. Blood samples were taken before and after premedication, immediately before induction of anaesthesia, every 15 min during anaesthesia, and hourly in the recovery room for 8 h. The control group consisted of six healthy women who underwent a similar environment and light conditions as the study groups. Blood samples were analysed for melatonin and prolactin by commercial radioimmunoassay tests. The groups were compared using non-parametric tests (a P value < 0.05 was considered as significant).

In the isoflurane group, plasma melatonin concentrations gradually increased to a peak and then decreased during the time of general anaesthesia, as they did in the control group. During propofol anaesthesia, plasma melatonin concentrations remained elevated throughout general anaesthesia. In the isoflurane group, during the recovery period the mean plasma melatonin concentration was higher than that obtained in the propofol and control groups, between which there was no difference. Prolactin significantly increased after induction of anaesthesia and decreased postoperatively to the baseline (before premedication) in the isoflurane and propofol groups. In the control group there was no change in plasma prolactin concentrations.

Isoflurane and propofol anaesthesia as well as darkness led to elevated plasma melatonin concentrations which continued in the recovery period in contrast with prolactin. An increase in plasma melatonin during darkness did not lead to an increase in plasma prolactin concentrations. This evidence disputed the relationship between melatonin and prolactin release. The increased concentrations of melatonin may affect recovery from anaesthesia.

Patient-controlled analgesia and the plasma glucose response to surgery

V. O'Keefe, M. M. van Miert, C. J. R. Parker, P. Salmon and A. Shenkin
Departments of Anaesthesia, Clinical Psychology and Clinical Chemistry, University of Liverpool

Perioperative analgesia has a limited effect on the metabolic response to surgery [1]. Being able to control a stressful event may diminish its physiological effects [2]. Patient-controlled analgesia (PCA) requires the patients to assume control of part of their own treatment; we, therefore, decided to study the effect of PCA on the physiological response to a given surgical insult.

Thirty-three patients about to undergo mastectomy were studied. After written informed consent, they completed baseline questionnaires to assess trait and state anxiety (Spielberger inventories), and health-specific locus of control beliefs [3]. The latter has four subscales related to beliefs about the effect on health of self control, health care providers, chance and general threats. The patients were then randomized to receive either patient-controlled i.v., or conventional i.m. analgesia. Surgery was scheduled to start between 08.30 and 11.30. Premedication was with diazepam 10 mg orally, 2 h preoperatively. Anaesthesia was induced with morphine 0.1 mg kg^{-1}, up to a maximum of 10 mg, and thiopentone 150–425 mg, followed by atracurium, and maintained with oxygen, nitrous oxide and isoflurane. Venous blood samples were taken for plasma glucose estimation before induction of anaesthesia, and at 2, 4, 6, 8, 10, 12 and 24 h after skin incision. Postoperative analgesia was provided either with morphine 10 mg i.m., given by the nursing staff, on request from the patient, or by morphine from a patient-controlled analgesia device programmed to deliver a 1-mg bolus, with a 5-min lockout period and no background infusion. Prochlorperazine 12.5 mg i.m. was given if required. Pain was assessed with a visual analogue scale (0–10) at 4, 8, 12 and 24 h after incision. On the day after surgery the patient completed the Spielberger state anxiety inventory and other questionnaires to assess their perception of control over their pain relief. The area under the curve of plasma glucose vs time from 0–12 h after the incision was calculated. Differences between the groups were assessed using the *t* test, and the effect of other factors on the glucose response using univariate and multivariate regression.

Although the mean morphine dose was more than twice as great in the PCA group as in the i.m. group, average pain scores were not significantly different (table 5). There was a significant difference between the groups in the area under the curve of plasma glucose up to 12 h ($P < 0.05$). In multivariate regression, the plasma glucose response was also significantly greater in subjects with high trait anxiety ($P < 0.05$). There was no significant correlation between glucose response and either operation type, average pain score, morphine dose, preoperative state anxiety or any subscale of the locus of control inventory.

Patient-controlled analgesia reduced the glucose response in the first 12 h after mastectomy. The plasma glucose response was also significantly greater in subjects with high trait anxiety.

Flow cytometry evaluation of the *in vitro* effects of four i.v. anaesthetics on the respiratory burst of human neutrophils

M. Leuwer, J. F. Heine, L. Arseniev, D. Scheinichen, K. Jäger and S. Piepenbrock
Departments of Anaesthesiology and Haematology, Hannover Medical School, Germany

The production of oxygen radicals (respiratory burst) is one of the most important functions of neutrophil granulocytes [1]. Alteration of this defence mechanism by drugs may favour bacterial infections. Because it has not yet been shown that anaesthetic agents inhibit some other aspects of neutrophil function [2], we investigated the influence of propofol, thiopentone, methohexitone and midazolam on the respiratory burst (RB) of neutrophils *in vitro* via flow cytometry.

After the local Ethics Committee's approval venous blood was drawn from 20 healthy donors. Leucocytes were obtained as supernatant after sedimentation (1 g). The sedating, anaesthetic, 10-fold sedating and 10-fold anaesthetic plasma concentration effects of the four investigated agents on the RB were measured by means of the intracellular oxydation of dihydrorhodamine-123 to the fluorescent rhodamine-123 [3]. All results were expressed as a percentage of inhibition of the positive control response, which was the RB after maximum stimulation by phorbol myristate acetate (PMA) in the absence of anaesthetic agents. Prestimulation of neutrophils was quantified by negative controls (RB without stimulation by PMA in the absence of anaesthetic agents). Viability discrimination was performed by addition of propidium iodide just before measurement. Data were stored in listmode data files using FACScan software and analysed with PC-LYSYS software on a personal computer. Results are expressed as mean values and standard deviations. They were evaluated statistically using Wilcoxon or Mann-Whitney *U* test. $P < 0.05$ was considered to be significant.

At anaesthetic plasma concentrations propofol caused a significant ($P < 0.01$) higher depression of the RB (7.3 (SD 6.0)%) than thiopentone (4.5 (5.3)%), methohexitone (0.9 (1.6)%) and midazolam (2.2 (2.7)%) respectively. At sedating plasma concentrations propofol produced 3.5 (5.6)% inhibition. Methohexitone (1.3 (2.1)%) and midazolam (1.3 (1.7)%) showed minimum effects. At 10-fold anaesthetic concentrations the RB inhibition by propofol was almost complete (90.8 (3.9)%). At the given plasma concentrations the inhibitory effects of its solvent 10% Intralipid alone were nearly identical to those of propofol.

Propofol produced markedly more RB inhibition than thiopentone, methohexitone and midazolam at all plasma concentrations investigated. Its suppressive effects may be due to its lipid carrier 10% Intralipid. It may be worthwhile, therefore, to investigate the effects of other lipid solutions on the RB of neutrophils.

Pulmonary lactate flux after cardiopulmonary bypass

V. Kulkarni, H. McFarlane and N. R. Webster
University Department of Anaesthesia and Intensive Care, Aberdeen Royal Infirmary, Aberdeen

Postperfusion pulmonary dysfunction syndrome after cardiopulmonary bypass (CPB) is characterized by an increase in interstitial fluid, sequestration of neutrophils and increased pulmonary shunting. Though the injury commonly resolves after the operation, it can occasionally progress to adult respiratory distress syndrome (ARDS). The aetiology is manifold. Microaggregates in the pulmonary circulation and release of vasoactive mediators from platelets have been demonstrated [1]. A systemic inflammatory response to CPB with increasing concentrations of tumour necrosis factor-α (TNFα), IL-8 and C3 is accompanied by C3-mediated expression of CD18 and subsequent neutrophil sequestration [2]. During CPB there is no pulmonary circulation and bronchial blood flow is low. The pulmonary tissues are only reperfused after the return of normal circulation leading to ischaemia/reperfusion injury. Ischaemic tissues commonly produce lactate. Significant lactate production by the lung has been shown recently to occur in cases of lung injury from sepsis and ARDS [3]. Though it is known that whole body lactate concentrations increase after CPB there has been no study of pulmonary lactate production. The present study was designed to determine whether there is significant lactate production by the lung, following pulmonary ischaemia/reperfusion injury, after CPB.

Six patients aged 45–64 yr undergoing elective coronary artery bypass surgery were included in the study after Ethics Committee approval. Before commencement of CPB a 5-ml sample of blood was collected in a heparinized tube, simultaneously from the indwelling arterial and pulmonary artery catheters and stored in ice. Cardiac output and blood gases were also measured. Blood flow during bypass was maintained at 2.4 litre m^{-2} min^{-1}. After CPB, on resumption of normal circulation, the measurement sequence was repeated. Blood samples were centrifuged and the plasma stored at −20 °C before assay. Lactate measurements were made using the Analox PGM-7 analyser (Analox Instruments, London).

Normally there is either a slight decrease (negative flux), or no change in lactate across the lung. After bypass lactate concentrations were higher. Though the prebypass situation of a negative or zero flux was seen in most of the cases, two patients showed the lung producing significant quantities of lactate, calculated to be 190.8 mmol and 124.8 mmol every h. There was no relationship with the duration of bypass, the number of grafts or complications during operation. Both patients did, however, have documented preoperative pulmonary disease and needed prolonged postoperative management.

Table 6 Arterial (A) and mixed venous (MV) lactate concentrations (mmol $litre^{-1}$) before and after cardiopulmonary bypass

	Before bypass			After bypass		
No.	A	MV	Flux	A	MV	Flux
1	1.5	1.5	0	2.5	2.5	0
2	1.7	1.8	−0.1	3.7	4.0	−0.3
3	1.8	1.8	0	2.7	2.6	+0.1
4	1.7	1.6	+0.1	2.9	3.1	−0.2
5	1.6	1.7	−0.1	3.8	3.2	+0.6

Org 21465 a new i.v. anaesthetic agent

C. J. Daniell, M. Cross, J. R. Sneyd, P. Thompson,
M. M. Weideman* and C. J. Andrews
Department of Anaesthesia, Derriford Hospital, Plymouth, Phase I Clinical Trials Unit, Plymouth and Organon Teknika NV, Turnhout, Belgium

Org 21465 is a water-soluble steroidal i.v. anaesthetic. *In vitro* studies have shown that Org 21465 has a higher degree of selectivity for the GABA-A receptor than thiopentone or propofol. *In vivo* studies in rodents, dogs, pigs and primates have demonstrated favourable hypnotic properties.

Ten healthy male volunteers aged 22–28 yr weighing 63–98 kg each received a single dose of Org 21465, 0.8–1.8 mg kg^{-1} by infusion over 1 min. An infusion of the solvent vehicle of identical volume preceded each active infusion by 15 min.

After arterial and venous cannulae had been placed in opposite arms, subjects rested quietly and received supplementary oxygen by a nasal cannula. Direct arterial pressure, oxygen saturation, ECG, bio-impedance cardiac output, and EEG were monitored continuously. Arterial samples were obtained for pharmacokinetic analysis. Subjects held a 20-ml water-filled syringe in one hand.

Table 7 Clinical responses to Org 21465. Times (min) from the start of drug infusion (means) and individual values

	Dose (mg kg^{-1})				
	0.8	1.0	1.2	1.5	1.8
No.	1	2	3	2	2
Loss of verbal contact	2.5	(1.00) 1.17, 0.83	(1.11) 1.45, 1.00, 0.87	(0.91) 0.83, 0.98	(0.59) 0.42, 0.77
Drop syringe	N/A	(1.17) 1.35, 0.98	(1.01) 1.17, 1.25, 0.78	(0.97) 0.95, 0.98	(0.78) 0.78, 0.77
Loss of eyelash reflex	N/A	(2.98) 3.17, 2.80	(2.19) 2.50, 1.50, 2.58	(1.45) 1.33, 1.57	(2.27) 0.87, 3.66
Eyes open on command	N/A	(9.96) 5.87, 14.05	(11.72) 17.25, 8.78, 9.12	(15.92) 15.50, 16.33	(19.25) 17.5, 21.00
Move limbs on command	N/A	(9.87) 6.23, 13.5	(13.17) 18.00, 10.50, 11.00	(18.14) 16.35, 19.93	(20.00) 19.00, 21.00

All subjects complained of discomfort during injection of the solvent and during injection of Org 21465. The subject who received 0.8 mg kg^{-1} stopped speaking at 150 s but did not lose his eyelash reflex or drop the syringe. Subjects receiving 1.0 mg kg^{-1} or more, became anaesthetized (table 7).

There was no evidence of histamine release and apnoea did not occur, even at the highest dose. Cardiovascular stability was seen in all subjects. Excitatory phenomena were observed in seven subjects and were dose related, no spikes were seen on the EEG. One subject coughed repeatedly after receiving 1.8 mg kg^{-1} of Org 21465, another had episodes of sneezing after the same dose. Hypoxaemia did not occur in any subject.

A dose of 1.0 mg kg^{-1} of Org 21465 induced a short period of anaesthesia followed by a slow recovery. Higher doses caused excitation.

Effects of dopamine and dopexamine on splanchnic microcirculation during major surgery in humans

M. C. Bellamy, Y. Young, P. J. Guillou* and H. O'Beirne
Departments of Anaesthesia and Surgery, St James's University Hospital, Leeds

Most studies on splanchnic microcirculation have used microsphere techniques in animals. Relatively little is known of the factors governing intraoperative splanchnic blood flow in humans. We have, therefore, studied the effects of dopexamine and dopamine on small bowel and hepatic microcirculatory flow during major surgery in humans by a non-invasive technique (laser Doppler flowmetry).

Ethics Committee approval was obtained for this prospective randomized single-blind crossover study. Ten adult patients undergoing major upper abdominal surgery gave informed consent. After premedication with temazepam 20 mg, anaesthesia was induced with thiopentone 3 mg kg^{-1} and fentanyl 3 μg kg^{-1}. Neuromuscular block was facilitated by infusion of atracurium. The lungs were ventilated with isoflurane (1 MAC) in oxygen-enriched air. Patients were allocated randomly to receive dopexamine 1 μg kg^{-1} min^{-1} or dopamine 3 μg kg^{-1} min^{-1} by continuous i.v. infusion. After abdominal incision, steady-state jejunal (GBF) and liver blood flow (LBF) in segment III were assessed by laser Doppler flowmetry. The measurements were repeated after 30 min infusion of inotrope. The inotrope was then swapped and measurements repeated after a further 30 min. Data were analysed using paired Student's *t*-test and multiple regression analysis.

There were no differences in haemodynamics between periods of dopamine and dopexamine administration.

Multiple regression described liver blood flow as (CVP × 7.4) − (50 if dopamine rather than dopexamine) + 65, $P < 0.01$, $r^2 = 0.51$.

We have shown that during major surgery under isoflurane anaesthesia in humans, dopexamine produced higher liver microcirculatory blood flow than did dopamine. In this model, 51 % of the variability in liver blood flow was accounted for by the use of dopexamine rather than dopamine, and volume loading. However, dopexamine conveyed no improvement in gut blood flow over dopamine, nor were there any differences in haemodynamics between administrations of the two drugs (table 8). These results were consistent with local effects on hepatic arterial flow mediating the observed changes. These results may have important implications for anaesthesia of the high-risk surgical patient.

Table 8 Results

	Flow/PU Mean (SEM)	*P* value
Gut		
dopamine	170 (37)	0.81
dopexamine	160 (41)	
Liver

Predictability of tumour necrosis factor concentration: evidence for a mechanism for mutual regulation of autacoids in systemic inflammatory response syndrome

Alison J. Pittard, N. R. Webster and M. C. Bellamy
Intensive Care Unit, St James's University Hospital, Leeds and Department of Anaesthesia and Intensive Care, Aberdeen Royal Infirmary, Aberdeen

Uncontrolled release of cytokines and adhesion molecules is thought to be of major importance in the systemic inflammatory response syndrome (SIRS) and severe sepsis (SS) [1]. We have therefore studied inter-relationship of autacoids in SIRS and their effect on outcome.

Fifty-five consecutive patients presenting to intensive care with SIRS or SS were studied. A volume of 10 ml of blood were collected into a heparinized tube within 12 h of admission, centrifuged, aliquoted and frozen at −20 °C until analysis. ELISA was used to measure the following autacoids: soluble E selectin (sE-selectin), soluble P selectin (sP-selectin), soluble E cadherin (sE-cadherin), soluble tumour necrosis factor receptor type two (sTNF RII), tumour necrosis factor alpha (TNFα), interleukin-1 receptor antagonist (IL-1ra) and the interleukins 1b, 6, 8 and 10 (IL-1b, 6, 8, 10). Outcome was measured as survival until intensive care discharge. Data were fitted to a logistic regression model (for survival) or multiple linear regression (for cytokine inter-relationships) model using backward stepwise selection.

Forty-four patients died (80 %) and 11 survived (20 %). We were unable to identify a cytokine/adhesion molecule pattern predictive of survival. However, using TNFα as the dependent variable, a regression equation was derived which predicted TNFα levels from those of other autacoids: TNFα = 52.29 + 1.88 (sE-cadherin) − 0.07 (sE-selectin) + 0.21 (IL-10) − 0.09 (IL-1b) − 8.77×10^{-4} (IL-1ra) + 0.01 (IL-6) − 0.04 (sP-selectin) − 8.72×10^{-4} (sTNF-RII). $P < 0.00001$, $F = 7.0 \times 10^{15}$ and $r^2 = 1$.

This equation applied irrespective of patient outcome. It allowed accurate prediction of any autacoid given concentrations of other autacoids. These findings challenge the orthodox view that in SIRS, cytokine and inflammatory mediator release is excessive and uncontrolled [2, 3].

Key words
Protein, Autacoids. Complications, systemic inflammatory response syndrome.

White blood cell cytosolic calcium changes during human orthotopic liver transplantation

S. Enright* and M. C. Bellamy
Departments of Anaesthesia and Intensive Care, St James's University Hospital, Leeds

Reperfusion syndromes are frequently associated with increases in cytosolic calcium. The haemodynamic and biochemical effects of the reperfusion syndrome during human orthotopic liver transplantation (OLT) have been characterized [1–3]. Arachidonic acid

Table 9 Results (interquartile range). *Not significant, $P = 0.46$; **adjusted P value = 0.0008

	Baseline	Before reperfusion	After reperfusion
Intracellular calcium (nmol litre^{-1}) $P = 0.0002$	10.8 (6.4–23.1)*	16.7 (8.2–27)**	24.9 (16.2–50)**
Calcium influx (nmol litre^{-1} s^{-1}) $P = 0.009$		7.4 (4.6–13.5)	8.9 (5.7–33.3)

metabolites mediate increases in intracellular calcium, and thus potentiate the effect of free radicals. This study was carried out to characterize white blood cell (WBC) calcium changes as a mediator for white cell activation in human OLT.

Ethics Committee approval was obtained. Twenty consecutive patients scheduled for OLT gave informed consent. All patients were anaesthetized according to our standard technique [1]. Blood samples were drawn into lithium heparin tubes for estimation of WBC cytosolic calcium at induction of anaesthesia, 5 min before graft reperfusion, and 15 min after reperfusion. WBC were immediately separated using sucrose slope centrifugation, and intracellular calcium assayed using the FURA 2AM technique. Additionally, the rate of increase in intracellular calcium after addition of 1 mmol solution of calcium chloride to the extracellular milieu was used as an estimate of membrane calcium permeability. Induction, before and after reperfusion cytosolic calciums were compared using Friedman's two-way analysis of variance by rank for non-parametric data. Specific differences were assessed using Bonferroni-corrected Wilcoxon signed rank test for paired data. Pre- and post-reperfusion WBC membrane permeabilities were compared using Wilcoxon signed-rank test.

Results were expressed as median (interquartile range) (table 9).

We demonstrated a significant increase in WBC membrane permeability for calcium and cytosolic calcium concentration following reperfusion in human OLT. These results were consistent with WBC activation at reperfusion [2].

Immunoglobulin and interleukin 2 production *ex vivo/in vitro* during treatment with oral retarded morphine

S. Palm, S. Letzen, J. Steinmann and C. Maier
Clinic of Anesthesiology and Operative Intensive Care,
Department of Immunology, Christian-Albrechts-University, Kiel,
Germany

Clinical indications for the use of morphine have, nowadays, been extended towards non-malignant pain syndromes. Suspected inhibitory effects of morphine on immune functions, mostly described in animal experiments and in drug addicts, have thus to be investigated in clinical settings [1].

Ten patients (age 31–65 yr; eight non-malignant, two malignant pain syndromes) and healthy controls ($n = 9$) were investigated. Blood samples were drawn before (basal status), after 1 and 4 weeks of treatment with oral retarded morphine 30–240 mg day^{-1}. Peripheral mononuclear cells were cultured with/without concanavalin A (5 μg ml^{-1}) for interleukin-2 (pg ml^{-1}; IL2) production (24 h), pokeweed mitogen (PWM; 1 μg ml^{-1}) for immunoglobulin G/M (IgG/M) production (7 days). Variables were measured by ELISA. Statistics were performed using the Wilcoxon matched pairs and Mann-Whitney U test ($P < 0.05$).

Patients produced less IgG/M in comparison with controls at basal status. PWM stimulation of Ig production was reduced for IgM after 1 and 4 weeks of morphine treatment, whereas concentration ranges in controls remained unchanged, IL2 tended towards increased values during morphine treatment.

Table 10 Immunological variables in patients with chronic pain syndromes during treatment with oral retarded morphine (Depicted are medians, below 25th/75th percentile, * lower *vs* control († $P < 0.05$, ‡ $P < 0.1$), ** elevated *vs* basal status, (+) significantly stimulated over 0 μg ml^{-1} PWM ($P < 0.05$))

n	8	7	8	6	6	4

The results indicated that CD 19 cells of pain patients had a reduced ability to produce IgG/M after stimulation. Morphine treatment seemed to aggravate this defect. Distribution of lymphocyte subpopulations remained unchanged [2] (table 10). The clinical relevance of these results needs to be evaluated further during stimulation of immune function.

Parental or anaesthetist's ability to predict a 'stormy' induction in young children

B. Lyons, F. Kirby and W. Casey
Department of Anaesthesia, Our Lady's Hospital for Sick Children, Crumlin, Dublin, Ireland

Induction of anaesthesia is a frightening event for many children, and if stormy, may result in subsequent psychological disturbance [1]. Several features have been shown to increase the likelihood of an adverse emotional reaction to anaesthesia including patient age, previous anaesthetics and parental behaviour [2]. Premedication of these children may reduce the incidence of difficult inductions, but is often omitted in day-case patients to avoid delayed discharge. It would be useful to identify those children who will suffer a stormy induction, but anaesthetists are poor at predicting this [2]. Parents, however, have witnessed their child's reaction to a variety of stressful situations and thus are more likely to predict accurately the response to induction. The aim of this study was, therefore, to compare anaesthetists' and parents' ability to predict a child's reaction to induction of anaesthesia.

Eighty-five ASA I unpremedicated children, aged 1 to 5 yr and undergoing minor day-case surgery were enrolled after parental consent. Children were seen by an anaesthetist on the day ward, who tried to predict how difficult the induction was likely to be using a three-point scale (smooth, fair, difficult/stormy). Parents were also asked to predict how well their child would cooperate with induction. All children were accompanied by one parent to the anaesthetic room. The induction technique was decided on by an uninvolved, blinded anaesthetist who scored the child's cooperation with induction using a three-point scale [2]. Data were analysed using Student's-t or chi-square tests.

The 85 children included 49 males and 36 females of whom 59 (64%) underwent a difficult induction. Children who had undergone a previous general anaesthetic were less likely to co-operate with induction ($P < 0.05$), but sex, anaesthetist's grade or induction technique were not related to behaviour. Parents predicted correctly the behaviour of 48 of the 59 children (81%) who underwent a stormy induction, and 16 of the 26 (62%) who had a smooth or fair induction. The anaesthetist predicted correctly the behaviour of 49% and 62% of difficult and smooth/fair inductions respectively ($P < 0.05$ compared with parents).

This study demonstrated the high incidence of young children who undergo a difficult anaesthetic induction. Parents were more accurate at predicting unsatisfactory behaviour than the anaesthetist. Therefore prior consultation with parents may assist in identifying children who would benefit from additional psychological or pharmacological preparation before ambulatory surgery.

Midazolam *vs* trimeprazine premedication for children during day-care surgery

D. Nathwani*, P. Rich, K. M. Konieczko and V. Ramachandra
Academic Department of Anaesthesia, St Mary's Hospital Medical School, Northwick Park Hospital, Harrow

Premedication in children should reduce anxiety and facilitate induction of anaesthesia without prolonging the recovery period [1]. Midazolam has been shown to be an effective oral premedicant [2]. We compared midazolam and trimeprazine for children undergoing ear, nose and throat day-case surgery. After approval by Harrow Research Ethics Committee, and informed parental consent, 40 children [ASA I and II] aged 2–6 yr were studied. They received at random either oral midazolam 0.5 mg kg^{-1} and atropine 15 μg kg^{-1} 30 min before operation ($n = 20$) or trimeprazine 2 mg kg^{-1} and atropine 15 μg kg^{-1} 90 min before operation ($n = 20$). Induction was with thiopentone 5 mg kg^{-1} or by inhalation of halothane. Either a laryngeal mask airway or a tracheal tube was inserted (with suxamethonium 1 mg kg^{-1}). Anaesthesia was maintained using 67% nitrous oxide in oxygen and isoflurane. Postoperative analgesia was provided by diclofenac suppositories 12.5–25 mg. The rate and quality of recovery was assessed by the children inserting coloured shapes into a container through the appropriate holes in the lid, 2 and 4 h after the operation. The child had three attempts at the game and the number of shapes inserted in 45 s was recorded. Before induction an independent observer recorded anxiolytic and sedation scores and tolerance of induction. The ward nurses recorded vomiting up to 2 and 4 h. Fisher's exact test compared awake/asleep and vomiting, and the Mann-Whitney U test compared the median changes in scores.

At induction, sedation, anxiolytic and tolerance scores were not significantly different, confirming that the drugs at the doses given were equally effective. Within the 4-h recovery period none of the midazolam group vomited compared with eight of the trimeprazine group ($P = 0.003$). The psychometric testing could only be performed by awake children. At 2 h, seven trimeprazine and 18 midazolam children were awake, $P = 0.001$ (at 4, 15 and 20 h $P = 0.05$).

We found that midazolam had a faster rate and better quality of recovery from anaesthesia than trimeprazine (table 11). At 4 h none of the midazolam patients had any clinically significant impairment.

Table 11 Number of children showing a reduction (0 to 5) in psychometric scores from preoperative baseline. (T = trimeprazine and M = midazolam group)

Reduction in score from baseline	At 2 h T	At 2 h M		At 4 h T	At 4 h M	
0	0	4		1	11	
1	1	8		0	9	
2	3	5	$P = 0.001$	8	0	$P < 0.001$
3	1	1		2	0	
4	1	0		4	0

POSTER PRESENTATIONS

Evaluation of an oesophageal intubation detector device using electrical resistance

C. D. Deakin*
Department of Anaesthetics, Queen Victoria Hospital, East Grinstead, West Sussex

Difficult intubation is a common problem with maxillofacial and burns patients. As many as 30% of all deaths attributable to anaesthesia are due to failure to manage difficult airways, particularly unrecognized oesophageal intubation [1]. Several methods of confirming correct tracheal tube (TT) placement have been described [2] but none gives an immediate indication of successful intubation.

An electrical circuit was constructed to measure the resistance of the tissues between the skin overlying the cricothyroid membrane and the tip of the tracheal tube. A small self-adhesive foil patch (1 × 1 cm) was placed on the anterior surface of the cuff of an appropriately sized TT. Soft dental wire was attached behind the foil and run up the body of the tracheal tube. The TT body and wire were wrapped in polytetrafluoroethylene (PTFE) tape. An electrical meter measuring resistance was then attached to the dental wire and the circuit completed by connection to a disposable skin electrode placed over the cricothyroid membrane. The electrical resistance of the dental wire and foil patch alone was $< 0.01\ \Omega$.

Ten patients undergoing routine surgery requiring intubation were studied. After induction of anaesthesia and paralysis with vecuronium, the TT was placed first in the trachea under direct vision and the cuff inflated until any air leak ceased. Correct TT placement was confirmed by capnography. Resistance was measured. The cuff was then deflated and the oesophagus intubated under direct vision. The cuff was reinflated with the same volume of air used when placed in the trachea. A measurement of resistance was taken again. The experimental TT was then withdrawn and a standard TT inserted for the remainder of anaesthesia.

All results are expressed as mean (1 SD). Analysis of electrical resistance was by a single-tailed paired t test.

Five male and five female patients were studied, age 38.9 (16.0), body mass index 25.1 (5.1), neck circumference 36.2 (2.4) cm. The resistance when the TT was placed in the trachea was 65.1 (43.6) kΩ. The resistance when the TT was placed in the oesophagus was 1350.0 kΩ (503.9) $P = 0.0001$ (fig. 8).

There were no complications with this technique.

Measurement of electrical resistance across the tissues of the neck is a new method of detecting correct TT placement. Unlike other techniques, electrical resistance provides an instantaneous indication of tracheal or oesophageal intubation. This technique may have an application in the management of difficult intubation.

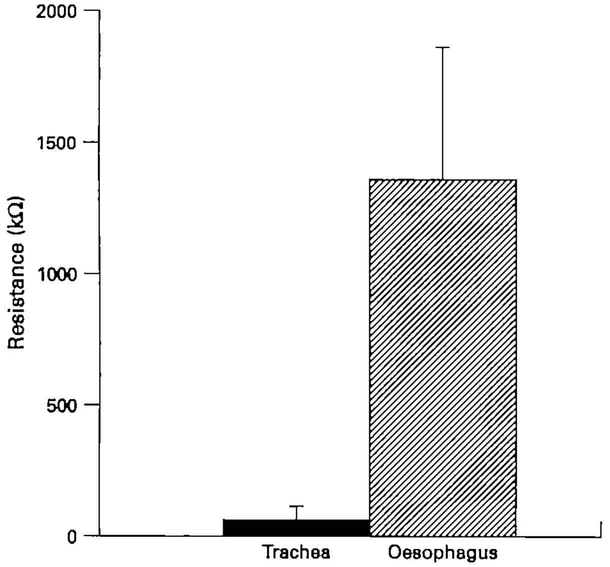

Figure 8 Mean resistance (1 SD) measured from the trachea and oesophagus.

Haemodynamic effects of air travel

I. Malagon
Intensive Care Unit, St James Wing, St George's Hospital, London

Cardiovascular events are the leading cause of death during commercial air travel. It is well known that arterial pressure suffers minimal changes at moderate altitude [1, 2]. Heart rate begins to increase at 4000 ft as a response to hypoxia [3]. This pilot study assesses the changes in cardiac output and stroke volume during air ambulance repatriation. The results show that exposure to moderate altitude during air ambulance transport induces changes in stroke volume not described before.

Five medical crew members and three patients with a median age of 30 (range 26–74) yr agreed to participate in the study. The subjects were transported by commercial air ambulance. Heart rate, ECG, oxygen saturation and arterial pressure were measured. There were no changes in respiratory rate, the ambient temperature inside the cabin remained between 18 and 21 °C, and two of the subjects had oxygen therapy. None underwent ventilation of the lungs.

Cardiac output was measured with suprasternal Doppler. Stroke distance (SD) is the length a column of blood travels along the aorta with each ventricular stroke, and it is equivalent to stroke volume. Minute distance (MD) is the product of stroke distance and heart rate. For the ascending aorta this is a linear index of cardiac output. Each reading is an average of three measurements.

Each patient had a reading taken before take off, 5 min after take off, 5 min after reaching cruising altitude (between 5000 and 8000 ft inside cabin pressure), and 5 min after descent was initiated. Statistical analysis of the results was performed using ANOVA with Scheffe correction. Between-group statistical significance of $P < 0.05$ is individually stated. The results are presented in table 12.

Is the dihydropyridine binding site on neuronal L-type calcium channels a target for i.v. anaesthetic agents?

K. Hirota and D. G. Lambert
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

Previous work from our group has implicated the voltage sensitive calcium channel as a potential target site for i.v. anaesthetic agents [1, 2]. Moreover, there are conflicting reports as to the interaction of anaesthetic agents with neuronal L, N, T or P channels [3]. In an attempt to assess the role of L-type voltage sensitive calcium channels in the process of anaesthesia we have examined the interactions of i.v. anaesthetic agents with the L-channel 1,4-dihydropyridine binding site in rat cerebrocortical membranes.

Rat cortical membranes were prepared in 50 mmol litre^{-1} Tris HCl, pH 7.4 by homogenization and centrifugation. Binding assays were performed in 1 ml volumes of 50 mmol litre^{-1} Tris HCl, pH 7.4 for 90 min at room temperature using approximately 200 µg of protein. Non-specific binding was defined in the presence of 10 µmol litre^{-1} nifedipine and bound and free radioactivity were separated by vacuum filtration. Total number of binding sites (Bmax) and the binding affinity (K_d) were determined by incubating with increasing concentrations (approx. 0.02–2 nmol litre^{-1}) of the dihydropyridine [^{3}H]PN200-110. The effects of anaesthetics were determined by displacing a fixed (0.2 nmol litre^{-1}) concentration of [^{3}H]PN200-110, and the concentration of anaesthetic producing 25 and 50% displacement were corrected for the competing mass of [^{3}H]PN200-110 to yield K_{25} and K_{50}.

The binding of [^{3}H]PN200-110 was dose dependent and saturable with a K_d and Bmax of 59 (5) pM and 152 (14) fmol mg^{-1} protein (mean (SEM), $n = 5$) respectively. With the exception of ketamine all other agents tested showed some interaction with the 1,4-dihydropyridine binding site (table 13).

Although these data supported the general hypothesis that i.v. anaesthetic agents interact with L-type voltage sensitive calcium channels, ketamine appeared inactive. Studies currently under way will determine if these interactions are more marked with a more physiologically relevant model, i.e. depolarized neuronal cells.

Table 13 Effects of i.v. anaesthetic agents on [^{3}H]PN200-110 binding. (Data are mean (SEM). *For both racemic and resolved)

Investigation into the effects of midazolam and propofol on human respiratory cilia beat frequency *in vitro*

H. C. L. Hann and J. H. Raphael
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester

Patients on intensive care receiving intermittent positive pressure ventilation (IPPV) are at risk of developing a chest infection primarily owing to the loss of the cough reflex. To facilitate IPPV it is usually necessary to administer sedative agents, the most frequently used being midazolam and propofol. Related drugs have been shown to impair mucociliary clearance (MCC) [1], an important defence against respiratory infections.

We have investigated the effect of midazolam and propofol on human respiratory cilia beat frequency (CBF), an important determinant of MCC, using the transmitted light technique [2]. Nasal turbinates from 16 patients who had undergone turbinectomy for a primary diagnosis of tissue hypertrophy were used as the source of ciliated epithelium. Ciliated discs, 4 mm in diameter, cut from these turbinates were divided into four groups; one group was exposed to midazolam 20 µmol litre^{-1}, a second group was exposed to propofol 70 µmol litre^{-1} and the final two groups acted as matched controls. The ciliated discs were mounted in modified, specially designed perfusion chambers [3] at 37 °C and connected to a control reservoir containing Hanks' balanced salt solution. The samples were perfused for 30 min, after which time a set of baseline readings of CBF were made (T30). One chamber was then connected to a reservoir containing the drug solution and measurements of CBF were made at T60 and T120 min. The drug exposure was then stopped and a final set of CBF measurements were made at T150 min. The investigator was unaware of which chamber had been exposed to the drug.

Mean CBF (SEM) Hz data for each time point in each experimental group are shown in table 14.

Statistical analysis was performed using MANOVA for repeated measures. Significance was taken at $P < 0.05$ (midazolam, $P = 0.212$; propofol, $P = 0.310$).

We concluded that at the concentrations used in this experiment, there were no significant effects of midazolam or propofol on human respiratory cilia beat frequency *in vitro*.

Table 14 Mean cilia beat frequency (SEM) Hz

Time (min)	Propofol	Control	Midazolam	Control
T30	13.7 (0.7)	11.8 (0.7)	13.8 (0.3)	13.7 (0.3)
T60	12.5 (0.6)	11.2 (0.8)	12.9 (0.3)	14.0 (0.2)
T120	13.6 (0.4)	12.0 (0.6)	13.0 (0.2)	12.9 (0.3)
T150	11.3 (0.7)	11.0 (0.6)	13.8 (0.3)	11.9 (0.3)

Morphine consumption in patients receiving rectal paracetamol and diclofenac alone and in combination

J. E. Montgomery*, I. G. Kestin, J. R. Sneyd and C. J. Sutherland*
Department of Anaesthesia, Derriford Hospital, Plymouth

Diclofenac is frequently used after major surgery in combination with morphine to enhance analgesia and reduce morphine-related side effects [1]. The efficacy of paracetamol in combination with morphine has not been established and as paracetamol and diclofenac have different mechanisms of action their effects may be additive. We have undertaken a randomized, double-blind, trial to assess the effects of paracetamol and diclofenac alone, and in combination, on postoperative morphine use.

Sixty patients, ASA grade I or II, scheduled for elective abdominal gynaecological surgery gave written informed consent. After premedication with temazepam patients were anaesthetized with thiopentone, morphine up to 0.2 mg kg^{-1} i.v., vecuronium, nitrous oxide and enflurane. Residual neuromuscular block was antagonized with glycopyrrolate and neostigmine. After induction of anaesthesia and before surgery patients were given suppositories of either 1.5 g paracetamol (P), $n = 20$, or 100 mg diclofenac (D), $n = 20$, or a combination of 1.5 g paracetamol and 100 mg diclofenac (C), $n = 20$. In recovery the patients received further boluses of i.v. morphine if required and were then given a patient-controlled analgesia system (PCA) programmed to give a bolus of 1 mg of morphine with 50 μg droperidol, a 5-min lockout and no background infusion. Cumulative morphine use was recorded at hourly intervals for 24 h.

One patient in group C was excluded from the analysis as she was unable to use the PCA owing to intractable vomiting. Morphine consumption was greatest in group P and lowest in group C (fig. 9).

Paracetamol may augment diclofenac analgesia. However, a larger study is needed to test this hypothesis.

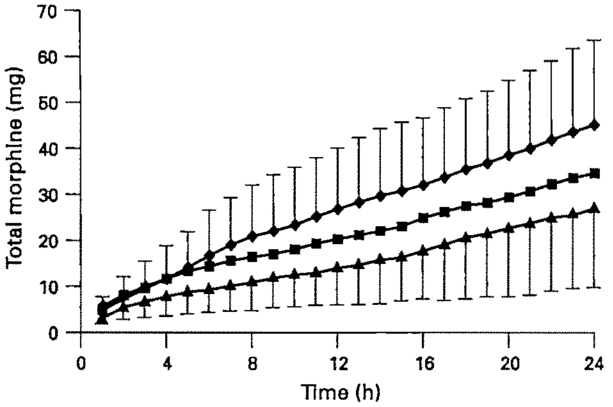

Figure 9 Morphine consumption, mean (SD). For clarity group D (■, diclofenac) error bars are omitted. The difference in morphine consumption between groups P (◆, paracetamol) and C (▲, paracetamol and diclofenac) is significant from 6 to 24 h, $P < 0.05$ ANOVA.

Key words

Effects of desflurane and isoflurane on splanchnic microcirculation during surgery

H. O'Beirne and M. C. Bellamy

Departments of Anaesthesia and Intensive Care, St James's University Hospital, Leeds

Isoflurane has been considered the agent of choice where preservation of splanchnic blood flow is required. Liver blood flow and hepatic artery buffer response are known to be maintained better in the presence of isoflurane than other volatile agents. Effects of desflurane have not been assessed in humans. We have, therefore, compared effects of isoflurane and desflurane anaesthesia on small bowel and hepatic microcirculatory flow during major surgery in humans using laser Doppler flowmetry.

Ethics Committee approval was obtained for this prospective randomized single-blind crossover study. Ten adult patients undergoing major upper abdominal surgery gave informed consent. After premedication with temazepam 20 mg, anaesthesia was induced with thiopentone 3 mg kg^{-1} and fentanyl 3 μg kg^{-1}. Neuromuscular block was facilitated by infusion of atracurium. Patients were randomized to receive desflurane or isoflurane (1 MAC) in oxygen-enriched air. Lungs were ventilated to normocapnea. Steady-state jejunal and liver blood flow in segment III or IV were assessed by laser Doppler flowmetry at steady state (after 30 min inhalation of agent and F_{I}agent/expired agent < 1.1). Volatile anaesthetics were then interchanged, and measurements repeated at steady state. Data were analysed using paired Wilcoxon rank sum test and multiple regression analysis.

Results are expressed as median (interquartile range). There were no differences in MAP, CVP or heart rate between periods breathing the two volatiles (table 15).

We have shown that during major surgery in humans, desflurane anaesthesia at 1 MAC was associated with significantly greater gut blood flow than 1 MAC isoflurane. These differences could not be explained by overall haemodynamic differences. Gut blood flow accounted for 85% of the variability in liver blood flow. This suggested that liver blood flow in this model was largely portal in derivation. The lack of difference in total hepatic flow between groups implied an intact hepatic artery buffer response. These results may have important implications for anaesthesia in high-risk surgical patients.

Table 15 Multiple regression described liver blood flow as (1.3 × gut blood flow) − 24, $P < 0.0001$, $r^2 = 0.85$

	Median blood flow (IQ range) perfusion unit	P value
Gut		
isoflurane	94 (75–154)	0.02
desflurane	186 (146–262)	
Liver		
isoflurane	137 (58–168)	0.26
desflurane	175 (54–453)

Effect of cooling on the force of contraction of rat and guineapig phrenic nerve hemidiaphragm preparations

A. J. England, K. Richards and S. A. Feldman

The John Hammond Department of Anaesthesia, East Surrey Hospital, Redhill and The Magill Department of Anaesthesia, Chelsea and Westminster Hospital, London

Previous researchers observed that cooling increases the force of contraction elicited from rat and hamster neuromuscular preparations. However, at temperatures below 10 °C failure of contraction with indirect but not direct stimulation occurs [1]. In evolutionarily more sophisticated animals, such as the dog and humans, the threshold at which the force of neuromuscular contraction starts to decrease with indirect stimulation is close to normal body temperature [2, 3]. This experiment was performed to compare the neuromuscular responses during cooling of the guineapig phrenic nerve hemidiaphragm with those of the rat.

Phrenic nerve hemidiaphragm preparations from freshly killed (carbon dioxide asphyxiated) male Wistar rats (300–400 g) or male Dunkin Hartley guineapigs (300–400 g) were suspended in Kreb's solution maintained at 37 °C. They were pretensioned to 8 *g* and, after stabilization, either indirect or direct supramaximal square wave stimuli were applied. The isometric force of contraction was measured at 5 °C intervals between 17 °C and 37 °C. The force of contraction at 37 °C was referenced as 100% for each experiment and the percentage change in force with temperature was calculated. The mean (SE) referenced force at each temperature was calculated. The changes in referenced force of contraction with temperature was calculated using linear regression (SE).

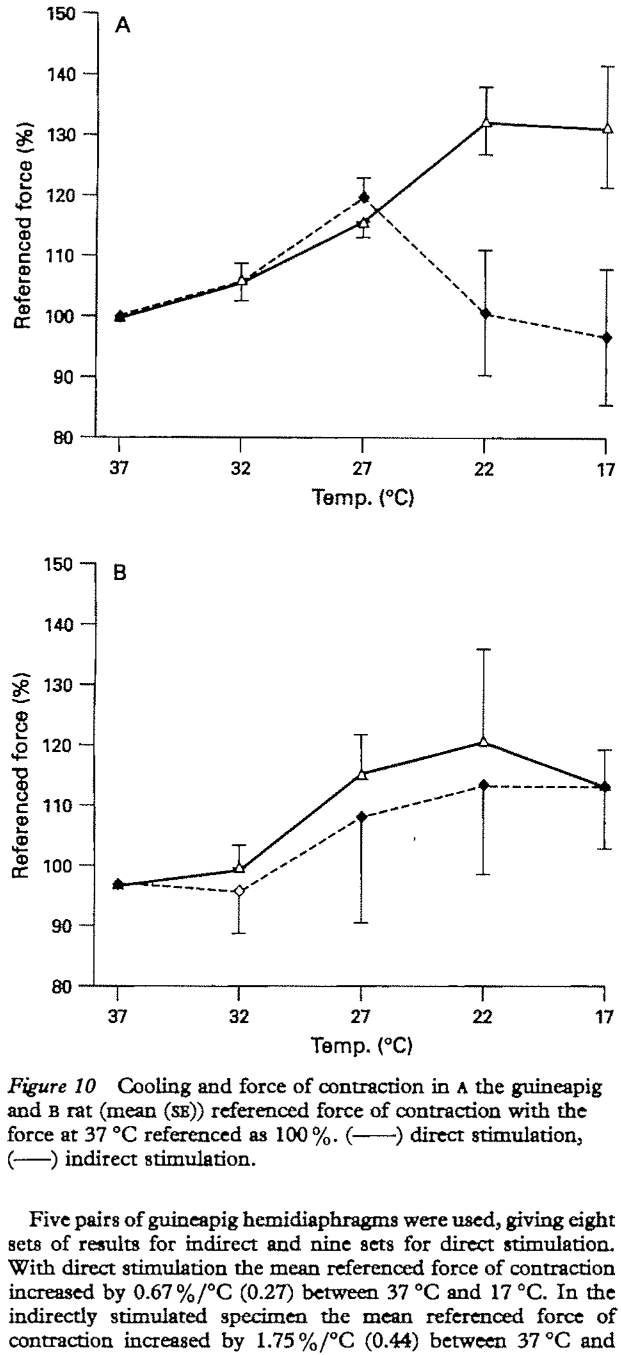

Figure 10 Cooling and force of contraction in A the guineapig and B rat (mean (SE)) referenced force of contraction with the force at 37 °C referenced as 100 %. (——) direct stimulation, (——) indirect stimulation.

Five pairs of guineapig hemidiaphragms were used, giving eight sets of results for indirect and nine sets for direct stimulation. With direct stimulation the mean referenced force of contraction increased by 0.67 %/°C (0.27) between 37 °C and 17 °C. In the indirectly stimulated specimen the mean referenced force of contraction increased by 1.75 %/°C (0.44) between 37 °C and 27 °C, but between 27 °C and 17 °C the force of contraction fell by −1.75 %/°C (1.08).

Five pairs of rat hemidiaphragms were used, giving six sets of results for indirect and light sets for direct stimulation. Between 37 °C and 17 °C the mean referenced force of contraction increased by 1.2 %/°C (0.25) in the direct and 1.1 %/°C (0.34) in the indirectly stimulated specimens.

Cooling to 17 °C enhanced directly and indirectly elicited force of contraction in the rat phrenic nerve diaphragm preparation predominantly by an increased contractility in the muscle. In a similar guineapig preparation moderate hypothermia also enhanced muscle contractility. However, below a threshold at about 27 °C failure of transmission of indirectly applied stimuli developed. This threshold lies at a temperature intermediate between that found by other researchers for the rat and hamster (below 10 °C) [1] and that for the dog [2] and humans [3] (above 32 °C) (fig. 10).

Use of regional i.v. morphine analgesia in patients undergoing total knee arthroplasty

A. R. CORBETT AND J. WISNEWSKI
Department of Anaesthesia, Fremantle Hospital, Fremantle, Western Australia, Australia

While there is substantial experimental evidence [1] for the existence of peripheral opioid receptors the studies looking at clinical applications have been equivocal. Feldman, in an anecdotal report, described decreased postoperative pain after i.v. regional morphine analgesia in major knee surgery [2]. This randomized double-blind placebo controlled study was designed to evaluate any improvement in postoperative analgesia using this technique.

Twenty-four ASA grade I, II or III patients undergoing elective unilateral total knee arthroplasty under tourniquet control were studied. Patients were allocated randomly to two groups. Group A received 50 ml of normal saline (placebo), group B received 5 mg of morphine in 50 ml normal saline. Patients with a previous history of reaction or hypersensitivity to morphine or other opioid derivatives were excluded.

After induction of general anaesthesia using a standard regimen a 22-gauge cannula was inserted into a dorsal foot vein aseptically. The limb was exsanguinated and an arterial tourniquet inflated to 350 mm Hg. The test solution was injected and the cannula removed. Anaesthesia was maintained with isoflurane and nitrous oxide with incremental vecuronium and fentanyl as required.

In the recovery room the patient received 1 mg i.v. boluses of morphine until they were pain-free and then patient-controlled analgesia (PCA) was used for the first 48 h. This provided a 1-mg bolus of morphine with a lockout time of 5 min. Analgesic requirements and visual analogue scores (VAS) were recorded at 0, 0.5, 1, 2, 4, 6 h and every 6 h thereafter. PCA was discontinued when clinically indicated.

Patient groups were well matched for demographic data and technical factors affecting postoperative pain. Eleven patients received placebo, 10 received morphine. Two patients were withdrawn from the control group, one owing to inability to use PCA and the other to incomplete data collection. One patient was withdrawn from the morphine group for surgical reasons.

There were no significant differences between the mean dose of intraoperative fentanyl, 240 µg (175–300 µg) in the placebo group and 257.5 µg (150–375 µg) in patients receiving morphine, or nurse-administered morphine 3.9 mg (0–11 mg) and 3.3 mg (0–10 mg) respectively.

Analysis of the results found no significant differences between the VAS pain scores or in the amount of PCA morphine used (table 16).

Table 16 Patient-controlled morphine dose (mean (SD))

	Time (h)				
	6	12	24	36	48
Placebo group (mg)	15.5 (4.68)	22.0 (7.32)	35.7 (13.71)	47.2 (21.60)	61.0 (38.05)
Morphine group (mg)	19.5 (6.31)	25.6 (9.42)	49.1 (20.11)	69.3 (26.89)	84.3 (27.54)

This study found i.v. regional anaesthesia with 5 mg of morphine did not decrease the pain scores or requirement for postoperative analgesia in patients undergoing total knee replacement.

CORRESPONDENCE

Psychological characteristics and patient-controlled analgesia

Sir,—Dr McConaghy writes [1] requesting clarification of some aspects of our study of psychological characteristics and patient-controlled analgesia [2]. We are grateful to Dr McConaghy for his appreciation of the importance of our findings for anaesthetists involved in the management of acute postoperative pain. He suggests that the anaesthetic technique may have been insufficiently standardized because "the analgesic component consisted of either fentanyl or papaveretum, together with an opioid premedicant (either pethidine or papaveretum)" and that the timing of intraoperative opioid may have affected consumption of postoperative analgesics. Further, he suggests that we chose to compare an inefficient i.m. regimen when an hourly "as required" regimen has been shown to be safe and effective [3]. With regard to premedication, as stated in the article, the majority (90 of 110) of patients received temazepam and some of the remainder received lorazepam; the few patients who received opioid premedication were approximately equally distributed between the groups, and therefore it is unlikely that this had any significant effect in this fairly large study. They received opioids because of occasional preoperative assessment by trainee anaesthetists who had been taught to use opioids during their previous appointments.

The other concerns are appropriate but must be viewed in the context of when and where this study was performed. It was for this reason that we gave the dates (1988–90) of the study. In planning the study it was necessary to obtain the co-operation of the career anaesthetists who regularly anaesthetized such patients. In a district hospital without a major research programme, individual clinicians are unaccustomed to modifying their clinical techniques in the interests of research. Two consultants were unable to agree: one because the study required that patients would not know before operation what pain relief regimen they would be prescribed, the other because it was his practice to use trichlorethylene for intraoperative analgesia–anaesthesia and he was not prepared to change to either fentanyl or papaveretum. The other anaesthetists normally used either fentanyl or papaveretum as a bolus dose immediately after induction of anaesthesia, with occasional increments if indicated clinically during the procedure. We felt that these techniques were sufficiently alike, together with randomization of patients, to ensure the absence of bias.

The problem of the effectiveness of the standard 4-hourly i.m. regimen is somewhat similar. For many years one of us has advocated shorter intervals but, at the time the study was planned (early 1988), colleagues were unwilling to change. Ethics Committee approval was obtained on the basis of the two regimens in routine use in the hospital. Our judgement was confirmed by the Cardiff study [3] but this was published long after our study was complete.

Ulnar and common peroneal nerve block revisited

Sir,—There has been much recent discussion in this journal on the incidence and mechanisms of nerve injury after local anaesthetic block [1, 2]. However, little attention has focused on particular blocks. After discussions of the advantages and disadvantages of ulnar nerve block at the elbow and common peroneal nerve block at the head of the fibula, we decided to investigate the evidence for and against these two nerve blocks.

It is commonly taught that the ulnar nerve should not be blocked at the elbow. The nerve is palpable as it runs around the medial epicondyle and is easily accessible at this point. However, it is said to be protected by a thick fibrous epineurium and therefore intraneural injection may be required to allow adequate axonal block, risking neuritis. Some standard texts reinforce this view. Bridenbaugh states: "block of the ulnar nerve at the elbow is often said to lead to residual neuritis" [3]. This is similarly described by Löfström [4]. Likewise, the common peroneal nerve is easily palpable at the head of the fibula and for similar reasons it is stated that block at this landmark carries a "considerable risk of post-anaesthetic neuritis" [5]. However, elsewhere these risks are not mentioned and the blocks described at these sites [6].

This variation in advice prompted us to carry out a comprehensive literature search to identify case reports of nerve damage after the two blocks. A Medline search back to 1966 revealed no case reports of ulnar or common peroneal neuropathy after block at the elbow or head of fibula. We then searched through textbooks on regional anaesthesia dating back to 1922 and could find no reports of such neuropathies. In fact the earlier texts described how to perform these blocks [7]. Furthermore, neuropathies are relatively common after anaesthesia and surgery and have been reviewed extensively, providing information on their aetiology. Ulnar neuropathy is the most common mononeuropathy in this situation and a study of closed malpractice claims by the American Society of Anesthesiologists found 77 cases of ulnar neuropathy from a total of 227 cases of nerve damage [8]. In the majority of cases the causative mechanism was unknown. Regional anaesthesia was uncommon but tended to be central or plexus block, and there was no mention of ulnar nerve block at the elbow. Another retrospective study reviewed the postoperative courses of 1129692 surgical patients undergoing non-cardiac surgery and found 414 cases of ulnar neuropathy [9]. This was associated with male gender, abnormally high or low body mass index and prolonged hospital stay. It was not associated with regional anaesthesia in general or ulnar nerve block in particular.

It would be wise to perform these blocks meticulously and only in awake patients to minimize the risk of intraneural injection. However, in this era of evidence-based medicine, there is nothing to support the contention that these nerve blocks are associated with neuritis. Should we therefore disallow ourselves the advantages presented by the convenient anatomy of these nerves?

Nebulized lignocaine before gaseous induction with desflurane

Sir,—I read with interest the recent study by Bunting, Kelly and Milligan [1] illustrating the failure of nebulized lignocaine to suppress airway irritation during gaseous induction with desflurane. The results of this study are alarming, and provide further evidence against the use of desflurane as an induction agent.

However, I am concerned that the authors have failed to document the duration of administration of the nebulized solution (4 % lignocaine or 0.9 % saline), nor formally tested the airway for the absence of reflexes (e.g. gag reflex) before administration of desflurane. It is therefore possible that insufficient time was allowed for the onset of action in those given lignocaine.

While the use of lignocaine in providing topical anaesthesia to the airway has been studied widely, the onset time of nebulized lignocaine is poorly documented. The information available in standard texts suggests an onset time of 5 min or less [2,3]. However, Vuckovic and colleagues [4] administered 4% lignocaine via a nebulizer (4–6 ml in total) for up to 7 min and found that 10% of patients required additional nebulized lignocaine after formal testing of upper airway reflexes. These findings suggest a variable onset of action which can only be proved by the absence of upper airway reflexes.

The "blinded" nature of the authors' study has precluded formal testing of the airway, making any assumption of the efficacy of nebulized lignocaine in decreasing respiratory responses during gaseous induction with desflurane misleading. Allowing sufficient time for verifiable onset of action may yet show this technique to be a useful adjunct to gaseous induction with desflurane.

4. Vuckovic DD, Rooney SM, Goldiner PL, O'Sullivan D. Aerosol anesthesia of the airway using a small disposable nebuliser. *Anesthesia and Analgesia* 1980; 59: 803–804.

Sir,—In our study we did not formally assess upper airway reflexes before induction of anaesthesia with desflurane. The site of initiation of reflexes with desflurane is unknown, but may be the sensitive larynx or smaller airways. We used a nebulizer and oxygen flow rate which produce particles small enough to reach the larynx and smaller airways so that they are not all deposited in the oral cavity and oropharynx. Rapid, simple tests would have permitted assessment of the oral cavity and gag reflex, but not the larynx and respiratory tree in which we were interested. It was not our intention to anaesthetize the airway completely, as for intubation, but to administer doses which, when given by nebulizer, have been shown to obtund circulatory responses to laryngoscopy and reduce respiratory responses to airway irritation. Assessment of upper airway reflexes may have caused airway irritation before induction of anaesthesia, particularly in the control group, and may therefore have influenced the cardiorespiratory responses to induction with desflurane, in which we were interested.

Using a Hudson AVA NEB and an oxygen flow rate of 8 litre min^{-1}, nebulization of 4 % lignocaine 4 ml requires approximately 8 min and 6 ml requires approximately 15 min. Although we cannot be certain that the dose of lignocaine or time for onset of action was adequate in all cases, the work of Vuckovic and colleagues [1] would suggest that these were sufficient in 90 % of cases.

We state that the conclusions regarding the effects of nebulized lignocaine refer only to the dose and method of administration used in this study. It is possible that different techniques and doses of lignocaine would yield better results.

Factors governing onset of neuromuscular block

Sir,—Audibert and Donati's article [1] demonstrated the phenomenon first reported by Hood, Campkin and Feldman [2], Campkin and Hood [3], and Feldman [4] that an increase in non-depolarizing block occurs despite cessation of drug delivery from the circulation. Hood, Campkin and Feldman [2] used a 0.1 × ED_{95} drug dose injected into the isolated forearm of conscious volunteers and released the tourniquet during onset at 50 % block. We found that the non-depolarizing blocks progressed to a much greater degree, and over a much longer time scale, than that of decamethonium; the results are shown in figure 1.

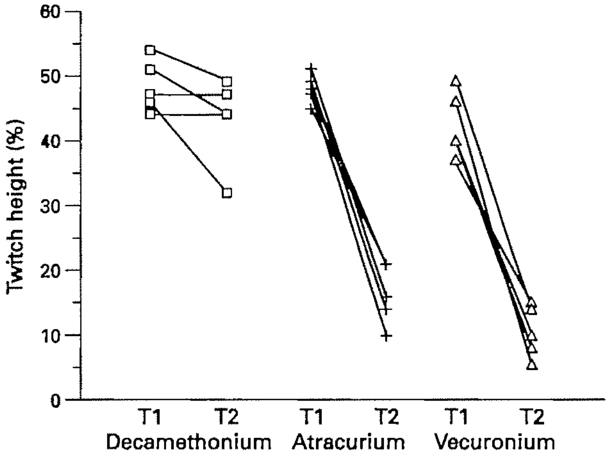

Figure 1 Isolated forearm blocks after decamethonium 0.15 mg, atracurium 2 mg and vecuronium 0.3 mg. These doses produced similar rates of onset before tourniquet release. Mean time courses of the increase in block after tourniquet release were 3.26 (SD 0.24) min for vecuronium, 2.6 (0.43) min for atracurium and less than 4 (4) s for decamethonium.

The isolated forearm is akin to a Bier's block: drug is flushed from the arm after tourniquet release, and recirculation of drug is not the cause of any subsequent increase in block [5]. Audibert and Donati's technique of inflating a tourniquet during onset of systemic block would presumably trap drug-containing blood in the arm. We suggest that transfer of drug from this reservoir would account for some of the subsequent increase in block thereafter and, in particular, that of suxamethonium over approximately 3 min, because intra-arterial administration of agonists reveals little delay in onset of block. While Bartowski and colleagues [6] observed that small doses of intra-arterial vecuronium took 1.39 min to achieve 90 % of maximum effect, Bacq and

Brown [7] found that acetylcholine achieved maximal block in 10 s.

We believe the sum of this previous work contradicts Audibert and Donati's explanation of their results. The suggestion that their observed increase in both suxamethonium and vecuronium block was caused by a common mechanism (drug transfer from the extracellular fluid to the junction) would appear unlikely unless some other differential existed. The likelihood that the two classes of drug achieve effect at very different receptor occupancies does not provide that differential, in our opinion.

The relationship between receptor occupancy and biophase drug concentration is described by a rectangular hyperbola. Non-depolarizing drugs, effective at 80% occupancy, are on the flat part of the curve, while suxamethonium, perhaps effective at less than 10% occupancy, is on the steep part. For equal percentage increases in biophase concentration, the latter has a much greater increase in percentage receptor occupancy than the former. Yet Audibert and Donati found a smaller increase in depolarizing block than non-depolarizing block after cessation of the blood supply to the arm, and we found a more marked difference between the two classes of drug (fig. 1). Some mechanism would appear to exist which produces the difference between the two classes of drug.

Buffered diffusion has been suggested by the authors as the mechanism causing the delay in onset of non-depolarizing drugs. However, it is not clear why depolarizing drugs should not also be subject to this process and so buffered diffusion alone would not appear to explain their shorter onset time occurring from intra-arterial or isolated forearm delivery.

We suggest that non-depolarizing drugs undergo extensive binding in the junction with non-specific biophase binding sites. These provide a reservoir which limits ingress [8] and egress [9, 10] from the junction at a specific rate for each drug. The studied depolarizing drugs do not act in the same way [11] which allows recovery from block with these agents to be affected by blood flow [12].

The authors' important conclusion is that redistribution of drug *within the muscle* may place intrinsic limits on the speed of onset of action of non-depolarizing drugs. Whatever the cause of this delay in transfer of drug between blood and biophase (suggested 25 yr ago [11]) its elucidation will aid the development of a safe non-depolarizing equivalent of suxamethonium.

Sir,—We thank you for the opportunity to respond to the letter of Feldman and Hood. In our view, there is no contradiction between the results of the isolated arm experiments [1–3], the delay observed after intra-arterial injection of drug [4] and our results [5]. A single explanation can account for all observations. In our article [5], we suggested diffusion of molecules from extrajunctional to junctional sites. Feldman and Hood prefer to talk about a reservoir. Both concepts are essentially the same. They provide for transfer of drug to the neuromuscular junction in spite of interruption of blood circulation. The only assumption that has to be made is that the affinity for this extrajunctional site or for the reservoir is less than the affinity for the neuromuscular junction. As a result, the concentration of the drug increases more rapidly in the extrajunctional sites or reservoir during onset.

In the isolated arm experiments, drug is injected i.v., distal to a cuff inflated above arterial pressure. Diffusion to high affinity sites (the neuromuscular junction) takes longer compared with other sites. If the cuff is released during onset, the concentration of drug at extrajunctional sites (the majority of the tissue) is greater than at the junction. Thus, on release of the tourniquet, transfer of drug from a high concentration area to a low concentration area (the junction) is possible, and neuromuscular block increases. In the intra-arterial injection experiments, drug concentration in plasma is presumed to be zero at all times, except for a large increase during injection. This drug has access to junctional and extrajunctional tissue. At the end of injection, its concentration is less at the junction because the affinity for junctional tissue is greater. Thus, drug is free to move along its concentration gradient, allowing block to increase after injection is finished. In our experiments, where the tourniquet was inflated during onset, the situation was the same. Drug had access, via arterial blood, to both junctional and extrajunctional areas. According to the same logic, the concentration of drug increased more rapidly in the latter. When the tourniquet was inflated, drug transfer occurred between extrajunctional areas and junctional areas, thus increasing neuromuscular block.

The reasons for the different affinity for both sites cannot be elucidated from these experiments, but there are data which give a few hints. Feldman, Xu and England [3] reported that decamethonium, atracurium and vecuronium behaved differently when the tourniquet used in the isolated arm experiments was deflated prematurely. Onset continued for the non-depolarizing drugs, but not for the depolarizing drug. We found the same, using a different mode of drug delivery, and interrupting delivery in a different way. Based on the above explanation, one has to conclude that the affinity of depolarizing drugs for junctional and extrajunctional tissue is approximately the same, while the affinity of atracurium and vecuronium for both types of tissue is different.

Feldman and Hood suggested that non-depolarizing drugs *undergo extensive binding in the junction with non-specific biophase binding sites*. We suggest that these sites need not be non-specific and may be the junctional receptors themselves. Binding of depolarizing drugs would be much less extensive, if they are effective at a lower proportion of receptor occupancy. Also, our hypothesis suggests that, for non-depolarizing drugs, the extent of binding depends directly on potency. This hypothesis was tested in another set of experiments which showed that for rocuronium, a less potent drug than vecuronium or atracurium, block is affected in much the same way as suxamethonium by tourniquet inflation. This result is also explained by the mechanism of buffered diffusion, which predicts that high affinity drugs (potency is a measure of affinity) have a slower onset [6].

Effects of propofol and isoflurane on right ventricular function

Sir,—We read with interest the article by Kellow and colleagues [1]. It would appear that they have not noticed our article [2] published over a year ago, which also studied the effects of propofol and isoflurane on right ventricular function. Interestingly we came to the opposite conclusion. Using a within-patient crossover design, we found that cardiac index and right ventricular ejection fraction were significantly higher when propofol was given for maintenance of anaesthesia compared with isoflurane. We found no differences in end-systolic volume index between the two agents, but agree with Kellow's study that end-diastolic volume was significantly higher with propofol. The differences in results probably reflect differences in the experimental design, although it is not possible to exclude differences in the populations studied.

In all studies comparing the effects of two anaesthetic agents on the function of a specific organ it is vital that equipotent or equivalent anaesthetic doses of the two agents are used for the comparison. Furthermore, comparisons must only be made when steady state anaesthesia with these equipotent doses has been achieved. Kellow and colleagues seem to have compared two "...generally accepted techniques...", whereas we took considerable care to compare similar anaesthetic doses of propofol and isoflurane, by using the same numerical values of minimal infusion rate for propofol and minimal alveolar concentration for isoflurane for each patient [3].

It is particularly important that observations on cardiac function are made during periods of steady state anaesthesia. It is likely that plasma concentrations of isoflurane and propofol were not constant for the measurement times in the current study. It is known that the inspired concentration of a volatile agent does not have a relationship to blood or brain concentrations, without taking into account other factors, particularly time. It appears from the study design that a constant inspired concentration of isoflurane was given throughout. This is likely to have resulted in greater brain concentrations of isoflurane at the end of operation than at the first datum point 20 min after starting isoflurane, implying that isoflurane concentrations and anaesthetic depth were not constant in the isoflurane group throughout the study. Similarly, kinetic models for plasma concentrations of propofol related to infusion rate take into account the age and weight of the subject [4]. In Kellow's study it appears that the age of the patient was not considered in controlling the propofol infusion rate, and no attempt was made to estimate plasma concentrations which continue to increase if a constant infusion rate is used. Consideration of both of these effects are accepted techniques for propofol infusion regimens [4].

Finally, and perhaps most importantly, in any study considering right ventricular function, it is vital that venous preload is standardized, and the same, in both groups, and that these filling pressures are maintained throughout the study. It is generally accepted practice to use right atrial pressure as a measure of preload. The authors did have this information available, as they were using a REF-1 pulmonary artery catheter, but they have not presented the data. Interestingly they gave only the changes in end-diastolic volume. In our study we have shown this to change, despite constant filling pressure, as compliance changed in response to propofol. Using end-diastolic volume, although there were no differences within each group over time, there were significant differences between the groups. Therefore, comparisons of cardiac function between the groups may not be appropriate.

We agree that it is difficult to compare two anaesthetic agents, particularly when they are given by different routes. Kellow's study showed that with the procedure used, propofol and isoflurane have different effects on right ventricular function. However, the experimental conditions may not have been equivalent for each agent, because of the difficulty in comparing the anaesthetics, and lack of standardization of anaesthetic administration over time and right ventricular filling pressures. We suggest that their study regimen may not have been appropriate to compare these two anaesthetic agents.

BOOK REVIEWS

Neuro-anaesthetic Practice. H. VAN AKEN (editor). Published by BMJ Publishing Group, London. Pp. 305; indexed; illustrated. Price £29.95.

This book forms part of a series on fundamentals of anaesthesia and acute medicine published by the BMJ publishing group. It is priced very competitively compared with other books on neuroanaesthesia intended for trainees preparing for examinations, and established neuroanaesthetists wishing to update their knowledge.

The chapters are written by contributors from several centres in Europe and North America, and include physiology and metabolism of the central nervous system, neurological diseases in the intensive care unit, radiological study of lesions of the central nervous system, anaesthetic agents, fluid management in neurological patients, intraoperative and postoperative monitoring of the CNS for neurosurgery, intraoperative and postoperative positioning of the neurosurgical patient, anaesthetic management of aneurysms and arteriovenous malformations, anaesthetic conditions for specific neurosurgical procedures, management of acute head injury and brain protection, and brain death.

The majority of chapters are well written and provide a good review of the subject matter, but there are several spelling mistakes and factual inaccuracies which spoil the flow of the text and may confuse the reader. A better title for chapter 2 would be "Neurological diseases encountered by neuroanaesthetists". This chapter is too long and I question the need to include details on fixation of pathology specimens and histological changes associated with ischaemia. However, the description of tumours and their classification provides a good reference source for neuroanaesthetists. The chapter on radiology is pitched at the right level for trainee and established neuroanaesthetists but anaesthetic considerations are not discussed. The reasons for including a chapter on intraoperative and postoperative positioning are not clear because this topic could be dealt with more effectively in the chapters on anaesthetic management of the various neurosurgical procedures. The chapter on anaesthetic considerations for specific neurosurgical procedures lacks sufficient detail for preparation for examinations or for reference purposes. In particular, the stages of spinal shock and hyperreflexia after spinal cord transection are not differentiated clearly.

This book provides good up-to-date reviews of many areas of neuroanaesthetic practice which established practitioners with an interest in neuroanaesthesia and neurointensive care will find useful. It is less suitable for trainee anaesthetists preparing for examinations because it is too detailed in some areas and lacks important details and accuracy in others. Although considerably more expensive, ***Anaesthesia and Intensive Care for the Neurosurgical Patient*** gives a better overview of the subject for the trainee preparing for the part 3 FRCA examination.

E. Moss

Intensive Care: A Concise Textbook, 2nd Edn. C. J. HIND AND D. WATSON. Published by W. B. Saunders, London. Pp. 477; indexed; illustrated. Price £29.95.

This book is aimed at doctors in training, both as an introduction to the practice of intensive therapy for anaesthetists and also for surgical or general medical trainees who are increasingly expected to have an understanding of the principles of management of the critically ill patient. This is a difficult task for a book of this size, but one that it achieves admirably.

The authors have drawn on the talents of several other experts, all working in the UK, to produce a well organized, concise and informative book. The text is supplemented with clear diagrams, tables and radiographs. The index is comprehensive and there are ample references at the end of each chapter. This book also includes brief, illustrated advice on the practical techniques of radial artery cannulation and placement of internal jugular catheters and chest drains.

The first chapter, "Planning, organizing and management", might have been titled better, as it includes the equally important topics of outcome and severity scoring systems. Many of the 20 chapters cover individual organ systems, such as the gastrointestinal and endocrine systems, but there are also separate chapters on infection, trauma, poisoning, the obstetric patient, disturbance of body temperature and transport of the critically ill. In addition, there are excellent chapters devoted to shock, applied cardiovascular and respiratory physiology, and assessment and monitoring of these systems, including the newer non-invasive investigations of cardiac function. The section dealing with sources of error in intra-arterial monitoring could perhaps have been expanded to include greater discussion on critical damping.

The chapter on "General aspects" is perhaps the only weak area in this book; it covers the often neglected topics of nutritional support, which probably deserves a chapter on its own, and sedation. Other important areas such as stress ulceration and thromboembolism are also covered here. The latter topic would have benefited from more discussion on the difficulty of diagnosing pulmonary embolism in the critically ill patient.

However, these are only minor criticisms of an excellent book. It achieves exactly what its authors set out to do. It will also be very useful for consultants when they are preparing tutorials and teaching sessions for trainees. Anaesthetic trainees should consider it essential reading and it deserves a place in every intensive therapy unit's library.

R. Wenstone

Handbook of Neonatal Anaesthesia. D. G. HUGHES, S. J. MATHER AND A. R. WOLF (editors). Published by W. B. Saunders, London. Pp. 387; indexed; illustrated. Price £22.50.

It is widely accepted that neonatal anaesthesia should be carried out only in hospitals that have the necessary specialized facilities and staff. It is perhaps unfortunate that it is not until page 165 of this handbook that the need for such specialist facilities is mentioned, and that at least one of the contributors appears to condone the practice of occasional neonatal anaesthesia. The book does, however, succeed in tackling the difficult task of presenting the essentials of such a specialized subject. Despite its small (approximately A5 size) format, its 15 chapters present well balanced coverage of both general principles and practice. Topics covered include physiology and pharmacology, general and regional techniques for most aspects of neonatal surgery, including cardiac surgery, monitoring, postoperative respiratory management, transport and resuscitation. Although most of the authors are British, others come from France, Canada, South Africa and the USA, and there is an interesting view from the developing countries. The important chapter on specific surgical conditions provides a useful consensus of views from around the world.

It is perhaps not surprising that some topics, such as aspects of physiology, are covered rather superficially, but there are remarkably few omissions. New drugs such as sevoflurane and rocuronium are mentioned, and all chapters are readable and comprehensively referenced. It is slightly irritating to find different doses of drugs such as thiopentone recommended in different chapters, and different formulae for calculating "acceptable blood loss". The suggestion that hypocapnia can be prevented by adding carbon dioxide to the fresh gas flow is not in line with current UK practice, and the recommendation that tracheal tubes should be inserted to the end of the black line, mentioned by several authors, applies only for some makes of tube. Some aspects of the chapter on the very premature infant, such as details of surfactant therapy, are of more value to a neonatologist than an anaesthetist, while elsewhere the intensive care management of congenital diaphragmatic hernia is stated to be beyond the scope of the text. However, many of the chapters are surprisingly comprehensive for a book of this size. Although this handbook does not contain enough detail for the aspiring neonatal anaesthetist, it does provide a useful introduction to the subject. I am sure it deserves a place in departmental libraries, and many anaesthetists will purchase their own copies.

EDITORIAL I

Perioperative inadvertent hypothermia: what do we need to prevent?

A non-intentional decrease in core temperature is by far the most common perioperative thermal disturbance, resulting from a combination of impaired thermoregulation and exposure to a cold microclimate.

Hypothermia during anaesthesia and surgery is characterized by an initial rapid decrease in core temperature (0.8–1.0 °C) followed by a slow linear decrease [1]. After 3–4 h of anaesthesia, the decrease stabilizes at approximately 34–35 °C, indicating a thermal state where body heat production equals heat loss.

Several studies have shown the immediate and delayed consequences of mild intraoperative hypothermia on organ function, such as excessive sympathetic stimulation [2,3], interference with drug metabolism [4], modified platelet activity [5], altered immune system with impaired wound healing [6] and increased postoperative breakdown of muscle protein [7,8]. However, from these data we cannot conclude that hypothermia *per se* is responsible for an adverse outcome.

Residual hypothermia at the end of surgery leads to shivering [9], increased circulating concentrations of plasma catecholamines, increased oxygen consumption and exaggerated haemodynamic responses [10]. These findings provide a possible mechanism for the hypothermia-related myocardial ischaemia reported in the period after major surgery [11].

A logical approach to unintentional hypothermia is to prevent it from occurring. This can be achieved to some extent by prewarming the patient's skin surface before induction of anaesthesia [12] or warming the inner and outer parts of the body throughout the course of anaesthesia and surgery [2, 8]. Most preventive methods aim to reduce the temperature gradient between patients and their immediate environment, thus minimizing heat loss via all routes (radiation, convection, conduction and evaporation) [13]. If these preventive measures are relatively unsuccessful in maintaining normothermia or are not easily instituted, the anaesthetist may use the alternative strategy of vigorously treating the residual heat debt by either pharmacological (opioids, vasodilators) or physiological (cutaneous warming) measures [14].

In a recent issue of the journal, Selldén, Bränström and Brundin [15] proposed a novel therapeutic approach to prevent perioperative hypothermia. They infused a mixture of amino acids i.v., before and during anaesthesia and surgery, with the aim of stimulating heat generation and whole body oxidative metabolism that otherwise would be depressed as a result of anaesthesia. The authors believed that such stimulation, started before anaesthesia and maintained during surgery, would counteract the perioperative loss of body heat and maintain the patient normothermic.

The thermic effect of feeding (also termed nutrient- or diet-induced thermogenesis) has been recognized for many years. It was thought originally that proteins had the major thermogenic effect, and indeed if nutrients are administered in isoenergetic amounts this is probably the case. Studies of the thermogenic effects of i.v. nutrients have shown that the response to a complete TPN mixture is only slightly larger than that to amino acids alone [16]. The normal diet contains only approximately 15% of the total energy content as protein, and when one considers the thermic effect of food ingested orally, carbohydrate is the major nutrient contributing to diet-induced thermogenesis. Indeed, ingestion of carbohydrate is sometimes accompanied by activation of facultative thermogenesis, an additional beta adrenoreceptor-mediated form of thermogenesis [17]. The amount of amino acids infused over 2 h by Selldén, Bränström and Brundin was equivalent to ingestion of 28 g of protein, that is approximately 50% of daily requirements. Thus some of the response observed was likely to be a result of an excessive rate of supply of amino acids, rather than a normally recruited physiological mechanism. This is even more likely given that the response observed in patients was much larger than that in healthy volunteers. It seems probable that preoperative medication, anaesthesia, or both, were responsible for this enhanced response to i.v. amino acids. It is interesting that infusion of amino acids at twice the rate used by Selldén, Bränström and Brundin increased resting energy expenditure (REE) by approximately 20% and that the effect was similar in healthy subjects and septic patients [18]. Thus the excessive thermogenic response to amino acids in the perioperative period appears to be restricted to that state, and does not interact with the metabolic disturbance accompanying sepsis. In the study of Selldén, Bränström and Brundin the increase in REE in patients was accompanied by an increase in body temperature. It seems unlikely that this increase in temperature was caused entirely by increased thermogenesis, and highly probable that there was also a reduction in heat loss compared with control subjects. Any decrease in body heat loss is likely to be achieved by a lower peripheral blood flow, presumably because of increased vascular tone. This effect, combined with the increased cardiorespiratory demands of amino acid-induced thermogenesis, would represent a considerable cardiovascular challenge to the patient in the perioperative period. This is likely to be tolerated well by healthy young patients, but could lead to problems in the elderly, or in those with impaired cardiorespiratory reserve. It would be valuable to determine the cardiorespiratory effect of an amino acid infusion during the perioperative period in patients of different ages.

Almost 50% of the thermogenesis caused by infusion of amino acids occurs in the splanchnic tissue. This represents the energy costs of protein synthesis, deamination and decarboxylation of amino acids, gluconeogenesis and urea synthesis. Although it is not clear which substrate is used mainly for these energy-requiring processes, it is speculated that amino acid oxidation contributes to a large extent.

Another remarkable finding of this study was the significant increase in oxidative metabolism in the amino acid infusion group at the end of anaesthesia and surgery, with values of 50–60% above baseline.

Administration of an amino acid mixture as a means of increasing REE and balancing the dissipation of body heat caused by anaesthesia and surgery over a period to time, poses several relevant questions; could the protective effect of perioperative hypothermia on body functions be disrupted by increased metabolic demand, increased splanchnic blood flow and cardiovascular workload? Second, could the combined effect of increased REE and sympathetic stimulation at the end of surgery and anaesthesia represent a major metabolic and cardiorespiratory load in compromised subjects with hepatic, renal or respiratory insufficiency?

A detailed evaluation of this method on the distribution of body heat in the anaesthetized patient and on the thermogenic interactions with different anaesthetic techniques is awaited. Similarly, the effect of infusion of amino acids on circulating concentrations of metabolites and hormones at the time of maximal stress may clarify the role of other substrates in the provision of energy.

The question remains as to whether or not the stress of hypothermia, as part of the overall injury response, should be prevented by further increasing REE or, in contrast, should measures be implemented to abolish or at least attenuate the sympathetic response associated with thermal and surgical stress. Large doses of i.v. opioids and regional block with local anaesthetics are valuable methods; however, the former method has several drawbacks in its application. In contrast, perioperative conduction block with local anaesthetics provides an excellent opportunity to attenuate significantly perioperative sympathetic stimulation, maintain cardiovascular stability, limit the postoperative increase in oxygen uptake and delay the rewarming phase [2,19].

The contention is not whether hypothermia should be prevented, but whether the stress associated with this disturbance is seen in the context of the injury response. Therefore, a rational approach would be aimed globally at modulating the production and loss of body heat, and the metabolic consequences.

EDITORIAL II

Gastric tonometry to monitor tissue oxygenation: more than a gut feeling?

Monitoring tissue oxygenation has a vital role in anaesthesia and intensive care. Oxygenation of arterial blood is monitored clinically with arterial blood-gas analysis and pulse oximetry. Continuous measurement of Pa_{O_2} using an intra-arterial probe is being developed, but clinical use is limited. Pulse oximetry measures Sp_{O_2} in arterial capillaries. It does not account for carboxyhaemoglobin or haemoglobin and tends to overestimate Sp_{O_2} in severe hypoxaemia. While useful clinically to follow changes in arterial oxygenation, it is not equivalent to co-oximetry.

Whole body oxygen delivery (Do_2) is derived from the product of arterial oxygen content and cardiac output. This necessitates insertion of a pulmonary artery catheter to measure cardiac output by thermodilution, a method which has variations of 10–15% between measurements. Oxygen consumption ($\dot{V}o_2$) is the uptake of oxygen from arterial blood, and reflects oxygen consumed by cellular metabolism of the whole body. Direct measurement of $\dot{V}o_2$ using metabolic monitors is more accurate than calculation using the Fick principle (as the product of cardiac output and the arterial–mixed venous oxygen content difference). Modern metabolic monitors allow relatively easy and highly accurate and reproducible measurements. Low $\dot{V}o_2$ values indicate tissue hypoxia.

Recently, the concept of a pathological oxygen supply dependency has been debated. This proposes that patients with severe illness (e.g. sepsis and ARDS) have high *critical* Do_2 values. *Critical* Do_2 is Do_2 at which $\dot{V}o_2$ begins to decrease (i.e. when $\dot{V}o_2$ becomes dependent on Do_2), and has been demonstrated in experimental haemorrhage to be 8–9 ml kg^{-1} min^{-1}. Impaired oxygen extraction and utilization is an explanation for pathological oxygen supply dependency in critically ill patients. Thus high ("supranormal") values of Do_2 have been proposed as therapeutic end-points [1, 2]. Monitoring Do_2 and $\dot{V}o_2$ then assumes great importance; a significant increase in $\dot{V}o_2$ after measures to increase Do_2 would indicate that oxygenation was inadequate. However, outcome after use of "supranormal" therapy is not always better [3], and the concept of pathological oxygen supply dependency is not universally accepted [4].

Mixed venous oxygenation represents oxygen that is left after perfusion of the capillary beds in the systemic circulation, and indicates the balance between whole body oxygen transport and consumption. It can be monitored clinically as mixed venous oxygen saturation ($S\bar{v}_{O_2}$) either continuously using a fibreoptic pulmonary artery catheter, or intermittently by blood sampling. A low $S\bar{v}_{O_2}$ (< 65%) usually indicates tissue hypoxia, but normal values do not guarantee adequate oxygenation to all organs. Mixed venous blood represents blood only from perfused tissue, and maldistribution of microcirculatory flow underlies beds of tissue hypoxia in the face of an acceptable $S\bar{v}_{O_2}$.

Other than indices of oxygenation, blood lactate concentration is used clinically to assess tissue oxygenation. In the presence of hypoxia, anaerobic glycolysis metabolizes pyruvate to lactate. Ratios of pyruvate and lactate are probably better indices of the redox state than lactate alone. However, pyruvate measurements are not available routinely, whereas lactate concentrations can be measured promptly by modern lactate analysers. Serious tissue hypoxia is suggested by high blood lactate concentrations, but normal values are not always safe. High concentrations may also occur late in hypoxia, or may be associated with non hypoxic–ischaemic situations, such as when pyruvate substrate is increased by high metabolic rates (Pasteur effect) or inhibition of pyruvate dehydrogenase.

Apart from the inherent problems of measurement and accuracy with each of the above indices, they all reflect global whole body oxygenation. Normal or near-normal values mask poor blood flow and oxygenation to individual tissue capillary beds. The indices do not disclose or measure regional or organ hypoxia. Gastric tonometry, recently introduced to clinical practice, takes one step towards that goal. The principle is simple—inadequate regional perfusion results in anaerobic metabolism and gut intramucosal acidosis which is measured indirectly. A special tube with a carbon dioxide permeable silicone balloon at its tip is placed in the stomach. The balloon is filled with saline, and after 30–90 min equilibration, saline Pco_2 approaches mucosal Pco_2. Saline Pco_2 and actual arterial bicarbonate concentration (from a simultaneously collected arterial blood sample) are measured using a standard blood-gas analyser. Gastric pH (pH_i) is then calculated by applying a modified Henderson–Hasselbalch equation. Measurements can also be obtained with the tube inserted in the colon. H_2 receptor antagonists affect pH_i in healthy subjects but not in critically ill patients, and their routine use is unnecessary [5, 6]. The difference between arterial pH and pH_i ($pH_a - pH_i$ gradient) may be a more specific measure of gastric mucosal hypoxia.

Gastric tonometry is an attractive technique. It does not require intravascular placement, and splanchnic organs are particularly vulnerable to a failing circulation. Early response to detected gut ischaemia may prevent translocation of bacteria and endotoxin into the blood stream. Using gastric tonometry, gastric mucosal acidosis was reported to be common in critically ill patients [7,8], and was associated with increased complications and mortality in these patients and in those after major surgery [9,10] and trauma [11,12]. Unexpected splanchnic hypoxia was detected in cardiac patients after surgery [13–17], despite increased cardiac output and splanchnic blood flow after administration of dopexamine [16] and dobutamine [17]. The study by Welte and colleagues from Munich [18] found that pH_i decreased during orthotopic liver transplantation, although $D\mathrm{O}_2$ and haemodynamic variables remained unchanged.

Measurement of pH$_i$ is not without problems. Arterial bicarbonate is not a valid index of intracellular or extracellular bicarbonate in the gut, and its use to compute pH$_i$ is questioned [19]. Errors in calculated pH$_i$ can arise from analyses of saline $P\mathrm{CO}_2$ with different blood-gas analysers [20]. Cut-off values of pH$_i$ above which patients met with favourable outcome varied considerably in reported studies. The effects of inotropic agents (e.g. dopexamine) on pH$_i$ are conflicting [16,21]. The Munich group's finding that pH$_i$ was not a good predictor of graft viability [18] contrasted with that of a previous study [22]. Gastric tonometry assumes that gut intramucosal acidosis is invariably caused by hypoxia, but this may not be the case in sepsis [23]. Nevertheless, there are increasing data to suggest that low pH$_i$ values reflect inadequate perfusion of the gut. This splanchnic hypoperfusion is not indicated by haemodynamic or oxygen transport variables or illness severity scores (APACHE II and ISS) [12]. Although conventional measurements of metabolic acidosis may provide a similar clinical picture [24], pH$_i$ may be a more sensitive and earlier marker of hypoxia. We now have a new tool to monitor oxygenation. To validate its use, however, many questions still need to be answered, such as whether or not assessment of pH$_i$ changes in response to therapy or to guide therapy is useful, and what are acceptable pH$_i$ values?

CLINICAL INVESTIGATIONS

Continuous extradural infusion of ropivacaine for prevention of postoperative pain after major orthopaedic surgery

G. Turner, D. Blake, M. Buckland, D. Chamley, P. Dawson, C. Goodchild, J. Mezzatesta, D. Scott, A. Sultana, S. Walker, M. Hendrata, P. Mooney and M. Armstrong

Summary

We studied 151 patients undergoing total hip or knee arthroplasty, or cruciate ligament reconstruction in a multicentre study in Australia and New Zealand. Patients were openly allocated randomly to one of five treatment groups or to a control group. General anaesthesia was induced after introduction of extradural block with 0.5% ropivacaine. After surgery, patients received an extradural infusion of 0.2% ropivacaine at 6, 8, 10, 12 or 14 ml h^{-1} or received no postoperative extradural infusion (control group). All patients had access to i.v. PCA morphine for supplementary analgesia. Morphine consumption was lower in all treatment groups compared with the control group, decreasing with increasing ropivacaine infusion rate. Median VAS scores were lower in all ropivacaine infusion groups compared with the control group for the first 10 h of the study; however by the end of the study, VAS scores were similar in all groups. The higher ropivacaine infusion rates caused a slower convergence of spread of the initial sensory block and a higher degree of motor block. The overall incidence of side effects was similar, with the exception of a higher incidence of urinary retention and hypotension in the groups receiving the higher rates of ropivacaine. The quality of treatment scores were similar for all treatment groups (*Br. J. Anaesth.* 1996; **76**: 606–610)

Key words

Anaesthetics local, ropivacaine. Anaesthetic techniques, extradural. Analgesia, postoperative. Pain, postoperative. Surgery, orthopaedic.

Ropivacaine is a new long-acting anaesthetic, belonging to the same homologous series of compounds as bupivacaine and mepivacaine. It is the first enantiomerically pure local anaesthetic and exists as the S-enantiomer. Ropivacaine has pharmacodynamic and pharmacokinetic properties resembling those of bupivacaine in animals [1–3] and humans [4–6]. However, ropivacaine has a lower potential for central nervous system and cardiovascular toxic side effects than bupivacaine in animals [7]. In preclinical studies, ropivacaine produced less central nervous system and cardiotoxicity than bupivacaine [8]. Furthermore, in human volunteers, ropivacaine has also been shown to be less prone than bupivacaine to produce central nervous system and cardiovascular changes after i.v. infusion [9].

In double-blind comparative studies of extradural anaesthesia, ropivacaine has shown overall clinical efficacy and tolerability similar to that of bupivacaine [10–12]. Similarly, ropivacaine has proved efficacious in producing postoperative analgesia after lower and upper abdominal surgery [13]. Studies in healthy volunteers and postoperative patients have found 0.2% ropivacaine to be the optimal concentration for infusion [13, 14].

In this study we investigated the volume response relationship of extradural infusion of 0.2% ropivacaine for analgesia.

Patient and methods

After obtaining Institutional Ethics Committee approval and written informed consent, we studied 151 patients in six institutions. All patients were ASA I–III, aged 24–75 yr and undergoing total hip or knee arthroplasty, or cruciate ligament reconstruction. Patients were premedicated with a benzodiazepine before insertion of an extradural catheter in the L1–5 interspaces. A test dose of 1.5% lignocaine 4 ml with adrenaline 5 μg ml^{-1} was used. After confirming satisfactory placement of the catheter, 0.5% ropivacaine 5–20 ml was injected over a 5-min period. Another 5 ml of 0.5% ropivacaine were injected if surgical anaesthesia was not achieved to T10, 30 min after the main dose. When adequate local anaesthesia was obtained, general anaesthesia

was induced with thiopentone or propofol i.v. Neuromuscular block was produced with either atracurium, vecuronium, pancuronium or suxamethonium. Anaesthesia was maintained with a volatile agent and nitrous oxide in oxygen. Up to 250 μg of fentanyl were administered i.v. during the procedure at the anaesthetist's discretion. During surgery, top-up doses of 0.5% ropivacaine 3–5 ml were given extradurally at 30-min intervals if required. Patients were allocated randomly to a control group or to receive an extradural infusion of 0.2% ropivacaine at one of the following rates: 6, 8, 10, 12 or 14 ml h^{-1}. The control group did not receive any postoperative extradural infusion. All patients had access to i.v. morphine or pethidine delivered by a patient-controlled analgesia (PCA) system. If for any reason patients did not tolerate morphine, PCA was continued with pethidine; pethidine 10 mg was equivalent to morphine 1 mg. The PCA was set to give a bolus dose of morphine 1 mg or pethidine 10 mg with a 5-min lockout period, and no 4 h dose limit.

The extent of motor and sensory block were determined before commencement of surgery. Motor weakness was determined according to a modified Bromage scale (0 = no motor block, 1 = inability to raise extended legs, 2 = inability to flex knees, 3 = inability to flex ankle joints). In cases of asymmetric block the highest (numerical) value was recorded. Sensory analgesia was determined as loss of sensation using a 27-gauge short Bayer dental needle. The amount of supplementary morphine or pethidine delivered by PCA, extent of sensory and motor weakness (Bromage scale) and pain scores at rest (on a 100-mm visual analogue scale) were recorded for 21 h after operation at three times: 0–4 h, 4–8 h and 8–21 h. After this time ropivacaine infusion was stopped. At the end of the 21-h infusion, patients were asked to rate the overall quality of their treatment on a four-point scale (1 = poor, 2 = fair, 3 = good, 4 = excellent).

Patient data were analysed using *t* and chi-square tests. Morphine consumption, VAS scores, sensory spread, motor block and quality of treatment were analysed with stratified Wilcoxon rank sum tests controlling for institution. Differences referred to as statistically significant corresponded to a two-sided *P* value less than 0.01.

Results

Of the 151 patients recruited into the study, 128 were valid for efficacy data analysis. Sixteen patients were excluded because they did not receive postoperative treatment according to the study procedure after enrolment. Of these an extradural catheter could not be sited satisfactorily in six patients, there was inadvertent subdural, subarachnoid or i.v. placement in five patients, there was inadequate spread of sensory block before surgery in two patients and no block at the end of surgery in one patient. Surgery was cancelled after extradural block was established on one occasion and surgery extended beyond 4 h on another occasion. Seven patients were excluded because of further study violations: two patients had catheter displacement causing leakage of the extradural infusion or loss of sensory block, three patients had the infusion turned off or the rate changed outside of study guidelines, one patient developed subarachnoid block from presumed catheter migration and one patient had an inadequate block before surgery. Patient data are shown in table 1. There were no significant differences between the groups. Two patients in the control group received pethidine instead of morphine via PCA and four, one, three, two and four patients in the 6-, 8-, 10-, 12- and 14-ml h^{-1} groups, respectively.

Total morphine consumption for all six groups is shown in figure 1 in addition to the amount consumed in the first 4 h after operation, 4–8 h and 8–21 h. Median total morphine consumption during the study was 36 mg in the control group, 13 mg in the 6-ml h^{-1} group, 26 mg in the 8-ml h^{-1} group, 12 mg in the 10-ml h^{-1} group, 11 mg in the 12-ml h^{-1} group and 3 mg in the 14-ml h^{-1} group. There was a trend towards a dose–response relationship with decreasing morphine requirements in groups receiving the higher extradural ropivacaine infusion rates. At each time morphine consumption was greatest in the control group, which was statistically significant compared with the other groups, except for the 8-ml h^{-1} group at all times and the 10-ml h^{-1} group at 8–21 h. Morphine consumption in patients who received ropivacaine 14 ml h^{-1} was significantly lower than the control, 6- and 8-ml h^{-1} groups at all times. Table 2 shows the *P* values for comparison of total morphine consumption over the 21-h period between the control and ropivacaine groups.

Median VAS scores in the control group were 18–30 for the first 10 h whereas VAS scores for the ropivacaine groups did not exceed 8 during the same period (fig. 2). At 10–21 h the difference in VAS scores between the groups was small, mainly because of a decrease in VAS scores in the control group. At 4 h, VAS scores were significantly lower in the ropivacaine groups compared with the control group, with the exception of patients who received the lowest ropivacaine infusion rate (6 ml h^{-1}). At 8 h, VAS scores were still significantly lower in the 10-, 12- and 14-ml h^{-1} groups compared with the control group and lower in the 12- and 14-ml h^{-1} groups compared with the 8-ml h^{-1} group. At 21 h the only significant difference in VAS scores was between the 14- and 8-ml h^{-1} groups.

The median upper limit of sensory block in the ropivacaine groups was different at 2 h after the start of the infusion (fig. 3): T10 in the 6- and 8-ml h^{-1} groups; T9 in the 10- and 14-ml h^{-1} groups; and T8 in the 12-ml h^{-1} group. These levels had receded by the end of the infusion to L2 in the 6-ml h^{-1} group; L1 in the 8- and 12-ml h^{-1} groups; and T12 in the 10- and the 14-ml h^{-1} groups. The lower limit of sensory block was S2–S1 in all groups 2 h after the start of extradural infusion but had receded by the end of the infusion, 21 h after operation to: L4–L3 in the 6-ml h^{-1} group; L4 in the 8-ml h^{-1} group; L5 in the 10- and 12-ml h^{-1} groups; and S1–L5 in the 14-ml h^{-1} group. The median upper and lower limits of sensory block in the control group were L1 and L5,

respectively, 2 h after the start of the infusion, and sensory block had resolved completely 6 h after operation.

The number of patients exhibiting significant motor block with muscle weakness and the severity of this effect diminished with time after operation, even during the 0.2 % ropivacaine infusions. This occurred in all ropivacaine groups (table 3). After 4 h there was no motor block in the control group yet

there was weakness of Bromage scale 2 or more in 5%, 18%, 32% and 36% of patients in the 6-, 10-, 12- and 14-ml h^{-1} groups, respectively. There was a statistically significant difference in motor block 4 h after operation between the control and all ropivacaine groups, between the 12-ml h^{-1} group and the 6- and 8-ml h^{-1} groups and between the 8- and 14-ml h^{-1} groups. At 8 h after operation there was still a statistically significant difference between the control and the 10-, 12- and 14-ml h^{-1} groups, between the 14-ml h^{-1} group and the 6- and 8-ml h^{-1} groups and also between the 8- and 12-ml h^{-1} groups. There was no block in the 6- or 8-ml h^{-1} groups, however motor weakness was Bromage scale 2 or more in 14%, 27% and 32% of patients in the 10-, 12- and 14-ml h^{-1} groups, respectively. After 20 h there was a statistically significant difference between the control and 12- and 14-ml h^{-1} groups and between the 14-ml h^{-1} and the 10- and 12-ml h^{-1} groups. At this time there were still 5% of the 8- and 12-ml h^{-1} groups and 27% of the 14-ml h^{-1} group with Bromage motor weakness of 2 or more.

There was no statistically significant difference between any of the treatment groups with respect to quality of treatment scores (table 4).

Table 5 shows the incidence of the most frequent side effects in the 21-h postoperative infusion period. The incidence of nausea and vomiting was similar for all treatment groups. More patients experienced urinary retention in the groups receiving higher infusion rates of ropivacaine, and hypotension (systolic arterial pressure ≤ 80 mm Hg or a decrease in arterial pressure requiring drug treatment) was more prevalent in the 14-ml h^{-1} group than in the other groups.

Discussion

We found that postoperative pain relief was better with extradural infusion of 0.2% ropivacaine combined with PCA morphine than with PCA morphine alone. PCA morphine is a common postoperative analgesia technique and is used frequently as a rescue medication in analgesia studies. Patients receiving extradural ropivacaine required less supplementary morphine from PCA and achieved lower pain scores than the control groups. There was a trend to a volume response relationship, the higher extradural ropivacaine infusion rates requiring less supplementary PCA morphine; 14 ml h^{-1} was significantly different from the control, 6-ml h^{-1} and 8-ml h^{-1} groups at all times.

VAS scores in the ropivacaine groups were acceptably low, although they were assessed only at rest. However, VAS scores in the morphine PCA group were higher at 4 and 6 h after operation before decreasing to lower levels.

The incidence of motor block was low, but more marked in the 12- and 14-ml h^{-1} infusion groups. The frequency and intensity of motor block decreased throughout the 21-h period. By 21 h, however, there were still 5% and 27% of patients, respectively, with a Bromage score of 2 or more in the 12- and 14-ml h^{-1} groups. Although the incidence of hypotension was similar in all groups, with the exception of the 14-ml h^{-1} group, there were more episodes of urinary retention in the 12- and 14-ml h^{-1} groups. This combined with the higher incidence of motor block at these infusion rates may increase the need for urinary catheterization and delay early postoperative mobilization. Infusion rates greater than 8 ml h^{-1} caused sensory block in all lumbar segments. This is in accordance with results of Zaric and colleagues [14] who found that an infusion of 0.2% ropivacaine 10 ml h^{-1} gave a sensory block of nine dermatomes decreasing to five dermatomes after 21 h. In this study, sensory block in the 10-ml h^{-1} group decreased from 10 to five dermatomes over the 21-h period.

In general, all infusion rates of ropivacaine gave satisfactory analgesia when used together with PCA morphine. However, the higher infusion rates of 12 and 14 ml h^{-1} caused increased incidences of motor block and urinary retention without providing significantly improved analgesia compared with the 10-ml h^{-1} group, while the 6-ml h^{-1} group failed to block all lumbar segments.

Patient-controlled extradural analgesia with bupivacaine, fentanyl, or a mixture of both, after Caesarean section

D. W. COOPER, D. M. RYALL, F. E. MCHARDY, S. L. LINDSAY AND S. S. ELDABE

Summary

In this randomized, double-blind study of 60 patients, we have assessed the analgesic efficacy of extradural bupivacaine and extradural fentanyl, either alone or in combination, after Caesarean section. Patients received 0.1% bupivacaine (group B), fentanyl 4 μg ml^{-1} (group F) or 0.05% bupivacaine combined with fentanyl 2 μg ml^{-1} (group BF) by patient-controlled extradural analgesia (PCEA). Adding fentanyl to bupivacaine reduced the dose of bupivacaine by up to 68%, improved analgesia at rest and decreased PCEA use. Motor and sensory block were decreased, but there was more pruritus. Overall patient satisfaction was increased. Adding bupivacaine to fentanyl reduced the dose of fentanyl by up to 57% without altering pain scores or PCEA use. Sensory block increased but pruritus did not decrease. Bupivacaine 0.05% produced clinically significant leg weakness in three patients. Overall patient satisfaction was not altered. There was a significant additive analgesic effect between 0.05% bupivacaine and fentanyl but no clinical benefit was demonstrated from using the combination compared with fentanyl alone for this group of postoperative patients. (*Br. J. Anaesth.* 1996; **76**: 611–615)

Key words

Extradural fentanyl produces effective postoperative analgesia with a low incidence of serious side effects. Extradural bupivacaine can produce excellent analgesia at the expense of dose-dependent side effects from sensory, motor and sympathetic block. Laboratory work has demonstrated a supra-additive analgesic effect between intrathecal local anaesthetics and opioids [1]. Despite this finding it is unclear if it is clinically beneficial to add bupivacaine to fentanyl for postoperative extradural analgesia. Some studies have shown no benefits from this practice [2–5], whereas others have demonstrated either reductions in fentanyl dose, improved analgesia, or both [6–10].

The aims of this study were to assess the effects of combining extradural bupivacaine with extradural fentanyl and to compare the two drugs for analgesia after Caesarean section. Half strength solutions were used for the combination group. This, in conjunction with patient-controlled extradural analgesia (PCEA), was to try to minimize the dose of each drug used in combination, while at the same time maintaining analgesic efficacy. Analgesic dose requirements, visual analogue pain scores, PCEA use, side effects and overall patient satisfaction were examined over the first 24 h after operation.

Patients and methods

The study was double-blind and approved by the local Hospital Ethics Committee. After obtaining informed consent, we studied 60 ASA I–II patients undergoing morning elective Caesarean section under extradural analgesia.

In the anaesthetic room, before insertion of the extradural catheter, baseline arterial pressure, heart rate and ventilatory frequency were recorded with the patient lying in the left lateral position. In all patients an extradural catheter was inserted at L2–3 or an adjacent space. Neural block was produced using 0.5% bupivacaine. After an initial 3-ml test dose the subsequent 10 ml contained fentanyl 50 μg. Thereafter sufficient bupivacaine was administered to achieve a block to T4–T6. Further intraoperative analgesia, if required, was provided by i.v. fentanyl or alfentanil.

From the end of operation patients were free to use a PCEA device which was allocated randomly to deliver either 0.1% bupivacaine (group B), fentanyl 4 μg ml^{-1} (group F) or 0.05% bupivacaine combined with fentanyl 2 μg ml^{-1} (group BF). The PCEA device was programmed to allow a 5-ml bolus with a 10-min lockout interval. Patient grouping was decided by opening a blank envelope from a set of 60 shuffled envelopes containing either the code for group B ($n = 20$), F ($n = 20$) or BF ($n = 20$). The investigator who set up the PCEA was not involved with subsequent patient management or assessment. Patients, nursing and medical staff were unaware of patient grouping.

The study lasted for 24 h from the end of operation. Patients were kept in a recovery area for 4 h and then transferred to the postnatal ward. Postoperative analgesia was provided solely by PCEA. All patients were educated in the use of PCEA and informed that they had to wait for 10 min

before the next dose would be available. If analgesia was judged to be inadequate by the patient herself, nursing or medical staff, then the study was stopped at that point. The extradural catheter was left in position for assessment by an anaesthetist and the patient was given alternative analgesia. Data were analysed provided the catheter had not become displaced.

Volumes of analgesic solution self-administered were recorded at 0.5, 4, 8, 12 and 24 h. At the same times visual analogue scores for pain (VAS) at rest and on coughing (100-mm scale; 0 = no pain, 100 mm = worst pain imaginable), and also sedation scores were recorded. The presence or absence of nausea, vomiting and pruritus was recorded for the time periods 0–0.5, 0.5–4, 4–8, 8–12 and 12–24 h. Pruritus was graded as mild, moderate or severe. A verbal rating score (VRS) for overall satisfaction (0 = excellent, 1 = adequate, 2 = fair, 3 = poor) was recorded for those patients completing 24 h. VRS = 3 if the patient stopped early because of side effects or inadequate analgesia, despite good catheter position. Arterial pressure and ventilatory frequency were measured every 1–2 h and more frequently if systolic arterial pressure (AP) was less than 100 mm Hg or ventilatory frequency less than 10 bpm.

Between 20 and 24 h, patients were assessed on one occasion by an anaesthetist for maximum sensory block, motor block, postural hypotension (supine, sitting and standing AP using an automated NIBP device) and ability to walk unaided. Maximum sensory block to ethyl chloride spray was assessed on a four-point scale: 0 = no area of reduced sensation, 1 = area of reduced sensation but still cold, 2 = area of reduced sensation but not cold and 3 = area of complete absence of sensation. Motor block was assessed on a four-point scale: 0 = no weakness detected, 1 = able to straight leg raise, but power reduced, 2 = unable to straight leg raise and 3 = unable to raise knee off bed. Ability to walk was assessed only if there was no leg weakness or postural hypotension and the patient felt sufficiently pain free.

A computer package (SPSS) was used for statistical analysis. Results were compared using Mann–Whitney and Kruskal–Wallis tests, with $P < 0.05$ taken as significant.

Results

We studied 60 patients, 20 in each group. Four patients (two in group B, one in group F and one in group BF) were subsequently excluded because the extradural catheter became dislodged in the postoperative period. Groups were matched for age, height, weight and operative analgesia (table 1).

Eight additional patients (seven in group B, one in group F) stopped before completing 24 h. Five stopped in group B because of inadequate analgesia despite good catheter position (one at 4–8 h and four at 12–24 h), compared with none in groups F or BF. Another two patients in group B stopped at 12–24 h because they did not like the feeling of numbness in their legs. One patient in group F stopped at 12–24 h because of a malfunction in the PCEA device. Data from these patients were included up to the assessment time before premature cessation of the study.

three groups at any of the assessment times. Pain scores were no lower at rest than on coughing in group B, whereas they were lower at rest in both groups F and BF. Mean pain scores at 8 and 12 h at rest compared with on coughing were as follows: group B 27 (13–33) mm at rest to 24 (10–51) mm on coughing; group F 17 (8–25) mm at rest to 29 (20–35) mm on coughing ($P < 0.01$); group BF 17 (7–20) mm at rest to 26 (16–47) mm on coughing ($P < 0.005$).

Volumes of analgesic solution self-administered are shown in figure 3. Group B had significantly greater PCEA use than both groups F and BF. There was no difference between group F and group BF.

Doses of bupivacaine and fentanyl self-administered are shown in table 2. Combining bupivacaine and fentanyl reduced significantly the doses of both drugs administered. For patients who completed 24 h, overall reductions in the doses of bupivacaine and fentanyl were 62 % and 53 %, respectively. The maximum reduction for bupivacaine (68 %) occurred at 8–12 h and for fentanyl (57 %) at 12–24 h.

The overall incidence of nausea or vomiting was low and there was no significant difference between groups (table 3). All sedation was mild (occasionally drowsy, easy to arouse) apart from one patient in group BF who had moderate sedation (frequently drowsy, easy to arouse). Pruritus was similar for groups F and BF and significantly more frequent than in group B.

Table 3 Incidence (%) of nausea, vomiting, sedation, pruritus, sensory block, motor block, postural hypotension and inability to walk. $^*P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ compared with group B; †††$P < 0.001$ compared with group F (Kruskal–Wallis)

Motor block	73	0***	16**
Postural hypotension	0 (0/3)	17	39 (7/18)
Inability to walk	82	24 (4/17)**	53

Eleven patients in group B, 18 in group F and 19 in group BF remained in the study for the full 24 h. Testing for sensory block, motor block, postural hypotension and ability to walk unaided was performed at 20–24 h (table 3).

Maximum sensory block was significantly greater for both groups B (0 = 10 %, 1 = 10 %, 2 = 40 %, 3 = 40 %) and BF (0 = 25 %, 1 = 25 %, 2 = 44 %, 3 = 6 %) than for group F (0 = 89 %, 1 = 11 %). Group B also had significantly greater sensory block than group BF. One of 11 patients in group B was not tested for sensory block.

Motor block was significantly greater for group B (0 = 27 %, 1 = 18 %, 2 = 45 %, 3 = 9 %) compared with group F (0 = 100 %) and group BF (0 = 84 %, 1 = 11 %, 2 = 5 %). The difference between groups F and BF was not significant ($P = 0.08$). The mean dose of bupivacaine administered in group BF at 12–24 h was 4.8 mg h^{-1} for those with leg weakness and 3.2 mg h^{-1} for those without.

Postural hypotension was tested in three patients in group B, 18 in group F and 18 in group BF who were sufficiently free from pain or motor block. Patients were considered to have postural hypotension if they were unable to stand because of dizziness or had a systolic arterial pressure (AP) < 90 mm Hg on attempting to sit or stand. One of three patients in group F with postural hypotension had a recorded AP < 90 mm Hg compared with four of seven patients in group BF with postural hypotension. There was no significant difference between the groups.

A total of 82 % of patients in group B were unable to walk (11 % because of pain, 89 % motor block), 24 % in group F (25 % because of pain, 75 % postural hypotension) and 53 % in group BF (30 % because of motor block, 70 % postural hypotension). The difference between groups B and F was significant but group BF was not significantly different from group B ($P = 0.12$) or group F ($P = 0.08$). One of 18 patients in group F was not tested for mobility.

Minimum postoperative arterial pressure was not significantly different between the three groups and hypotension (AP < 90 mm Hg) was not recorded for any patient other than during testing for postural hypotension. Minimum ventilatory frequency was not significantly different between groups and no patient had a recorded rate of less than 12 bpm.

Verbal rating scores for overall patient satisfaction were significantly poorer for group B (33 % excellent, 28 % adequate, 0 % fair, 39 % poor) compared with both group F (67 % excellent, 28 % adequate, 6 % fair, 0 % poor) ($P < 0.05$) and group BF (63 % excellent, 26 % adequate, 11 % fair, 0 % poor) ($P < 0.05$). There was no significant difference between groups F and BF.

Discussion

Intrathecal local anaesthetics and opioids have been shown to have a synergistic analgesic action in laboratory work [1]. Studies examining extradural analgesia, after abdominal aortic and orthopaedic surgery [7, 8], have shown that combining bupivacaine and fentanyl can result in reductions in doses of the order of 20 % for each drug while maintaining or improving analgesia. Despite these findings several studies have failed to demonstrate any benefit from adding dilute bupivacaine to fentanyl [2–5]. However, evidence increasingly shows that adding solutions of bupivacaine of 0.1 % or greater to fentanyl can either improve analgesia, reduce fentanyl requirements, or both [6–10].

In this study we found a clear overall benefit from adding fentanyl to bupivacaine. It allowed a reduction in bupivacaine dose of up to 68 %, with improved analgesia for rest pain, decreased PCEA use and increased patient satisfaction. As a result of the reduced bupivacaine dose there was less motor and sensory block, but the addition of fentanyl led to an increase in predominantly mild pruritus.

Overall benefits from adding bupivacaine to fentanyl were less apparent. It allowed a reduction in the dose of fentanyl of up to 57 % without altering the low pain scores, PCEA use or the high level of patient satisfaction. However, the decreased dose of fentanyl did not reduce pruritus, whereas the addition of bupivacaine increased sensory block. Clinically significant leg weakness also occurred in 16 % of patients who received 0.05 % bupivacaine. Although the finding was not statistically significant ($P = 0.08$) this was probably a type II error as fentanyl by itself would not be expected to produce motor block. The mean dose of bupivacaine administered during the period that motor block was assessed was only 3.5 mg h^{-1} (4.8 mg h^{-1} for those with leg weakness). This dose was similar to that from two previous studies (approximately 4 mg h^{-1}) which also found problems from bupivacaine-related side effects [10, 11].

Our study also compared bupivacaine alone with fentanyl alone for postoperative analgesia. Bupivacaine produced a similar degree of analgesia on coughing to fentanyl but was less effective at relieving rest pain, even though PCEA use was greater. As a result of inadequate analgesia, 28 % of those receiving bupivacaine, compared with none receiving fentanyl, requested premature cessation of the study. Bupivacaine was also associated with a higher incidence of clinically significant side effects than fentanyl. Sensory block with bupivacaine resulted in two patients stopping early because they found the lack of sensation unpleasant and motor block reduced mobility on the first morning after operation. Of the side effects commonly associated with extradural opioids, there was a high incidence of mild pruritus with fentanyl, but no nausea or vomiting. More effective analgesia, combined with fewer side effects, produced greater patient satisfaction with fentanyl.

The difference in pain scores at rest between bupivacaine and the two fentanyl-containing groups did not occur until 12 h after operation. This may have been because of residual operative analgesia or tachyphylaxis. By 24 h there was again no significant difference. This was probably because of a reduction in the numbers of patients in group B, especially as the majority who stopped early did so because of inadequate analgesia.

At 12 h, when pain scores at rest were significantly lower for each fentanyl-containing group than for bupivacaine alone, pain scores on coughing were similar for all three groups. This suggests that when fentanyl-containing solutions inhibited somatic pain to a similar degree to bupivacaine alone, they were more effective at inhibiting visceral pain. In order to satisfactorily inhibit visceral pain, greater rostral spread of an analgesic solution would be required than to inhibit somatic pain. Lumbar extradural administration of fentanyl can result in detectable cervical CSF concentrations of the drug [12]. A greater degree of rostral spread for fentanyl than for bupivacaine could therefore explain this finding. Pain at rest was similar to pain on coughing within the bupivacaine only group whereas it was lower at rest than on coughing in the fentanyl groups. This could be explained by the same mechanism.

This study has demonstrated an additive analgesic effect between extradural 0.05 % bupivacaine and fentanyl, but it failed to demonstrate any clinical benefit from using the drugs in combination compared with fentanyl alone. Our patients undergoing Caesarean section are mobilized routinely on the first morning after operation and bupivacaine-related side effects that occurred with very low-dose bupivacaine inhibited this process. For postoperative patients where early ambulation is not routine, the improvement in analgesia that can be achieved by adding bupivacaine to fentanyl is more likely to contribute to an overall clinical benefit.

Maternal and uteroplacental haemodynamic state in pre-eclamptic patients during spinal anaesthesia for Caesarean section

J. Karinen, J. Räsänen, S. Alahuhta, R. Jouppila and P. Jouppila

Summary

We have studied the effects of crystalloid (Ringer's acetate 1 litre) preloading and subsequent spinal anaesthesia in 12 pre-eclamptic parturient patients undergoing elective Caesarean section. Maternal placental uterine artery circulation was measured using a pulsed colour Doppler technique with simultaneous measurement of maternal haemodynamic state. Despite preloading, mean maternal systolic arterial pressure (SAP) decreased significantly and marked maternal hypotension (SAP $<$ 80% of baseline value) was recorded in two patients after induction of spinal anaesthesia. Mean central venous pressure increased significantly after preload, but decreased to baseline shortly after induction of spinal anaesthesia. Mean pulsatility index (PI) in the uterine artery did not change during preload or spinal block. In one patient, uterine artery PI increased significantly when SAP decreased to 71% of the baseline value, 14 min after induction of spinal anaesthesia. These results suggest that preload with crystalloid solution does not prevent maternal hypotension in pre-eclamptic patients, and that changes in uterine artery velocity waveforms were minor when SAP was 80% or more of baseline during spinal anaesthesia. These changes did not appear to have any major effect on the clinical condition of the neonate, as assessed by Apgar score and umbilical artery pH values. (*Br. J. Anaesth.* 1996; **76**: 616–620)

Pre-eclamptic parturient patients present a challenge to the anaesthetist because of the problems that preeclampsia poses to the fetus and mother. The wellbeing of the fetus is jeopardized by poor placental perfusion which may result from immunologically mediated abnormal trophoblastic invasion or microvascular disease [1] and is reflected as high vascular resistance in the uterine arteries [2]. The mother may develop cardiopulmonary and cerebrovascular emergencies in addition to acute renal failure, severe thrombocytopenia and activation of the coagulation cascade [3].

Extradural anaesthesia is widely accepted as the method of choice for Caesarean section for preeclamptic parturients. There is evidence to suggest that extradural anaesthesia blunts the haemodynamic and neuroendocrine stress responses caused by Caesarean delivery in women with severe preeclampsia [4]. Because uterine blood perfusion is reduced in pre-eclampsia, it is important to prevent maternal hypotension; measures used during regional anaesthesia include left uterine displacement, volume preloading and vasopressor infusion. With these prophylactic measures, it has been shown that plain bupivacaine as an anaesthetic for extradural Caesarean section does not change uteroplacental circulation in hypertensive patients [5].

Severe maternal hypotension is more common during spinal anaesthesia for Caesarean delivery than during extradural anaesthesia. This is one reason why spinal anaesthesia has not been considered widely as an alternative to extradural anaesthesia in pre-eclamptic parturient patients. Preloading and vasopressor infusion did not prevent hypotension during spinal anaesthesia [6, 7]. However, it is crucial to avoid hypotension, especially in pre-eclamptic patients, because of the threat of impaired uterine circulation. We have not found any earlier studies on uteroplacental circulation in preeclamptic patients immediately after induction of spinal anaesthesia. Therefore, in this study we examined the effects of crystalloid preloading and subsequent spinal anaesthesia on maternal, and especially uteroplacental, haemodynamic state in pre-eclamptic patients, using a pulsed colour Doppler technique during the first 20 min of spinal anaesthesia.

Patients and methods

The study was approved by Oulu University Ethics Committee and written informed consent was obtained from each patient. We studied 12 preeclamptic patients (gestation 31–40 weeks) undergoing elective Caesarean section. Of the 12 patients who volunteered for the study, six had severe preeclampsia with an arterial pressure constantly greater than 160/110 mm Hg and proteinuria exceeding 5.0 g 24 h^{-1}. The other six patients had an arterial

Correspondence to J.K.

pressure of 140/90–160/110 mm Hg and proteinuria of 0.3–5.0 g 24 h^{-1}. Ten patients were receiving an antihypertensive peroral regimen of labetalol 300–600 mg day^{-1} and one patient was also receiving nifedipine 5–10 mg day^{-1}. None of the patients was in labour. Exclusion criteria included eclampsia, chronic hypertension, chronic renal disease, thrombocytopenia (platelet count < 100000 ml^{-1}) and maternal haemorrhage or signs of fetal distress requiring emergency Caesarean section.

Patients were given 30 ml of sodium citrate 0.3 mol $litre^{-1}$ orally, 60 min before entering the operating theatre, where they were placed in the supine position with a left lateral tilt. Monitoring comprised a three-lead ECG, pulse oxymetry and automated non-invasive arterial pressure (Cardiocap, Datex, Instrumentarium Group, Finland). Oxygen 3 litre min^{-1} was administered via a nasal cannula. A peripheral vein was cannulated for administration of i.v. fluids, and a vein in the right antecubital fossa was cannulated during local anaesthesia with a 16-gauge central venous catheter for continuous monitoring of central venous pressure (CVP) [8]. Correct location of the tip of the CVP catheter was confirmed by recording the CVP waveform. Baseline maternal heart rate (HR), non-invasive systolic (SAP) and diastolic (DAP) arterial pressures and CVP were recorded, and the first Doppler ultrasound examination was performed before i.v preloading. In all patients the bladder was catheterized to measure urine output during Caesarean section.

The maternal uterine artery (main branch on the placental side of the uterus) was identified by colour Doppler near the cervix before its divisions and the blood velocity waveform recorded using the pulsed Doppler method (with a 3.75-MHz sector probe, 120-Hz high-pass filter). Pulsatility index (PI = (systolic peak velocity – end-diastolic velocity)/mean velocity during cardiac cycle) was measured from the blood velocity waveform profile. Three consecutive correctly imaged blood velocity waveforms were analysed and the mean value was used in further analysis. All blood flow velocity waveform recordings were obtained during periods of fetal rest without breathing movements. Maternal HR, SAP, DAP and CVP readings were recorded every 2 min during the study.

After the first Doppler measurement, patients received a preload of crystalloid (Ringer's acetate) solution 1 litre over a 15–20-min period. Immediately after preloading, the second Doppler measurement was obtained. Patients were then placed in a right lateral position, an extradural catheter was inserted 3 cm cephalad through the L1–2 interspace, a 27-gauge spinal needle was inserted into the subarachnoid space at the L3–4 interspace and 0.5 % hyperbaric bupivacaine 2.5 ml (range 2.4–2.6 ml) was injected intrathecally. Patients were then returned to the supine position with a left lateral tilt. Doppler measurements from the same uterine artery were obtained at 2-min intervals during the first 20 min after injection of bupivacaine. Each Doppler measurement required an average of 1 min and was performed by the same obstetrician (J.R.) in every case. During these measurements sensory block was assessed by loss of cold sensitivity and extended to T4 in most patients. After completion of the ultrasound measurements, patients were prepared for surgery. Plain 0.5 % bupivacaine was given later via the extradural catheter if the spinal block began to wear off.

After induction of spinal anaesthesia, crystalloid solution was infused at approximately 1000 ml per 60 min until delivery. The infusion rate of the crystalloid solution was adjusted carefully according to CVP in all subjects to avoid overhydration. The time from induction of spinal anaesthesia to delivery was recorded. Maternal hypotension was defined as a decrease in SAP to 80 % of baseline and was treated by increasing the rate of crystalloid infusion. The minimum percentage value of SAP was recorded. If hypotension was not corrected within 1–2 min, ephedrine 5 mg was injected i.v. repeatedly until SAP was at least 80 % of baseline. A paediatrician assessed the condition of the neonates at delivery using Apgar scores at 1 and 5 min, and blood samples from double-clamped umbilical arteries were obtained immediately after delivery for determination of acid–base status.

Values are presented as mean (SD, range or 95 % confidence intervals (CI)), where appropriate. Values for maternal SAP were also computed as percentage changes from baseline values for later analysis. Paired Student's *t* test was used for evaluation of maximum haemodynamic changes from baseline. Analysis of variance for repeated measures was used to assess the statistical significance of the haemodynamic changes during spinal anaesthesia. The association between the changes in maternal haemodynamic variables and uterine artery PI was assessed by calculating Pearson's correlation coefficient. Differences were considered statistically significant if $P < 0.05$. All statistical tests were performed on a standard PC using the program SPSS for MS Windows release 6.1 (SPSS Inc., USA).

thesia ($P = 0.55$) (fig. 1). Atropine was not required. Mean maternal SAP and DAP decreased significantly after induction of spinal anaesthesia ($P = 0.021$ and 0.017, respectively) (fig. 2). Mean SAP decreased from 169 (95 % CI 157–180) mm Hg to a minimum of 137 (120–154) mm Hg ($P < 0.001$) and mean DAP from 112 (105–118) mm Hg to 90 (79–101) mm Hg ($P < 0.001$) during spinal anaesthesia. The mean maximum percentage decrease in SAP from baseline was 19 (12–26) %. The incidence of maternal hypotension was 17 % (two of 12 patients). Of these two patients, one had marked hypotension and her SAP decreased to 51 % (80 mm Hg) of baseline, 6 min after induction of spinal anaesthesia. In this patient, sensory block extended to C5 and the patient needed assisted ventilation of the lungs with 100 % oxygen via a face mask and a bag for 10–15 min. Oxygen saturation remained at 98–99 %, however, and hypotension responded to the increased crystalloid infusion and ephedrine 10 mg i.v. The patient remained conscious and co-operative and had no convulsions and, therefore, general anaesthesia was not considered. This patient delivered a 1925-g male infant with Apgar scores of 9 and 8 at 1 and 5 min, respectively. Unfortunately, determination of umbilical artery pH was not managed satisfactorily. In the other hypotensive patient, SAP decreased to 71 % (124 mm Hg) of the baseline value and was also corrected rapidly with ephedrine 10 mg.

Mean CVP increased significantly after preloading from 2.3 (95 % CI 1.0–3.7) mm Hg to 6.8 (4.8–8.9) mm Hg ($P < 0.001$) and returned towards baseline values shortly after induction of spinal anaesthesia, after which CVP tended to increase until delivery (fig. 3). In two patients, CVP increased to 10 and 13 mm Hg after preload, but decreased immediately after induction of spinal anaesthesia to 5 and 6 mm Hg, respectively. The total volume of crystalloid infused before delivery was approximately 2108 (range 1500–2400) ml. No patient had any signs of pulmonary oedema during the study.

Mean PI of the uterine artery did not change significantly ($P = 0.28$) during the study (fig. 4) and there was no significant correlation with changes in SAP. In one patient, there was a marked increase in uterine artery PI from 0.73 to 4.22 during a period of maternal hypotension, when SAP decreased to 71 % (124 mm Hg) of baseline, 12 min after induction of spinal anaesthesia. In the case of the most marked decrease in SAP to 51 % of the baseline value, PI of the uterine artery increased from 0.73 to 2.17. We also divided the group into two subgroups of mild and severe pre-eclampsia and found no significant difference in changes in maternal haemodynamic variables (HR, SAP, DAP and CVP) or utero-placental circulation (uterine artery PI) between these subgroups.

Eight of the 12 newborns were small for gestational age (<2.5th percentile). Umbilical artery pH was obtained in seven patients and varied from 7.14 to 7.42. All neonates had Apgar scores of 7 or more at 5 min. After operation, all mothers were observed intensively for the first 24 h, and recovery was uncomplicated in every case.

Discussion

We found reasonably stable maternal and utero-placental haemodynamic values in pre-eclamptic parturient patients undergoing Caesarean section during spinal anaesthesia after prophylactic pre-loading with 1 litre of crystalloid solution. Severe hypotension was seen in only two patients, and this was corrected rapidly by increasing the crystalloid infusion and giving small doses of ephedrine 5–10 mg i.v. However, the absolute mean decrease in SAP in our study was 19 %, which is similar to the decrease of 23 % reported in an earlier study [9]. That retrospective study failed to reveal any significant difference between extradural and spinal anaesthesia for Caesarean section in severely pre-eclamptic parturients with regard to changes in maternal haemodynamics or total intraoperative ephedrine doses used.

The cardiovascular state of severely pre-eclamptic patients has been studied intensively and hyper-dynamic function of the left ventricle has been demonstrated in 73–80 % of patients [10, 11]. In these two studies, there was a normal-to-high cardiac output with inappropriately high peripheral resistance. Cotton and colleagues [11] hypothesized that the increased left ventricular afterload contributes to an increase in pulmonary capillary wedge pressure despite the hypovolaemic state associated with pre-eclampsia and that central venous pressure may therefore reflect the intravascular volume status more accurately than pulmonary capillary wedge pressure. Because none of our patients had pulmonary oedema or persistent oliguria, we used CVP monitoring instead of pulmonary capillary wedge pressure to assess central blood volume during preloading and spinal anaesthesia.

Pre-eclamptic parturients have been shown to suffer from relative hypovolaemia throughout their pregnancy compared with normal parturients [12], and rapid volume expansion with crystalloid [13, 14] or colloid solution [15, 16] has therefore resulted in beneficial effects in pre-eclamptic patients. Infusion of crystalloid solution 15 ml kg^{-1} led to a decrease in systemic vascular resistance [13, 14] and an increase in cardiac output [14] in pre-eclamptic mothers. Infusion of 5 % albumin 500–1000 ml [15] or 3.5 % colloid plasma substitute 200–600 ml [16] also resulted in an increase in cardiac index and a decrease in systemic vascular resistance. After rapid volume expansion, mean SAP was unchanged [16] or slightly reduced [15]. Grunewald and colleagues [13] demonstrated no change in uterine artery PI after rapid volume expansion. Hence, volume expansion in pre-eclamptic patients with either crystalloid or colloid solution appears to be a reasonable first measure to restore central blood volume and to stabilize maternal haemodynamic state, especially before induction of central neural block. In our study, mean initial CVP was 2.3 mm Hg, it increased markedly to 6.8 mm Hg after volume expansion and remained slightly less than 6 mm Hg after induction of spinal anaesthesia. These stable values during spinal anaesthesia, which were at physiological normal levels, imply that spinal block did not significantly affect maternal central blood volume in pre-eclamptic patients, as there were no large alterations in CVP.

Mean maternal HR did not change significantly during the study despite the significant decrease in SAP. There is at least one potential explanation for this stability. Of the 12 patients in our study, 10 were using labetalol. This drug may have prevented a compensatory increase in maternal HR. Labetalol, on the other hand, does not appear to affect uteroplacental blood flow in pre-eclampsia [17, 18].

Robson and colleagues [19] have reported a decrease in uteroplacental blood flow secondary to reduced maternal cardiac output and stroke volume during spinal anaesthesia in healthy parturients. In this study, uterine artery PI values did not change significantly during preload or spinal anaesthesia. This is in contrast with our recent findings [20], which demonstrated occasionally high but transient increases in uterine artery PI in some healthy parturients during spinal anaesthesia. These increases, which reflected increased vascular resistance, did not, however, relate to any obvious changes in individual maternal SAP, HR, or CVP. This difference in the changes in uterine artery resistance (PI) between normal and pre-eclamptic parturients was surprising, and we can only speculate on the underlying reasons. Although we did not have a control group in this study, we are able to compare our results with those of an earlier study by our team using extradural anaesthesia [5]. In that study, Alahuhta and colleagues demonstrated no change in uterine artery PI in hypertensive mothers with chronic fetal asphyxia after extradural anaesthesia with plain bupivacaine and no patient had profound hypotension or required a vasopressor. Eneroth-Grimfors and colleagues [21] observed decreased vagal control of the heart in pre-eclampsia. These changes in the cardiovascular state of pre-eclampsia together with the α and β blocking agent, labetalol, used by the majority of our patients may account for the different results obtained in healthy and pre-eclamptic parturients during spinal anaesthesia.

Our finding, that uteroplacental blood flow did not change markedly during spinal anaesthesia, is in accordance with our earlier data [22]. In that study, placental blood flow, recorded with an isotope technique, did not change in seven healthy parturients and even increased in one patient with pre-eclampsia during spinal anaesthesia. In the 12 pre-eclamptic patients in this study, a marked increase in uterine artery PI as a sign of increased vascular resistance was seen in only one patient simultaneously with a period of severe hypotension lasting 4–6 min after induction of spinal anaesthesia. This was, however, corrected promptly with adequate measures. In the other patient, with even more marked hypotension, uterine artery PI increased only slightly and normalized rapidly. It seems therefore that PI levels in uterine arteries are stable and not sensitive to a moderate decrease in maternal arterial pressure. The good condition of the neonates was a further indication of undisturbed uterine haemodynamic state during the study. The small number of pre-eclamptic subjects examined here may, however, have limited the possibility of observing significant changes in uterine artery PI values after marked maternal hypotension.

Effect of antagonism of mivacurium on recovery of extraocular muscle function

D. J. MELLOR, E. MOSS, E. M. MCATEER AND M. V. SHAH

Summary

We have measured extraocular muscle function in 41 patients who received neuromuscular block with mivacurium 0.2 mg kg^{-1} during anaesthesia with propofol, ketorolac, fentanyl and isoflurane in nitrous oxide and oxygen, which was antagonized at the end of surgery with neostigmine 0.05 mg kg^{-1} and glycopyrronium 0.01 mg kg^{-1} in 21 of these patients. Extraocular muscle function was measured before and after surgery in each group with the Maddox Wing apparatus and compared with a control group ($n = 20$) who breathed spontaneously the same gaseous anaesthetic mixture via a reinforced laryngeal mask airway. In patients where the action of mivacurium was antagonized, extraocular muscle function was improved significantly 20 min after antagonism ($P < 0.001$) compared with those who received no antagonism. At 60 min after antagonism, there were no differences between the groups. There were no differences between patients who received no neuromuscular blockers and those who received blocker and antagonist. (*Br. J. Anaesth.* 1996; **76**: 621–623)

Neuromuscular block, mivacurium. Neuromuscular block, antagonism. Eye, extraocular muscles.

Mivacurium is a new non-depolarizing neuromuscular blocking agent with a short duration of action and rapid offset of effect because of its rapid metabolism by plasma cholinesterase. This occurs *in vitro* at approximately 80% of the rate at which suxamethonium is degraded [1, 2].

The rapid recovery from mivacurium-induced neuromuscular block allows patients to recover from the block without the use of anticholinesterase drugs [3]. However, there is wide inter-patient variability in response to neuromuscular block with mivacurium [2] and neuromuscular monitoring should be used to demonstrate satisfactory antagonism of its effects before termination of anaesthesia.

Traditionally, recovery from neuromuscular block is monitored by train-of-four stimulation. However, in clinical anaesthesia, the train-of-four is observed visually and is a relatively poor indicator of recovery [4].

The ability of neostigmine to antagonize neuromuscular block produced by mivacurium has been demonstrated [1] using train-of-four stimulation and electromyogram recording or adductor pollicis force transduction [3]. However, neostigmine blocks the metabolism of mivacurium *in vitro* in a dose-dependent manner [5]. This has been demonstrated *in vivo* with prolongation of intense mivacurium-induced block by administration of neostigmine [6]. Faced with the difficulty of measuring subtle degrees of muscular weakness, many anaesthetists use neostigmine to antagonize any residual effects of mivacurium after anaesthesia. Our study aimed to demonstrate the benefit of this practice, using the Maddox Wing apparatus to detect residual neuromuscular dysfunction.

Patients and methods

After obtaining Ethics Committee approval and informed consent, we studied 61 patients undergoing day-case anaesthesia for minor oral surgery. Patients were allocated randomly to one of three groups by choosing sealed envelopes.

The Maddox Wing is a device used by orthoptists to measure latent squint. It consists of a black metal screen with baffles to present an image of two perpendicular arrows to the right eye. The left eye is presented with an image of two perpendicular scales. These are graduated in prism dioptres and the amount of esophoria or exophoria is the number on the horizontal scale where the arrow is superimposed onto the scale. Before surgery, the visual function of each subject was tested with the Maddox Wing apparatus. Esophoria and exophoria were recorded, as measured on the horizontal scale of the Maddox Wing. No results were recorded from the vertical scale. No premedication was used and patients requiring spectacles for refractive correction were allowed to use them.

After attaching full monitoring, anaesthesia was induced with propofol 2.5 mg kg^{-1} i.v. Each 20-ml syringe of propofol contained lignocaine 10 mg to relieve pain on injection. Each patient received fentanyl 1 μg kg^{-1} and ketorolac 10 mg i.v. At termination of anaesthesia, ketorolac 20 mg was administered.

Patients in groups MIV and REV were given mivacurium 0.2 mg kg^{-1} at induction of anaesthesia. The trachea was intubated via the nasal route and the lungs ventilated to normocapnia with 1–2 % inspired isoflurane and 66 % nitrous oxide in oxygen. The time of administration of mivacurium was recorded as time A. At termination of surgery, isoflurane was discontinued and neostigmine 0.05 mg kg^{-1} and glycopyrronium 0.01 mg kg^{-1} administered to group REV. The time of antagonism and discontinuing isoflurane was recorded as time B.

Patients in the laryngeal mask airway (LMA) group were used as a control; these patients did not receive mivacurium or a reversal agent. Time A was recorded as the time of administration of propofol 2.5 mg kg^{-1}. Fentanyl 1 μg kg^{-1} and ketorolac 10 mg, followed by 20 mg after operation, were administered and an LMA inserted. Patients breathed a mixture of 1–2 % isoflurane and 66 % nitrous oxide in oxygen. Time B was recorded at termination of surgery when isoflurane was discontinued.

At the end of anaesthesia in groups MIV and REV, neuromuscular function was assessed using a peripheral nerve stimulator before waking the patient to ensure against prolonged neuromuscular block caused by atypical plasma cholinesterase. A train-of-four count of four twitches with no fade was taken as demonstrating adequate antagonism.

Extraocular muscle function was tested 45 min after time A, and 20 and 60 min after time B. Visual function was tested by the same observer who performed the preoperative test, who was blinded to the anaesthetic technique used.

As the data were not from a normally distributed population, visual disturbance in prism dioptres for the three treatment groups was tested with the Kruskal–Wallis one-way analysis of variance and the Mann-Whitney *U* test. $P < 0.05$ was considered significant.

Results

Three patients were excluded from the study, one because of uniocular blindness, one because of severe squint, unsuccessfully corrected by surgery and one because of excessive sleepiness after anaesthesia. The mean duration of anaesthesia was 23 min and there were no significant differences in operative time between the groups (table 1). The values obtained 45 min after time A and 20 min after time B were similar.

The mean preoperative degree of exophoria did not differ significantly between the three groups (Kruskal–Wallis) (table 1).

Table 1 Median (range) operation time and preoperative visual function in the groups in which neuromuscular block was (REV) and was not (MIV) antagonized, and in the laryngeal mask airway (LMA) control group. No significant differences between groups

Group	*n*	Operation time (min)	Preop. exophoria (prism dioptres)
REV	21	23 (10–45)	2 (0–10)
MIV	20	22 (10–61)	2 (0–6)
LMA	20	25 (8–33)	2 (0–10)

Table 2 Median (range) change in visual function (exophoria) 45 min after induction of anaesthesia (A45) and 20 (B20) and 60 (B60) min after antagonism of neuromuscular block or completion of anaesthesia

Group	A45	B20	B60
REV	6 (0–14)	4 (0–12)	2 (0–6)
MIV	12 (4–16)	12 (6–16)	4 (0–6)
LMA	6 (0–29)	6 (0–29)	2 (0–12)
P (MIV *vs* LMA)	< 0.01	< 0.001	ns
P (REV *vs* LMA)	ns	ns	ns
P (MIV *vs* REV)	< 0.001	< 0.001	ns

Table 2 shows the degree of exophoria measured after operation. The values shown were corrected by subtracting the degree of pre-existing exophoria from the postoperative result. A45 is the change at 45 min after induction time A. B20 and B60 are the changes at 20 and 60 min after reversal time B.

When group MIV and both groups REV and LMA were compared, there were significant differences at both times A45 and B20. There were no significant differences between groups REV and LMA. There were no significant differences between the groups at time B60.

Discussion

The Maddox Wing apparatus has been used in several studies of postoperative recovery. Its use as a test of recovery from general anaesthesia was first described in 1970 [7]. It is a simple, non-painful test to perform in the immediate postoperative period.

Recovery from anaesthesia is a multidimensional phenomenon in the same way that a balanced anaesthetic consists of components of anaesthesia, analgesia and paralysis. The Maddox Wing has been used as an indicator of residual paralysis [8, 9] comparing one neuromuscular blocker with another. In an analysis of six recovery tests [10] the Maddox Wing was used as an indicator of sedation. It has been used to assess sedation after propofol infusions [11] and alcohol consumption [12]. As far as we are aware, the Maddox Wing has not been used to monitor the effects of reversal drugs on extraocular muscle function.

In designing a study to demonstrate neuromuscular dysfunction using the Maddox Wing, it is crucial to eliminate the effects caused by sedative agents. For this reason we included a control group (LMA) who received neither mivacurium nor reversal agents, breathing spontaneously the same gaseous anaesthetic mixture via a reinforced laryngeal mask airway.

Our results demonstrated significant changes in extraocular muscle function in the hour after anaesthesia. Of note was the significant ($P < 0.001$) difference in the early postoperative period between those treated with mivacurium and those who received mivacurium and antagonism. This was demonstrated at 20 min after termination of anaesthesia (B20) and at 45 min after the start of anaesthesia (A45). At 20 min after operation, there was significantly less exophoria in the LMA group than in those who received mivacurium alone ($P < 0.001$).

Our results suggest an improvement in extraocular muscle function in the first hour after operation in patients whose mivacurium block was antagonized by neostigmine and glycopyrronium. This improvement may result from antagonism of acetylcholinesterase at the neuromuscular junction.

Neostigmine is well known to have central effects on cholinergic receptors, despite poor penetration of the blood–brain barrier. It also has an effect on cholinergic transmission in the eye [13]. It is not possible to rule out the central, analeptic effects of neostigmine, the peripheral cholinergic effects of miosis and accommodation caused by neostigmine as explanations of our findings. Glycopyrronium should antagonize these effects but it also poorly penetrates the blood–brain barrier.

Recovery of neuromuscular function has been shown to be more rapid after antagonism with neostigmine from both bolus doses and infusions of mivacurium [2]. However, there is evidence to support withholding anticholinesterase drugs. Patients undergoing laparoscopic surgery receiving mivacurium followed by antagonism with neostigmine have been shown to have a greater incidence of nausea and vomiting compared with patients receiving no antagonism [14]. This effect was also demonstrated in children [15]. We did not specifically examine postoperative nausea and vomiting in our study. In another study using mivacurium without antagonism for outpatient dentoalveolar surgery, the incidence of nausea and vomiting was 6% [unpublished results].

In addition, neostigmine antagonizes plasma cholinesterase [5, 16]. Thus in the presence of high degrees of block, corresponding to high concentrations of unmetabolized mivacurium, administration of neostigmine may paradoxically increase recovery time. This effect may result from development of channel block.

In each of our three groups, extraocular muscle function was the same 1 h after anaesthesia, which indicates spontaneous recovery from minor degrees of neuromuscular block. Spontaneous recovery of mivacurium-induced neuromuscular block has been demonstrated to be safe, allowing adequate neuromuscular function for spontaneous respiration and airway maintenance [3]. However, our results showed that antagonism of an intubating dose of mivacurium significantly improves extraocular muscle function during the first hour after operation, which indicates improved antagonism of subtle degrees of neuromuscular block. The clinical benefit of achieving this degree of antagonism of a single dose of mivacurium in patients undergoing day-case surgery is debatable.

Pharmacokinetics and pharmacodynamics of cisatracurium in patients with end-stage liver disease undergoing liver transplantation†

A. M. De Wolf, J. A. Freeman, V. L. Scott, W. Tullock, D. A. Smith, D. F. Kisor, S. Kerls and D. Ryan Cook

Summary

We determined the pharmacokinetics and pharmacodynamics of cisatracurium, one of the 10 isomers of atracurium, in 14 patients with end-stage liver disease undergoing liver transplantation and in 11 control patients with normal hepatic and renal function undergoing elective surgery. Blood samples were collected for 8 h after i.v. bolus administration of cisatracurium 0.1 mg kg^{-1} (2 × ED$_{95}$). Plasma concentrations of cisatracurium and its metabolites were determined using an HPLC method with fluorescence detection. Pharmacokinetic variables were determined using non-compartmental methods. Neuromuscular block was assessed by measuring the electromyographic evoked response of the adductor pollicis muscle to train-of-four stimulation of the ulnar nerve using a Puritan–Bennett Datex (Helsinki, Finland) monitor. Pharmacodynamic modelling was completed using semi-parametric effect-compartment analysis. Volume of distribution at steady state was 195 (SD 38) ml kg^{-1} in liver transplant patients and 161 (23) ml kg^{-1} in control patients ($P < 0.05$), plasma clearance was 6.6 (1.1) ml kg^{-1} min^{-1} in liver transplant patients and 5.7 (0.8) ml kg^{-1} min^{-1} in control patients ($P < 0.05$), but elimination half-lives were similar: 24.4 (2.9) min in liver transplant patients *vs* 23.5 (3.5) min in control patients (ns). The time to maximum block was 2.4 (0.8) min in liver transplant patients compared with 3.3 (1.0) min in control patients ($P < 0.05$), but the clinical effective duration of action (time to 25% recovery) was similar: 53.5 (11.9) min in liver transplant patients compared with 46.9 (6.9) min in control patients (ns). The recovery index (25–75% recovery) was also similar in both groups: 15.4 (4.2) min in liver transplant patients and 12.8 (1.9) min in control patients (ns). After cisatracurium, peak laudanosine concentrations were 16 (5) and 21 (5) ng ml^{-1} in liver transplant and control patients, respectively. In summary, minor differences in the pharmacokinetics and pharmacodynamics of cisatracurium in liver transplant and control patients were not associated with any clinically significant differences in recovery profiles after a single dose of cisatracurium. (*Br. J. Anaesth.* 1996; **76**: 624–628)

Key words

Cisatracurium besylate (51W89; NIMBEX), one of the 10 isomers of atracurium, is approximately three times more potent than atracurium, with an ED$_{95}$ of 0.05 mg kg^{-1} [1], a similar neuromuscular blocking profile to that of atracurium except for a slower onset [1–4] and less propensity to release histamine than atracurium [5]. Cisatracurium undergoes spontaneous degradation in the body at physiological pH and temperature by organ-independent Hofmann elimination to form laudanosine and a monoquaternary acrylate metabolite. The monoquaternary acrylate metabolite undergoes hydrolysis by non-specific plasma esterases to form a monoquaternary alcohol [6]. Hydrolysis of cisatracurium by plasma esterases is not an important pathway for elimination of cisatracurium [6]. In contrast, atracurium is eliminated by Hofmann degradation and hydrolysis by non-specific esterases [7, 8].

Although cisatracurium predominantly undergoes spontaneous degradation by Hofmann elimination [6, 9], liver disease may be associated with changes in the pharmacokinetics, pharmacodynamics, or both, of cisatracurium. In this study, we evaluated the safety, pharmacokinetics and pharmacodynamics of cisatracurium in adults with end-stage liver disease undergoing liver transplan-

tation and in adults with normal kidney and liver function undergoing elective surgery (control patients).

Patients and methods

We studied 25 (18 men) surgical patients, aged 19–65 yr, after obtaining approval from the hospital Institutional Research Review Board and informed written consent from each patient. Fourteen patients (ASA III or IV) had end-stage liver disease and were undergoing liver transplantation; 11 patients (ASA I or II) without known hepatic or renal disease served as controls. Patients in the liver transplantation group did not have clinical evidence of renal insufficiency, although glomerular filtration rate was not determined; the highest serum creatinine concentration was 140 μmol litre^{-1}. Patients did not receive aminoglycoside antibiotics within 48 h of the study or antihistamine drugs within 8 h of the study, and none had any disease known to affect neuromuscular transmission. Age, weight and laboratory data for both groups are summarized in table 1.

Anaesthesia was induced with thiopentone 4.8 (SD 1.3) mg kg^{-1} and fentanyl 4.4 (2.6) μg kg^{-1}. In addition, 17 of 25 patients received midazolam 0.026 (0.016) mg kg^{-1} before induction of anaesthesia. Tracheal intubation was facilitated by administration of suxamethonium 1.3 (0.7) mg kg^{-1}. Anaesthesia was maintained with isoflurane (0.5 % end-tidal concentration) and 50–70 % nitrous oxide in oxygen. Incremental doses of fentanyl were given if needed. Ventilation was controlled to maintain end-tidal $P\text{CO}_2$ at 4.6–5.3 kPa. Arterial pressure was monitored directly using an indwelling radial arterial cannula. Body temperature was maintained at 35.0–37.5 °C.

After induction of anaesthesia, neuromuscular function was monitored by supramaximal stimulation of the ulnar nerve at the wrist with repetitive train-of-four stimuli (0.2-ms square waves at a frequency of 2 Hz for 2 s at 20-s intervals) using surface electrodes. The evoked compound electromyogram of thumb adduction (adductor pollicis) was recorded using a Puritan–Bennett Datex (Helsinki, Finland) monitor. After full recovery of neuromuscular transmission from suxamethonium and re-establishment of a baseline evoked response, a single bolus injection of cisatracurium 0.1 mg kg^{-1} (2 × ED$_{95}$) was administered via an i.v. cannula over a 5–10-s period. The degree of neuromuscular block was described as percentage of control; the height of the first train-of-four response (T1) was compared with the baseline T1 response (T0). Time from injection of cisatracurium to maximum neuromuscular block and the times for T1:T0 to reach 5 %, 25 %, 75 % and 95 % were noted from the tracings. The time for T1:T0 to reach 25 % was considered to be the clinically effective duration of action. Recovery indices (time for T1:T0 to recover from 25 % to 75 % and from 5 % to 95 %) and the time to T4:T1 $\geqslant$ 70 % were calculated from these data.

Table 1 Patient characteristics and preoperative clinical laboratory data (mean (SD or range)). ALP = Alkaline phosphatase; AST = aspartate transaminase; ALT = alanine transaminase. *$P < 0.05$ compared with liver transplant patients.

	Liver transplant patients (n = 14)	Control patients (n = 11)
Age (yr)	48 (19–65)	37 (21–65)*
Weight (kg)	81 (26)	80 (12)
Haemoglobin (g litre^{-1})	122 (27)	131 (16)
Creatinine (μmol litre^{-1})	80 (35)	80 (27)
ALP (iu litre^{-1})	233 (215)	69 (24)*
AST (iu litre^{-1})	139 (184)	36 (25)
ALT (iu litre^{-1})	74 (41)	49 (43)
Bilirubin (μmol litre^{-1})	75 (63)	10 (3)*
Albumin (g litre^{-1})	30 (9)	39 (5)*

Arterial blood samples (5 ml) were collected before (time 0) and 2, 4, 6, 8, 10, 12, 15, 20, 25, 30, 45, 60, 90, 120, 240 and 480 min after administration of *cis*-atracurium. Blood samples were added to chilled tubes containing ethylenediamine tetra-acetic acid (EDTA), mixed thoroughly, and centrifuged; 1-ml aliquots of plasma were added to 4.0 ml of sulphuric acid 15 mmol litre^{-1} within 3 min of blood sample collection, mixed thoroughly and stored frozen at −20 °C. Urine was collected into bottles containing sodium citrate buffer 0.5 mol litre^{-1} from an indwelling urinary catheter for 10 h after administration of cisatracurium to estimate renal excretion of cisatracurium.

Plasma and urine concentrations of cisatracurium, laudanosine and the monoquaternary alcohol metabolite (MQA) were quantified by high-performance liquid chromatography with fluorescence detection. The lower limit of quantitation was 10 ng ml^{-1} for each compound. The coefficients of variation for cisatracurium were < 14 % at concentrations between 10 and 2000 ng ml^{-1}. The coefficients of variation for laudanosine and MQA were < 9 % and < 13 %, respectively, at concentrations between 15 and 750 ng ml^{-1} for both analytes. The presence of the monoquaternary acid metabolite was assessed qualitatively by examination of the chromatograms.

Plasma concentrations of cisatracurium and its metabolites were used to construct plasma concentration–time profiles for each patient. Pharmacokinetic analysis was performed using non-compartmental methods to determine area under the concentration–time curve (AUC), plasma clearance (*Cl*), volume of distribution at steady state (V^{ss}), and elimination of half-life ($T_{\frac{1}{2}}$) of cisatracurium. The maximum concentration (C_P max), AUC, $T_{\frac{1}{2}}$ and the ratio of the metabolite AUC to cisatracurium AUC were calculated for the laudanosine and MQA metabolites.

Urine concentration data were used to calculate the total amount of cisatracurium excreted unchanged, amount of metabolites in urine and renal clearance of cisatracurium, laudanosine and MQA.

Plasma cisatracurium concentration and percentage T1 suppression data were analysed using semi-parametric effect-compartment analysis [10] to estimate concentrations in the effect compartment (site of action) and the rate constant (k_{eo}) describing the rate of equilibration between plasma concentration and neuromuscular block. The effect-compartment concentration required to produce 50% T1 suppression (EC_{50}), which is an index of patient sensitivity, and the variable (γ) describing the steepness of the effect-compartment concentration *vs* %T1 suppression curve was calculated using the sigmoid Emax model [11].

In addition, each patient was observed for adverse reactions before (baseline), during and after the treatment phases of the study. In particular, arterial pressure and airway pressures were observed closely to detect evidence of clinically significant histamine release.

One-way analysis of variance was performed to evaluate differences in the calculated variables between the two groups. Statistical significance was assumed at $P < 0.05$. Values are expressed as mean (SD).

Results

Two patients from the liver transplant group were excluded from the pharmacodynamic analysis because they received clindamycin, which may potentiate the effects of neuromuscular blocking agents. Another three patients were excluded in the liver transplant group for determination of EC_{50} because of insufficient data to accurately define EC_{50}. There was no difference in EC_{50} or the degree of maximum neuromuscular block after cisatracurium 0.1 mg kg^{-1} between the two groups (table 2). Time to maximum block was shorter in the liver transplant patients, but the clinical effective duration of action (time for T1:T0 to reach 25%), times for T1:T0 to reach 5%, 75%, and 95%, recovery indices (time for T1:T0 to recover from 25% to 75% and from 5% to 95%), and time to T4:T1 ≥ 70% were similar (table 2). There were no significant differences between the two groups in the rate constant (k_{eo}) describing the rate of equilibration between plasma concentration and neuromuscular block or in the variable (γ) describing the steepness of the effect-compartment concentration compared with the %T1 suppression curve (table 2).

Table 2 Pharmacodynamic variables for cisatracurium ($2 \times ED_{95}$) in liver transplant and control patients (mean (SD)). Cl (ml min^{-1} kg^{-1})	6.6 (1.1)	5.7 (0.8)*
V^{ss} (ml kg^{-1})	195 (38)	161 (23)*
$T_{\frac{1}{2}}$ (min)	24.4 (2.9)^1	23.5 (3.5)

One patient in the liver transplant group did not have complete blood sampling and was eliminated from the pharmacokinetic analysis. Plasma cisatracurium concentration *vs* time data were similar in the two groups (fig. 1). The pharmacokinetic variables of cisatracurium are shown in table 3. Patients with liver disease had a higher clearance and larger volume of distribution at steady state than control patients. However, elimination half-life was similar in both groups. There was no or a poor correlation between albumin concentrations and *Cl* or V^{ss}.

The percentage of cisatracurium recovered unchanged from the urine was 11.4 (6.6)% in 11 liver transplant patients and 14.3 (4.0)% in eight control patients. Renal clearance of cisatracurium was 0.62 (0.32) ml min^{-1} kg^{-1} in liver transplant patients ($n = 10$) and 0.80 (0.26) ml min^{-1} kg^{-1} in control patients ($n = 8$).

Maximum plasma laudanosine concentrations were 16 (5) ng ml^{-1} and 21 (5) ng ml^{-1} in liver transplant and control patients, respectively. Maximum plasma MQA concentrations were 73 (14) ng ml^{-1} and 82 (12) ng ml^{-1}, respectively. Monoquaternary acid was not detected on any chromatogram from any plasma or urine sample.

The $T_{\frac{1}{2}}$ of laudanosine was determined in only two liver transplant and four control patients. In the other patients, plasma concentrations were less than the detection limit or there were less than three quantifiable concentration–time points in the terminal phase. The laudanosine $T_{\frac{1}{2}}$ values in liver transplant patients were 7.2 and 8.2 h, and in control patients the $T_{\frac{1}{2}}$ ranged from 1.6 to 4 h. The $T_{\frac{1}{2}}$ of MQA was 61.9 (9.4) and 39.8 (9.9) min for 11 liver transplant and seven control patients, respectively.

The mean amount of laudanosine excreted in the 10-h urine collection period was 602 (280) µg in 11 liver transplant patients and 503 (260) µg in eight control patients. Renal clearance of laudanosine was 0.6–1.2 ml min^{-1} kg^{-1} in two evaluable liver transplant patients. Renal clearance of laudanosine was 1.35 (0.89) ml min^{-1} kg^{-1} in four control patients.

Mean amount of MQA in urine were 449 (213) and 391 (139) µg in 11 liver transplant and eight control patients, respectively. Renal clearance of MQA was 0.59 (0.33) and 0.90 (0.39) ml min^{-1} kg^{-1} in liver transplant ($n = 8$) and control ($n = 6$) patients, respectively.

There were no clinically significant changes in arterial pressure, heart rate or airway pressure after administration of cisatracurium, and no other untoward effects were noted in any patient after bolus administration of cisatracurium.

Discussion

The pharmacokinetics and pharmacodynamics of cisatracurium were determined in liver transplant and control patients. Cisatracurium is eliminated from the body via Hofmann elimination in the central (plasma) and peripheral (tissue) compartments; elimination from the peripheral compartment cannot be estimated *in vivo*. Therefore, non-compartmental, rather than compartmental, methods were used to calculate pharmacokinetic variables. Non-compartmental methods are based on the assumption that elimination occurs only from the central compartment. *Cl*, an exit-site independent variable, is similar whether or not it is determined using compartmental or non-compartmental methods. V^{ss}, however, is underestimated when elimination from the peripheral compartment is ignored (i.e. when non-compartmental methods are used) [12].

We found that the pharmacokinetic variables (*Cl*, $T_{\frac{1}{2}}$ and V^{ss}) of cisatracurium in our control patients were similar to those observed in other studies of cisatracurium [3, 13]. In addition, these variables (*Cl*, $T_{\frac{1}{2}}$ and V^{ss}) in our control patients were similar to those of atracurium in healthy patients [8, 14–17]. The presence of liver disease changed the pharmacokinetics of cisatracurium to a limited degree: V^{ss} of cisatracurium was approximately 20% larger and mean plasma clearance was approximately 16% greater in liver transplant patients than in control patients, although $T_{\frac{1}{2}}$ was not different. Similar findings have been reported for atracurium in patients with liver disease [8, 14–16]. Because a chemical degradation process (Hofmann elimination) is the major elimination pathway for cisatracurium [9], the higher clearance in liver transplant patients is most likely explained by the larger volume of distribution rather than a change in organ clearance.

The clinical effective duration of action (time for T1:T0 to reach 25%) in our control patients was similar to that observed in other studies of cisatracurium [1, 2]. Recovery indices (time for T1:T0 to recover from 25% to 75% and from 5% to 95%) in our control patients were similar to those observed by Belmont and colleagues [1] but were shorter than those observed by Boyd and colleagues [2]. The time to maximum block in our control patients was shorter than that found in other studies of cisatracurium [1–4]. Furthermore, the time to onset for cisatracurium was shorter in liver transplant than in control patients, although the duration of action was similar in both groups. These findings are in contrast with results reported for atracurium: the time to onset of action was longer and the duration of action shorter for atracurium in patients with hepatic dysfunction [18]. It is possible that our patients had more severe liver disease than those studied by Bell and co-workers, as most of their patients had only mild liver disease [18]. Therefore, our patients may have had a more hyperdynamic circulation with higher perfusion of muscles, resulting in a shorter time to onset. A slightly lower EC_{50} (although not statistically significant) in our patients with liver disease may have contributed to this observation.

Plasma laudanosine and MQA concentrations after cisatracurium 0.1 mg kg^{-1} were much lower than those observed after administration of atracurium besylate 0.3 mg kg^{-1} [8]; this dose of atracurium besylate is less potent than the dose of cisatracurium we used. Although cisatracurium is approximately three times more potent than atracurium expressed in terms of its cation, the dose of atracurium is expressed as its besylate salt, whereas that of cisatracurium is not, indicating that 0.1 mg kg^{-1} of cisatracurium is equipotent to approximately 0.5 mg kg^{-1} of atracurium besylate. Peak laudanosine concentrations after atracurium were 180 (80) and 190 (40) ng ml^{-1} in patients with liver disease and in normal patients, respectively [8]. Similar laudanosine concentrations were observed in another study [16]. However, after cisatracurium, peak laudanosine concentrations were 16 (5) and 21 (5) ng ml^{-1} in liver transplant and control patients, respectively. Similarly, peak MQA concentrations after atracurium were as high as 480 (180) and 490 (70) ng ml^{-1} in patients with liver disease and in normal patients, respectively [8] while after cisatracurium, peak MQA concentrations were 73 (14) and 82 (12) ng ml^{-1}, respectively. These differences may be related, at least in part, to the higher potency of cisatracurium, resulting in less substrate for metabolization.

The number of patients with evaluable $T_{\frac{1}{2}}$ data for laudanosine was small and therefore no conclusions can be drawn on the effect of liver disease on the elimination characteristics of laudanosine. Nevertheless, the pharmacokinetics of laudanosine and MQA after cisatracurium in both patients with liver disease and controls were similar to those reported after atracurium [8, 16]. The $T_{\frac{1}{2}}$ of laudanosine was also longer in patients with liver disease after atracurium administration [8, 16, 19], indicating that the liver plays an important role in the clearance of laudanosine. Similar observations have been made for MQA [8]. Because of the altered pharmacokinetics of these metabolites in patients with liver disease, cisatracurium may be the preferred drug compared with atracurium because of the significantly lower plasma concentrations of laudanosine and MQA after equipotent doses of these neuromuscular blocking agents.

Liver disease does not appear to have an effect on the urinary excretion of cisatracurium. Similar findings have been published for atracurium [19]. In fact, renal clearance and renal elimination of unchanged drug may be slightly greater for cisatracurium than for atracurium [17, 19, 20]. This may be related to the fact that atracurium contains short-acting isomers that are less likely to appear in the urine.

Acknowledgement

Cisatracurium was provided by Glaxo Wellcome, who also supported the study financially. We thank Karen Latta for the expert technical assistance and Cindy Rawls for analytical support.

Soluble E-cadherin concentrations in patients with systemic inflammatory response syndrome and multiorgan dysfunction syndrome

A. J. PITTARD, R. E. BANKS, H. F. GALLEY AND N. R. WEBSTER

Summary

We have assessed the role of the cell–cell adhesion molecule, E-cadherin, in the pathogenesis of multiorgan failure in 24 intensive care patients with sepsis and varying degrees of organ dysfunction, compared with 21 healthy subjects. Plasma soluble E-cadherin (sE-cadherin) was measured by enzyme immunoassay. The median concentration of sE-cadherin in normal subjects was 3.21 μg ml^{-1} compared with 6.00 μg ml^{-1} in patients with sepsis and organ dysfunction ($P = 0.0019$). There was no statistically significant difference in concentrations of sE-cadherin in survivors compared with non-survivors. Concentrations of sE-cadherin tended to increase with the severity of organ failure. We conclude that sE-cadherin is increased in inflammation and injury, and may be related to the degree of multiorgan failure after sepsis. (*Br. J. Anaesth.* 1996; **76**: 629–631)

Key words

Complications: multiple organ dysfunction syndrome. Complications, septicemia. Pharmacology, cadherin.

Sepsis, septic shock and multiorgan failure are important contributors to mortality and morbidity in patients in the intensive care unit [1–3]. Shock and infection are the two most common predisposing factors in the development of multiorgan dysfunction [3], causing an inflammatory response initiating a cascade of events leading to widespread endothelial damage [2, 4, 5] and failure of the microcirculation. Adhesion molecules are important in cell–cell and cell–matrix interactions. Integrins and selectins play fundamental roles in the interaction between leucocytes and endothelial cells [6, 7]. Cadherins mediate cell–cell adhesion and are important in maintaining tissue architecture and consequently organ function. E-cadherin is a cell adhesive molecule found in a variety of tissues [8]. Soluble forms of integrins, selectins and cadherins have been identified.

Increased concentrations of immunoreactive soluble forms of endothelial adhesion molecules have been found in patients with sepsis and multiorgan dysfunction [9–11]. Increased concentrations of soluble E-cadherin (sE-cadherin) have been reported in patients with various cancers [8, 12]. There has been no previous study on the role of E-cadherin in patients with sepsis. Circulating sE-cadherin may reflect tissue turnover or regeneration, and may be important in the regulation of normal organ function. We have measured plasma sE-cadherin concentrations in patients with sepsis and varying degrees of multiorgan dysfunction.

Patients and methods

After approval by the local Clinical Research Ethics Committee, we studied 24 consecutive patients admitted to the intensive care unit, who were more than 18 yr of age, when they fulfilled the Bone sepsis criteria [13]. Fourteen patients were medical patients, nine were postoperative and one was post-trauma. Blood samples were obtained from an indwelling arterial cannula and collected into a heparinized tube. APACHE II score and numbers of dysfunctioning organs (table 1) [14] were recorded at sampling. In four patients sequential samples were obtained when patients developed increasing numbers of dysfunctional organs. After immediate centrifugation, plasma was separated into aliquots and stored at −20 °C for assay of sE-cadherin. Venous blood samples were also obtained from 21 healthy subjects (11 male) aged 21–54 yr.

Samples were assayed for sE-cadherin using a commercially available sandwich enzyme immunoassay (Takara Shuzo Co. Ltd, Japan). Briefly, a microtitre plate was coated with a mouse monoclonal anti-human E-cadherin antibody, non-specific binding was blocked using a blocking buffer and diluted samples and standards were added to the wells. After incubation and washing steps, an anti-mouse IgG antibody conjugated with horseradish peroxidase was then added to each well, incubated, washed and bound sE-cadherin detected by incubation with substrate (*o*-phenylenediamine). After the addition of stop solution, the absorbances of the wells were measured at 490 nm using a Titertek Multiskan MCC reader and the concentration of sE-cadherin determined by comparison with the standard curve

Table 1 Definitions of organ dysfunction [14]

Organ system	Definition
Cardiovascular	Systolic AP < 90 mm Hg or requiring vasopressors
Respiratory	Ventilatory frequency < 5 or > 20 bpm, requiring mechanical ventilation, or Pa_{O_2}/FI_{O_2} < 36.8 kPa
Renal	Creatinine > 280 mmol litre^{-1}
Hepatic	Bilirubin > 51 mmol litre^{-1}
Haematological	Platelet count < 100 × 10^9 litre^{-1}
Neurological	Glasgow coma scale < 8 (in the absence of sedation)
Gastrointestinal	Stress ulcer requiring > 2 u. transfusion

using Flexicalc software (Wallac, Finland). All standards and samples were assayed in duplicate. The coefficient of variation (CV) of replicate samples was less than 10 % and a between-plate CV based on a sample with a mean value of 3.3 µg ml^{-1} was 13.1 % ($n = 4$).

Data were analysed using Microsoft Excel 5.0 with Astute statistical software add-in. When tested for normality using the Komolgorov–Smirnov goodness-of-fit test and normal plots, the data were found to be non-normally distributed and accordingly non-parametric statistical tests were used. Comparison of sE-cadherin concentrations at study entry between survivors and non-survivors, and healthy subjects was made using the Mann–Whitmey *U* test. Pearson rank linear regression was used to assess the relationship between APACHE II score and sE-cadherin concentrations. Kruskal–Wallis ANOVA was used to assess the relationship between sE-cadherin concentrations and the degree of organ failure. $P < 0.05$ was considered statistically significant.

Results

We studied 24 patients, median age 65 (range 19–79) yr, 18 of whom were male. The median APACHE II score at the time of sampling was 26 (13–39). Sixteen patients died (67 %). The median APACHE score in those who died was 25.5 (16–37) and 20.5 (13–31) in survivors (ns). Immunoreactive sE-cadherin concentrations were significantly higher in patients with sepsis and organ dysfunction (6.00 (0.98–19.98) µg ml^{-1}) than those in healthy subjects (3.28 (1.18–6.88) µg ml^{-1}) ($P = 0.0019$) (fig. 1). There was a tendency for sE-cadherin concentrations to increase with the degree of organ dysfunction, although this failed to reach statistical significance (fig. 2). There was no difference in sE-cadherin concentrations between patients who died (5.53 (2.10–19.98) µg ml^{-1}) and those who survived (8.63 (0.98–11.98) µg ml^{-1}) ($P = 0.86$). sE-cadherin concentration did not correlate with APACHE II score ($r = -0.25$, $P = 0.25$).

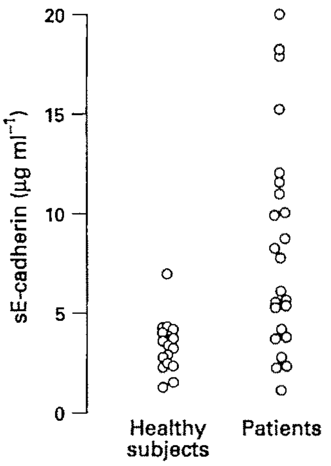

Figure 1 Plasma soluble E-cadherin (sE-cadherin) concentrations in healthy subjects compared with samples obtained at study entry in intensive care patients with sepsis and organ failure ($P = 0.0019$, Mann–Whitmey *U* test).

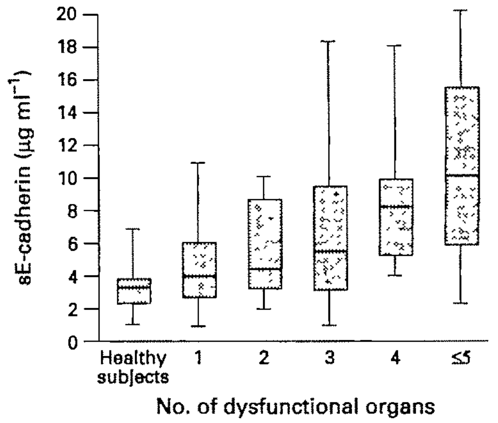

Figure 2 Plasma soluble E-cadherin (sE-cadherin) concentrations in 21 healthy subjects and 24 patients with increasing degrees of organ failure. The box and whisker plots represent median with 25 and 75 percentile concentrations; maximum and minimum concentrations are shown as bars ($P = 0.51$, Kruskal–Wallis ANOVA in patients).

Discussion

We have demonstrated significantly increased concentrations of the cell–cell and cell–matrix adhesion molecule, soluble E-cadherin, in patients with sepsis and organ dysfunction. Plasma concentrations tended to correlate with increasing severity of illness, as reflected by the increasing numbers of organ systems failing. It is possible that these increased concentrations reflect the severity of tissue damage and degree of epithelial turnover and may suggest a role for abnormalities in intercellular adhesion in the pathogenesis of multiorgan dysfunction and failure.

Cadherins play an essential role in normal growth and tissue development. There have been three forms described, E-, N- and P-, with characteristic tissue distribution [8]. They share a common primary structure and all mediate cell–cell adhesion and maintenance of normal tissue architecture. Several studies have shown that loss of cell surface immunoreactive E-cadherin is associated with tumour progression and tissue invasion [8, 12]. Soluble forms of E-cadherin have been identified in plasma representing functionally active degradation fragments and may indicate either regeneration or loss of cell surface E-cadherin.

We suggest that increased sE-cadherin concentrations represent increased cleavage of tissue E-cadherin secondary to increased protease activity [15] or free radical release [14] from activated neutrophils resulting in loss of tissue architecture and function. However, it is possible that there is a generalized increase in epithelial cell turnover with an associated requirement for E-cadherin regeneration. *In vitro*, interleukin-1 causes shedding of biologically active E-selectin (an endothelial cell adhesion molecule) from the cell surface of cultured human endothelial cells [10]. It is not clear if cytokines present in the circulation of septic patients as a result of the inflammatory process can cause similar shedding of other adhesion molecules.

In the present study, measured immunoreactive sE-cadherin concentrations may have been underestimated as high concentrations of proteolytic enzymes may have yielded smaller fragments which may not have been detected in the assay system used. However, concentrations in our patients with sepsis were generally higher than those reported previously with various tumours [12]. Moreover, marked differences were found between plasma from patients with sepsis and that from healthy subjects.

In summary, we have shown increased circulating concentrations of sE-cadherin in patients with sepsis and varying degrees of multiple organ failure. Further studies are required to elucidate the mechanism of shedding and the pathophysiological role of E-cadherin in such patients.

Preoperative inhibition of angiotensin-converting enzyme improves systemic and renal haemodynamic changes during aortic abdominal surgery

M. LICKER, M. BEDNARKIEWICZ, P. NEIDHART, R. PRÊTRE, M. MONTESSUIT, H. FAVRE AND D. R. MOREL

Summary

We studied 22 patients undergoing aortic surgery, allocated randomly to receive, before induction of anaesthesia, a single i.v. dose of enalapril 50 μg kg^{-1} or saline. During infrarenal aortic cross-clamping, we observed similar reductions in oxygen uptake in the two groups, despite greater systemic oxygen delivery in enalapril-treated patients; angiotensin-converting enzyme inhibition prevented the reduction in cardiac output and attenuated the decrease in glomerular filtration. Changes in glomerular filtration secondary to aortic clamping were related positively to changes in renal plasma flow ($r = 0.83$ (saline group) and $r = 0.65$ (enalapril group)). Creatinine clearance on the first day after operation was significantly higher in the enalapril compared with the saline group. We conclude that enalapril pretreatment is effective in improving systemic oxygen delivery, renal plasma flow and glomerular filtration during aortic abdominal surgery. (*Br. J. Anaesth.* 1996; **76**: 632–639)

Key words

Surgery, vascular. Kidney, blood flow. Kidney, function. Pharmacology, ACE inhibitors.

Major haemodynamic disturbances are often encountered during aortic abdominal surgery. In most instances, infrarenal aortic cross-clamping causes decreases in cardiac output, oxygen delivery and oxygen uptake that are associated with reduced renal blood flow and glomerular filtration rate [1]. After release of the aortic clamp, systemic haemodynamic and metabolic changes revert rapidly to normal, whereas renal function remains impaired, at least temporarily [2].

Although the mechanisms of perioperative renal insufficiency were believed to be related to relative hypovolaemia, decreased myocardial function and increased sympathetic nervous activity, neither fluid volume expansion nor sympathetic block, nor the use of mannitol or dopamine have been shown to attenuate these perioperative changes consistently [3, 4]. Powerful endogenous vasoconstricting substances such as thromboxane A_2, oxygen-derived free radicals and endothelin-1 have been shown to be released during aortic clamping, and all might contribute to prolonged impairment of renal function [5–7]. The importance of the renin–angiotensin system (RAS) has also been emphasized in the regulation of arterial pressure, blood flow distribution and renal function [8]. Experimental evidence suggests that angiotensin II mediates widespread vasoconstriction by causing direct activation of transmembrane calcium transport and indirectly facilitating release of noradrenaline, by sensitizing adrenergic receptors, and also by enhancing the synthesis of thromboxane and endothelin-1 [9]. Clinical investigations have reported increased plasma renin activity (PRA) and angiotensin II concentrations during major surgical procedures, including aortobifemoral bypass [10, 11], suggesting that angiotensin II may account to some extent for perioperative circulatory and renal haemodynamic impairment.

Recently, angiotensin-converting enzyme inhibitors (ACEI) have been prescribed successfully for the treatment of hypertension and congestive heart failure [12]. In addition to normalizing elevated arterial pressure, ACEI treatment improves cardiac output by lowering vascular resistances and also produces renal vasodilatation and natriuresis. Interestingly, these agents have been advocated to prevent deterioration of renal function in hypertensive and diabetic patients [13]. Based on these beneficial effects, and as the RAS is known to be stimulated during aortic abdominal surgery, we hypothesized that ACE inhibition would potentially attenuate systemic haemodynamic and renal functional impairments. Therefore, we tested, in a double-blind randomized study, if a single dose of ACEI administered before operation would preserve systemic oxygen delivery and provide protective renal effects in adult patients undergoing infrarenal aortic surgery.

Patients and methods

We studied 22 patients undergoing elective infrarenal aortic surgery because of aortic aneurysm or atherosclerotic occlusive disease. Informed consent was obtained and the study was approved by the Committee for Ethics in Clinical Research of our institution. Patients with preoperative renal dysfunction (creatinine clearance < 50 ml min^{-1} 1.73 m^{-2}), cardiac insufficiency (episodes of congestive heart failure or left ventricular ejection fraction $< 40\%$), myocardial infarction within the last 6 months, renal artery stenosis detected on the angiogram or those receiving ACEI therapy were excluded.

Usual cardiac medications, except diuretics, were continued up to and including the morning of surgery. Patients were premedicated with midazolam 7.5 mg orally and morphine 0.1 mg kg^{-1} i.m. In the induction room, radial and thermodilution pulmonary arterial catheters were inserted during local anaesthesia for measurement of mean arterial (MAP), central venous (CVP) and pulmonary capillary wedge pressures (PCWP), and intermittent cardiac output (CO) determination. Electrocardiographic leads II and V5 were attached for monitoring heart rate (HR) and ST changes.

Anaesthesia was induced with alfentanil 30–40 µg kg^{-1} i.v., given over 1–2 min, followed by thiopentone to loss of the eyelid reflex (3–5 mg kg^{-1}). Neuromuscular block was achieved with pancuronium 0.1 mg kg^{-1}. After tracheal intubation, mechanical ventilation with an air–oxygen mixture was adjusted to maintain arterial blood-gas tensions within the normal range (end-expiratory carbon dioxide fraction 4–4.5% and arterial oxygen saturation greater than 94%). A Foley urinary bladder catheter was inserted after induction of anaesthesia for urinary sampling and urine flow measurement. Throughout the surgical procedure, anaesthesia was maintained with an i.v. infusion of alfentanil 80–120 µg kg^{-1} min^{-1} supplemented with inhaled isoflurane (up to 2%). Phenylephrine was administered at the discretion of the anaesthetist in order to maintain MAP within a clinically acceptable range (20% of preoperative values).

Before operation, crystalloids 12 ml kg^{-1} (containing Na$^+$ 130 mmol litre^{-1}, Cl$^-$ 118 mmol litre^{-1} and K$^+$ 5.4 mmol litre^{-1}) were infused over 20 min in all patients. During surgery, fluid loading was titrated to maintain PCWP at 10–15 mm Hg. Red blood cell concentrates were given when packed cell volume (PCV) decreased to less than 25%. A blood salvage device (Cell Saver 4; Haemonetics Braintree, MA, USA) was used in each case to reduce the need for homologous blood transfusion.

Patients were allocated in a randomized, double-blind manner to one of two groups: the enalapril group received enalapril 50 µg kg^{-1} (Reniten, Merck, Sharp & Dohme Research Laboratories, NJ, USA) diluted in 20 ml of normal saline and injected i.v. over 5 min ($n = 12$); the saline group received the same volume of saline solution ($n = 10$). In a dose-finding study, conducted in similar surgical patients, we demonstrated that a single 50-µg kg^{-1} i.v. injection given before surgery produced marked inhibition ($> 90\%$) of plasma angiotensin-converting enzyme activity for more than 20 h whereas lower doses (10 and 30 µg kg^{-1}) produced ACE inhibition of shorter duration (90% ACE inhibition up to 4 and 8 h after administration of enalapril 10 and 30 µg kg^{-1}, respectively). The drugs were given 25 min before induction of anaesthesia, when a stable basal systemic haemodynamic state had been reached and while patients were fluid loaded with i.v. crystalloids. The subsequent changes in haemodynamic state, oxygen uptake and renal function were assessed in the two groups before and during aortic cross-clamping and after aortic unclamping.

Blood temperature and cardiac output, determined in triplicate by injection of 10 ml of 5% glucose solution, were measured by a cardiac output computer (Model 9520A, American Edwards Laboratories, Irvine, CA, USA). Systemic haemodynamic data (HR, MAP, CVP, PCWP, CO) were recorded at end-expiration at the following times: (1) before anaesthesia (i.e. before and 20 min after administration of drug), (2) during the surgical aortic approach (i.e. 2 min after skin incision, and 2 min before aortic cross-clamping), (3) during aortic cross-clamping (i.e. 5 min after aortic cross-clamping and immediately before ilio–femoral unclamping) and (4) after vascular unclamping (i.e. 2 min after "first leg" unclamping, and during peritoneal closure). Systemic vascular resistance index (SVRI) and cardiac index (CI) were calculated according to standard formulae.

Glomerular filtration rate (GFR) and effective renal plasma flow (ERPF) were estimated using a constant infusion technique of inulin and para-aminohippuric acid (PAH). Priming doses of inulin 30 mg kg^{-1} (10% Inulin; Laevosan GmbH, Linz, Austria) and PAH 8 mg kg^{-1} (Merck, Sharp & Dohme, NJ, USA) were given i.v. followed by a continuous infusion of both drugs at doses of 0.20 mg kg^{-1} min^{-1} and 0.15 mg kg^{-1} min^{-1}, respectively. After an 80-min equilibration period, urine was collected over at least 30 min before (pre-clamping) and during aortic cross-clamping (clamping), and after "first leg" reperfusion (post-clamping); arterial blood was sampled in the middle of each collection period. Urinary and plasma inulin and PAH concentrations were assayed spectrophotometrically. Inulin and PAH clearances (C_{IN}, C_{PAH}) were calculated as the respective urine concentration divided by arterial plasma concentration multiplied by urine volume in ml min^{-1}; these data were corrected for standard body surface area (1.73 m^2). As PAH handling within the kidney is altered during surgery and anaesthesia, the renal extraction fraction of PAH (E_{PAH} = arterial − venous plasma concentration divided by arterial concentration of PAH) was determined. Therefore, the surgeon directly punctured the renal vein and slowly withdrew venous blood as close to the kidney as possible. A "corrected" ERPF was obtained (ERPF = C_{PAH}/E_{PAH}) and RBF was calculated as: RBF = ERPF × 100/(100 − PCV). During the pre-clamping, aortic clamping and post-clamping periods, systemic haemodynamic variables (MAP, CVP, CO) were averaged as the mean of three measurements obtained 15 min apart at the beginning, middle and end of urine sampling. Renal vascular resistance (RVR) and fractional renal blood flow (RBF) were calculated using the following equations: RVR = (MAP − CVP)/RBF × 79.9 and fractional RBF = RBF/CO × 100.

Additional renal functional tests comprised calculation of creatinine clearance (C_{Creat}), fractional sodium excretion (FE_{Na^+}), total sodium excretion (U_{Na^+}) and protein excretion. FE_{Na^+} was calculated by dividing the urine-to-plasma sodium ratio by the urine-to-plasma creatinine ratio times 100; U_{Na^+} equals the product of urinary sodium and urinary flow. Proteinuria and C_{Creat} were also assessed on the day before surgery and 12 h after operation (12-h urine collection period). Serum and urinary sodium and creatinine concentrations were measured with a standard flame emission photometer. Diuretics, mannitol and dopamine were not given during the entire study.

In arterial and mixed venous blood samples, haemoglobin (Hb), oxygen tension and oxygen saturation (Sa_{O_2}, $S\bar{v}_{O_2}$) were measured directly (ABL Radiometer OSM3, Copenhagen, Denmark). Total body oxygen consumption ($\dot{V}O_2$) was estimated as the product of CO and the arteriovenous oxygen content difference. Total body oxygen delivery (DO_2) was derived as CO × arterial oxygen content.

STATISTICAL ANALYSIS

All data are expressed as mean (SD). The influence of enalapril treatment was tested by the Mann–Whitney two-sample test. To determine if differences existed between times, repeated measures analysis of variance was performed followed by the two-tailed paired Student's t test and Dunnett's correction for multiple comparisons. Regression analyses between changes in systemic and renal haemodynamic state and renal functional variables in response to aortic clamping and after aortic unclamping were analysed within each group. Correlations were also determined between inulin and creatinine clearance and between changes in DO_2 and $\dot{V}O_2$. For all statistical comparisons, significance was defined as $P < 0.05$.

Results

Two patients (one in each group) were excluded from the study because the surgeon had to proceed with vascular clamping involving one (or both) renal artery(ies). Therefore, there were nine and 11 patients in the saline and enalapril groups, respectively. There were no differences between the two groups in preoperative clinical characteristics and surgical management (table 1). All patients (except one in the saline group) were treated with either β-blockers, calcium-channel blockers, diuretics or a combination of these drugs. Preoperative creatinine clearance was within the normal range in both groups. Intraoperative fluid requirements tended to be slightly greater in the enalapril group compared with the saline group, but this was not statistically significant for red cell transfusion and crystalloid infusion.

SYSTEMIC HAEMODYNAMIC AND METABOLIC DATA (fig. 1, table 2)

Before anaesthesia and after fluid loading, enalapril 50 μg induced increases in CI (+12%; $P = 0.023$) and DO_2 and decreases in SVRI, without changes in MAP and HR. In the saline group, CI tended to increase, although this was not significant (+7%). General anaesthesia was associated with similar decreases in $\dot{V}O_2$ in the two groups (−19% in the

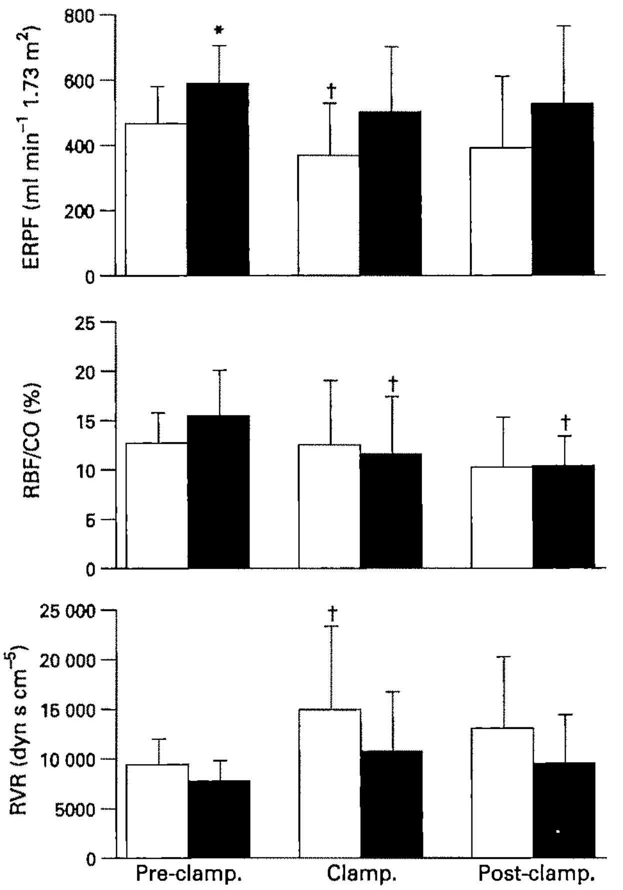

Figure 2 Effective renal plasma flow (ERPF), fractional renal blood flow (% RBF/CO) and renal vascular resistance (RVR) at the pre-clamping, clamping and post-clamping periods, in the saline (☐) and enalapril (■) groups. $*P < 0.05$ compared with saline group; $\dagger P < 0.05$ compared with pre-clamping.

saline group and −16% in the enalapril group). Two patients in the enalapril group and one in the saline group required an i.v. bolus of phenylephrine 100 μg after induction of anaesthesia.

There was no significant difference in HR or MAP between the two groups at any time. Towards the end of surgery, MAP and SVRI were decreased significantly in the two groups, compared with pre-anaesthesia baseline values.

In the saline group, aortic cross-clamping induced a decrease in CI (−29%; $P = 0.001$); the associated reduction in $\dot{D}o_2$ (−28%) correlated with the reduction in $\dot{V}o_2$ (−24%; $P < 0.001$; $r = 0.85$) and was accompanied by decreased oxygen saturation in mixed venous blood ($S\bar{v}_{O_2}$, −9%; $P = 0.030$). In contrast, in the enalapril group, CI was maintained at pre-clamping values and the reduction in $\dot{V}o_2$ (−20%; $P < 0.001$) induced by aortic cross clamping was not associated with significant changes in $\dot{D}o_2$ or $S\bar{v}_{O_2}$. After aortic unclamping, $\dot{V}o_2$ increased to pre-clamping values in the two groups; this was accompanied by a significant increase in $\dot{D}o_2$ in the saline group only (+19%; $P = 0.034$).

RENAL HAEMODYNAMIC VARIABLES AND FUNCTION (fig. 2, table 3)

During the pre-clamping period, in enalapril-treated patients, C_{Creat} was increased compared with the preoperative period (+27%; $P = 0.035$) and higher ERPF values were noted compared with saline-treated patients ($P = 0.027$).

In the saline group, aortic cross-clamping was associated with significant decreases in C_{Creat}, C_{IN} and ERPF, whereas the fraction of CO (RBF/CO ratio) delivered to the kidney did not change. In the enalapril group, after aortic cross-clamping, the RBF/CO ratio decreased significantly and GFR was greater than in the saline group, as indicated by C_{Creat} (78 (28) *vs* 53 (17) ml min^{-1} 1.73 m^{-2}; $P = 0.052$) and C_{IN} (79 (32) *vs* 49 (22) ml min^{-1} 1.73 m^{-2}; $P = 0.033$). The simultaneous changes in systemic and renal haemodynamic variables resulted in unchanged RVR in the enalapril group whereas renal vasoconstriction occurred in the saline group, as indicated by increases in RVR ($P = 0.044$). In both groups, a positive linear relationship was found between aortic clamping-induced changes in ERPF and GFR ($r = 0.83$ in the saline group and $r = 0.65$ in the enalapril group). No such relationship was found between CI and ERPF and between CI and GFR.

After vascular unclamping and until 24 h after surgery, C_{Creat} values in the saline group remained

significantly lower than during the preoperative period. In contrast, in the enalapril group, C_{Creat} did not differ from preoperative values, and postoperative C_{Creat} was significantly higher than in the saline group. During operation, urinary output was comparable, whereas FE_{Na^+}, U_{Na^+} and proteinuria were significantly increased compared with preoperative values in the two groups.

We found a close correlation between C_{IN} and C_{Creat} ($r = 0.89$; $n = 59$; $P < 0.001$) and no significant change in E_{PAH} at the three intraoperative study times.

All patients survived the operation; the trachea was extubated in the operating theatre and they were monitored in a post-anaesthesia recovery unit for 24 h. No patient had ECG evidence of myocardial infarction and no episode of delayed renal failure occurred until discharge from hospital in the two groups.

Discussion

In this study we have demonstrated that preoperative administration of enalapril, a long-acting ACEI, prevented the decrease in CI and Do_2 induced by infrarenal aortic cross-clamping, without influencing changes in oxygen uptake. Acute RAS block is associated with improved intraoperative renal perfusion and better preservation of GFR, lasting at least 24 h after surgery.

We administered enalapril in an unusually high dose (50 µg kg^{-1}) with the aim of inhibiting plasma ACE activity, and hence angiotensin II synthesis, for at least 24 h. Indeed, elevated PRA has been reported after surgical incision and increased angiotensin II plasma concentrations are known to culminate at the time of unclamping and to persist for more than 6 h after operation [9, 10, 14]. We also found that lower enalapril doses (10 and 30 µg kg^{-1}) did not afford suppression of plasma ACE activity for the whole perioperative period.

Acute removal of angiotensin II vasopressor effects could potentially contribute to intraoperative hypotension because of synergistic effects between ACEI and other chronic antihypertensive drugs given before operation. Surprisingly, acute block of the RAS was associated with a stable haemodynamic state and there were no differences in vasopressor and fluid requirements between the two groups. We believe that haemodynamic tolerance to enalapril pretreatment was attributed to optimal i.v. fluid loading. In addition, the other arterial pressure regulating mechanisms (the sympathetic nervous system and arginine vasopressin), were either unaffected or blocked incompletely; hence, these mechanisms were presumably activated after surgical incision, to maintain arterial pressure homeostasis after withdrawal of the vasoconstricting influence of angiotensin II [15].

In accordance with previous investigations [16], we observed a marked decrease in CO (−29%) despite stable arterial and cardiac filling pressures after exclusion of the lower body compartment in saline-treated patients. Several physiological mechanisms are thought to be implicated in the haemodynamic changes associated with aortic cross-clamping. First, mechanical occlusion of the aorta directly increases cardiac afterload whereas activation of the sympathetic nervous system and the RAS results in increased arteriolar vasomotor tone and myocardial contractility. Second, using radioisotopic techniques, it has been shown that blood volume is redistributed from the lower body to the more compliant splanchnic compartment [17]. Third, decreased right ventricular end-diastolic volume has been reported, despite unchanged cardiac filling pressures, suggesting lower cardiac preload associated with reduced ventricular diastolic compliance [18]. Taken together these data suggest that the reduction in CO results mainly from reduced blood flow return to the heart (partly attributed to the slower time constant of blood flow within the splanchnic compartment) combined with a sudden increase in impedance to blood flow as a result of mechanical aortic occlusion and arteriolar vasoconstriction. Interestingly, several studies have demonstrated less haemodynamic changes after aortic cross-clamping in patients with aorto-occlusive disease than in those with abdominal aortic aneurysm. It is currently believed that the amount of collateral vascularization in patients with aorta-occlusive disease could afford some protection against major reductions in CO and increases in arterial pressure after aortic cross-clamping [19].

An important finding of this study was that enalapril pretreatment prevented the decrease in cardiac output induced by aortic cross-clamping. Experimental data suggest that the splanchnic vascular bed is extremely sensitive to vasoconstrictor agents, including catecholamines and angiotensin II, particularly during pathological conditions such as hypovolaemia or cardiac failure [20–22]. Acute administration of ACEI in dogs with congestive heart failure has also been shown to increase the unstressed splanchnic vascular volume and to improve circulatory output by promoting active vasodilatation [23]. Based on these results, we speculate that block of the RAS prevented the reduction in CI by alleviating elevated angiotensin II-dependent vascular impedance and hence by promoting "adaptive" splanchnic vasodilatation to accommodate for the sudden shift in blood volume from the lower to the upper body compartment. Other vasodilatators such as nifedipine [24], urapidil [25] and nitroglycerine [26] were also found to reverse the decrease in cardiac output induced by cross-clamping; however, in contrast with ACEI, they are associated with increased sympathetic discharge, that may affect the extent and pattern of changes in blood volume redistribution and in haemodynamic response.

Although pretreatment with enalapril produced maintenance of CI and Do_2, $\dot{V}o_2$ decreased similarly during infrarenal clamping in the two groups. Gelman and co-workers [25] reported similar results when nitroglycerine was infused at a rate of 1 to 2 µg kg^{-1} min^{-1} in order to maintain cardiac output. As whole body oxygen utilization was not restored after the pharmacologically induced increase in Do_2, we assume that maximal vasorelaxation had already occurred in ischaemic tissues located below the aortic clamp (in response to local vasodilators) and that enalapril (and nitroglycerine) increased shunt blood flow in the upper body compartment with no improvement in nutritive flow or tissue oxygen extraction, or both. Hence, systemic oxygen supply was matched adequately to the cross-clamp "adapted $\dot{V}O_2$" in the saline group whereas "unnecessary" elevated oxygen supply and myocardial work were achieved during aortic cross-clamping in the enalapril group.

Considering the stimulatory effects of surgical stress on the RAS and the potent renal vasoconstrictor effects of angiotensin II, it was not surprising to find that suppression of circulating and, presumably, intrarenal angiotensin II generation in enalapril-treated patients was associated with higher ERPF (a mean difference of 17%) compared with saline-treated patients. Animal studies have demonstrated that enhanced renal blood flow was the most impressive regional haemodynamic change after administration of different types of ACEI [26]; blood flow within the inner cortex was predominantly increased and accompanied by enhanced GFR [27]. The renal haemodynamic actions of ACEI have at least two components: suppression of angiotensin II synthesis and prolongation of bradykinin half-life through inhibition of its degradation. This latter component is thought to mediate renal vasodilatation even when RAS activation is prevented by preoperative β blocker treatment [28], as renin secretion from the juxtaglomerular cells is dependent on β_1 receptor stimulation.

Before aortic cross-clamping, ACEI-treated patients had higher GFR compared with saline-treated patients, because of higher ERPF as increased cortical blood flow would transform "silent" nephrons into new filtering units. During aortic cross-clamping, a reduction in GFR occurred in both groups and the changes in GFR correlated positively with changes in ERPF, indicating that the neurohumoral mediators that regulate renal haemodynamic state ultimately influence glomerular filtration properties. Deterioration of systemic haemodynamic state and release of vasoconstrictor mediators such as angiotensin II, thromboxane A_2 and endothelin-1 after aortic cross-clamping are believed to contribute to impaired renal function [29]. In this study, maintenance of GFR in enalapril-treated patients could be attributed to a lesser decrease in ERPF or to an increase in the glomerular ultrafiltration coefficient as a consequence of the withdrawal of the constricting effects of angiotensin II on mesangial cells, or both. Endothelin-1 has several additional synergistic interactions with the RAS, including enhanced ACE activity (conversion of angiotensin I to angiotensin II), potentiation of endothelin constriction by angiotensin II and activation of endothelin-1 synthesis by angiotensin II. The clinical importance of these interactions has recently been emphasized by demonstration that ACEI pretreatment abolishes renal vasoconstriction and the decrease in GFR induced by endothelin-1 [30].

In the saline group, GFR remained depressed after aortic unclamping, at a time when CI had recovered to pre-clamping values. Adenosine and oxygen-derived free radicals liberated from the ischaemic reperfused tissues are potential candidates for this transient renal dysfunction. Adenosine requires a normally functioning RAS to mediate its pre-glomerular vasoconstrictor action and administration of an ACEI has been shown to attenuate adenosine-mediated vasoconstriction [31]. Colson and co-workers [32] studied patients who received enalapril 10 mg orally, for 2 days before undergoing vascular surgery during i.v. anaesthesia. In agreement with our results, they found lesser haemodynamic changes induced by aortic cross-clamping in the treated group. However, there was no positive effect on renal haemodynamic state or function, as assessed from clearance of ^{99}technetium-diethylenetriaminepenta-acetic acid and ^{131}iodo-hippuran, respectively. Differences in dose regimen, anaesthetic management and measurements methods could account for these contradictory results.

In summary, we have demonstrated that a single i.v. dose of enalapril can be administered safely in patients undergoing elective abdominal aortic surgery when optimal fluid loading is maintained. This pretreatment is associated with suppression of the aortic clamping-induced reduction in cardiac output, renal vasodilatation and better preservation of glomerular filtration. Oxygen consumption decreased markedly after aortic-clamping, despite ACEI-induced maintenance of systemic oxygen supply. The renoprotective effect of enalapril could be attributed to withdrawal of the constricting action of angiotensin II, reduced kinin degradation and antagonism of endothelin-1. These effects would also be potentially helpful in patients undergoing suprarenal aortic cross-clamping or kidney transplantation. However, it should be kept in mind that ACE inhibitors could precipitate onset of renal failure in hypovolaemic subjects or in the presence of renal artery stenosis. Before suggesting specific indications, further studies are needed to define in which population subgroups RAS block may be beneficial.

Laparoscopic cholecystectomy: haemodynamic and neuroendocrine responses after pneumoperitoneum and changes in position†

E. O'LEARY, K. HUBBARD, W. TORMEY AND A. J. CUNNINGHAM

Summary

We have assessed the potential for myocardial ischaemia during laparoscopic cholecystectomy in 16 otherwise healthy patients. Continuous ambulatory ECG monitoring was commenced 12 h before operation and continued for 24 h after operation. The neuroendocrine stress response was assessed by measuring plasma concentrations of adrenaline and noradrenaline, human growth hormone, cortisol, renin and aldosterone, and prolactin, at specified times during surgery. Acute ST segment changes in the ECG occurred in only two patients. These episodes were independent of creation of pneumoperitoneum and changes in position. Acute intraoperative increases in MAP were noted during insufflation of carbon dioxide and reverse Trendelenburg positioning ($P < 0.05$). A four-fold increase in plasma concentrations of renin and aldosterone was noted after pneumoperitoneum and reverse Trendelenburg positioning ($P > 0.05$). There was a linear correlation between changes in plasma renin and aldosterone concentrations and MAP ($r = 0.97$ and $r = 0.85$, respectively). Prolactin concentrations increased four-fold after induction of anaesthesia. Cortisol, HGH, adrenaline and noradrenaline concentrations increased after deflation of the pneumoperitoneum. The time profile–concentration changes of increased MAP and renin–aldosterone suggests a cause–effect relationship. Increased intra-abdominal pressure and reverse Trendelenburg positioning may reduce cardiac output and renal blood flow. The early increase in prolactin concentration was probably secondary to the effect of the opioid fentanyl. (*Br. J. Anaesth.* 1996; **76**: 640–644)

Key words

Monitoring, electrocardiography. Cardiovascular system, effects. Hormones, renin. Hormones, aldosterone. Surgery, hormonal response. Surgery, laparoscopy. Position, effects. Position, Trendelenburg.

Laparoscopic cholecystectomy has four potential causes of major physiological changes in the anaesthetized patient: initial Trendelenburg position, creation of the pneumoperitoneum, potential for systemic absorption of carbon dioxide and reverse Trendelenburg position [1].

The extent of the cardiovascular changes associated with the creation of pneumoperitoneum depends on the intra-abdominal pressure attained, volume of carbon dioxide absorbed, patient's intravascular volume, ventilatory technique, surgical conditions and anaesthetic agents used [2, 3]. The haemodynamic effects include an increase in mean arterial pressure (MAP), decrease in cardiac output (CO) and increase in systemic vascular resistance (SVR).

Induction of pneumoperitoneum and changes in position appear to be associated with a biphasic haemodynamic response, with an early reduction followed by partial recovery of cardiac index [4]. Joris and colleagues [5] used flow-directed pulmonary artery catheters to assess the haemodynamic effects of peritoneal carbon dioxide insufflation to an intra-abdominal pressure (IAP) of 14 mm Hg in healthy non-obese patients with no cardiac disease. Cardiac index was reduced to 50% of its preoperative value 5 min after the beginning of insufflation. The relative roles of the factors which contribute to changes in CO are difficult to separate, but may include mechanical factors and neurohumoral responses [5, 6]. Increased venous resistance and compression of the abdominal aorta may contribute to the increase in cardiac afterload. Potential mediators of increased SVR include catecholamines, prostaglandins, the renin–angiotensin system and vasopressin [5, 7, 8]. During pneumoperitoneum, plasma concentrations of dopamine, vasopressin, adrenaline, noradrenaline, renin and cortisol increase significantly. Of particular interest is the time course of the increase in vasopressin and noradrenaline. The plasma time course profile parallels that of changes in CI, MAP and SVR, suggesting a possible cause and effect relationship.

In this study, we quantified some of the neuroendocrine stress responses during and after pneumoperitoneum and also the incidence of intraoperative ST segment changes in the ECG.

Patients and methods

After obtaining local Ethics Committee approval, we studied 16 consecutive patients, free of cardiac

disease, undergoing elective laparoscopic cholecystectomy. Preoperative assessment included history and physical examination, specifically documenting the presence of ischaemic heart disease, for example previous myocardial infarction (MI), angina, left ventricular failure (LVF) or hypertension. Preoperative investigations included full blood count, urea and electrolyte concentrations, chest x-ray and resting 12-lead electrocardiograph (ECG).

Exclusion criteria included patients with documented ischaemic heart disease (history of angina, previous MI, hypertension) or signs of left ventricular failure. Patients who refused to participate and those in whom ECG interpretation was difficult, that is pre-existing left bundle branch or left ventricular hypertrophy with strain, and patients with hypokalaemia or those receiving digoxin therapy were also excluded from the study.

Continuous ambulatory electrocardiographic (CAECG) monitoring was commenced the evening before surgery and continued for 30 h after operation. Ambulatory ECG monitoring was performed using a Reynolds Medical Tracker model using leads II and V_5. A Reynolds Medical Pathfinder, Mark111, 24-h Holter monitoring system, incorporating Reynolds Medical version 2.2 software and hardware system, was used for analysis of ST segment changes. The Holter tape was run through the system for the full 24 h (or the duration of the tape). The software produces a trend or graph of ST changes against time for the duration of the recording. A reference ST level is determined and all ST changes are calibrated to this (the reference ST is usually calibrated using patients' resting ST level). Changes are not considered significant unless greater than ± 1 mm from the reference. All ST changes were printed with an accompanying ECG strip. The software system is heavily dependent on human intervention. For the purpose of standardizing intraoperative management and indications for treatment, tachycardia was considered as 20 % above the mean preoperative heart rate or 90 beat min^{-1}. Acute changes in heart rate and arterial pressure had to be $\geqslant 4$ min duration. Myocardial ischaemia was defined as > 0.1 mV or more positive or negative horizontal ST segment shift, which extended at least 80 ms beyond the J point of the QRS and was at least 1 min duration. Heart rate, arterial pressure and ST segment analysis were measured for a minimum of 12 h before operation, during operation and for 24 h after operation.

A standard general anaesthetic technique was used for all patients. Patients were premedicated with diazepam 10 mg orally, 1 h before surgery. Anaesthesia was induced with fentanyl 1–2 $\mu\text{g kg}^{-1}$ and thiopentone 3–4 mg kg^{-1}. Vecuronium 0.1 mg kg^{-1} was administered to facilitate tracheal intubation. Anaesthesia was maintained with 0.5–1 % end-tidal isoflurane and 50 % nitrous oxide in oxygen. Intraoperative monitoring included continuous ECG, systemic arterial pressure using an automated cuff, pulse oximetry, inspired oxygen fraction and peak airway pressure. Intermittent positive pressure ventilation was used with an Ohmeda volume cycle ventilator maintaining the end-tidal carbon dioxide partial pressure at 4–5.3 kPa. Intraoperative i.v. fluids were administered at 3 $\text{ml kg}^{-1}\ \text{h}^{-1}$.

The surgical technique involved intraperitoneal insufflation of carbon dioxide via a Verres needle inserted into a small umbilical incision in the 15–20° Trendelenburg position. An electronic variable-flow insufflator terminated flow when the intra-abdominal pressure reached 15 mm Hg. A cannula was inserted in place of the needle to provide and maintain insufflation adequate for surgery. A video laparoscope was inserted through the cannula and the operative field was seen. The patient's position was changed to steep reverse Trendelenburg, with lateral tilt, to facilitate retraction of the gall bladder fundus.

Neuroendocrine stress responses were assessed by measuring resting plasma concentrations of adrenaline and noradrenaline, renin and aldosterone, prolactin, growth hormone and cortisol in 20-ml blood samples obtained via a catheter inserted in the antecubital fossa. Samples were obtained on the evening before surgery (T1), before induction (T2), after induction (T3), 5 min before insufflation of carbon dioxide (T4), 5 min after insufflation of carbon dioxide (T5), 5 min after tilting in the reverse Trendelenburg position (T6) and after exsufflation in the recovery room (T7). Plasma adrenaline and noradrenaline concentrations were measured by high pressure liquid chromatography with electrochemical detection [5]. The sensitivity of both assays was 10 pg ml^{-1} and intra-assay and inter-assay coefficients of variation were 5 % and 8 %, respectively, for both. Human growth hormone, cortisol and aldosterone concentrations were measured by direct radioimmunoassay with a sensitivity of 0.5 ng litre^{-1}, 30 nmol litre^{-1} and 6.0 pg ml^{-1}, respectively. The intra-assay and inter-assay coefficients of variation were 6.3 % and 13.1 %, 11.2 % and 13.5 %, and 4.12 % and 3.82 %, respectively. Plasma renin activity was measured as the amount of angiotensin produced in $\text{ng ml}^{-1}\ \text{h}^{-1}$. The sensitivity of this assay was 0.039 ng ml^{-1} and the intra-assay and inter-assay coefficients were 5.82 % and 4.82 %, respectively. Prolactin was measured by immunofluorometric assay with a sensitivity of 9 miu litre^{-1} and the intra-assay and inter-assay coefficients of variation were 4.3 % and 6.5 %, respectively.

Perioperative cardiac morbidity was defined as including the presence of myocardial ischaemia, unstable angina, arrhythmias, congestive heart failure or death. History, physical examination, daily 12-lead ECG and cardiac specific enzymes were performed before operation and after surgery for 2 days. Criteria for diagnosing an MI included serial ECG and cardiac enzymes. Criteria for diagnosing left ventricular failure included chest pain, a gallop rhythm or basal crepitations. Daily ECG were performed noting the presence of new Q waves > 0.04 s and > 1 mm deep, or new left bundle branch block (LBBB). Measurement of serial cardiac enzymes was performed and a creatine kinase MB fraction (CK-MB) greater than 8 %, using an immunoinhibition method, was considered indicative of myocardial damage.

Data are expressed as mean (SD). Data were analysed by one-way analysis of variance for repeated measures (ANOVA) followed by Scheffé's *post hoc* tests. For inter-group comparisons, $P < 0.05$ was considered significant.

Results

We studied 16 (12 females) ASA I–II patients, mean age 40 (range 24–72) yr. Mean duration of surgery was 94 (SD 30) min (table 1).

Ambulatory ECG recordings revealed that patient No. 4 had an episode of acute ST segment changes before insufflation of carbon dioxide. This was associated with hypotension (MAP 45 mm Hg) and bradycardia (heart rate of 38 beat min^{-1}), which responded to i.v. fluids and atropine. Patient No. 8 had an episode of ST segment changes which began during exsufflation of carbon dioxide and continued for 69 min. Serial ECG, cardiac enzymes and physical examination for 2 days after operation revealed no evidence of cardiac morbidity in either patient. No abnormalities were detected in the recordings of the other 14 patients.

There were no significant changes in heart rate throughout the study. There was a significant increase in MAP after insufflation of carbon dioxide and reverse Trendelenburg positioning ($P = 0.01$ and 0.0003 respectively) (fig. 1).

Plasma concentrations of noradrenaline increased after exsufflation of carbon dioxide. However, this increase was not statistically significant ($P = 0.48$). Plasma concentrations of adrenaline increased after reverse Trendelenburg and exsufflation of carbon dioxide. Again, these increases were not statistically significant (fig. 2).

Table 1 Patient data (mean (SD or range) or number)

n	16
Age (yr)	40 (24–72)
Sex (M/F)	4/12
Duration of surgery (min)	94 (30)

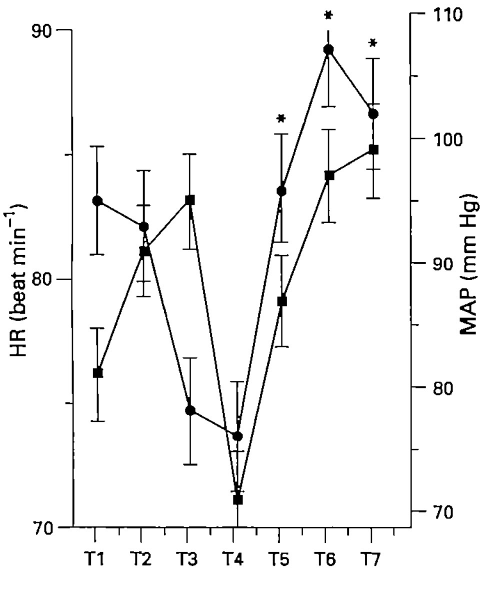

Figure 1 Mean (SD) changes in heart rate (HR) (■) and mean arterial pressure (MAP) (●) 5 min before (T2) and 5 min after (T3) induction, 5 min before (T4) and 5 min after (T5) insufflation of carbon dioxide, 5 min after reverse Trendelenburg positioning (T6) and after exsufflation of carbon dioxide (T7). T1 = Baseline. Significant difference ($^*P < 0.05$) in MAP from T4 to T5, T6 and T7.

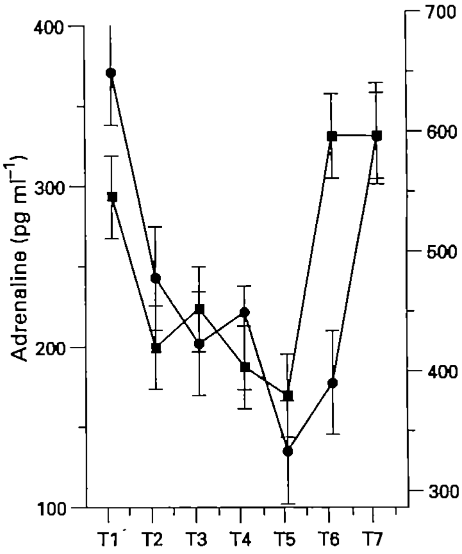

Figure 2 Mean (SD) changes in plasma concentrations of adrenaline (■) and noradrenaline (●). Times T1–T7 as in figure 1.

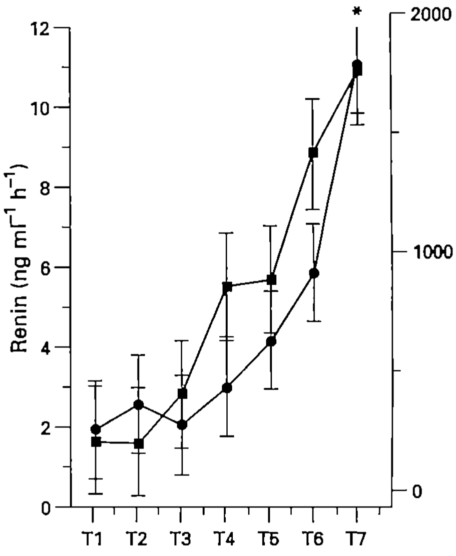

Figure 3 Mean (SD) changes in plasma concentrations of renin (■) (normal range 0.5–4.2 ng ml^{-1} h^{-1}) and aldosterone (●) (normal range 30–1000 pg ml^{-1}). Times T1–T7 as in figure 1. Significant difference ($^*P < 0.05$) in: plasma renin from T1, T2 and T3 to T7; plasma aldosterone from T1, T2, T3, T4, T5 and T6 to T7.

Plasma concentrations of renin increased four-fold during changes in position but this was not significant ($P = 0.31$). This increase continued after exsufflation of carbon dioxide and reached statistical significance ($P = 0.005$). Similarly, plasma concentrations of aldosterone increased four-fold after reverse Trendelenburg positioning but was not significant. The increase continued during exsufflation and achieved statistical significance ($P = 0.0001$) (fig. 3).

There was a linear increase in plasma prolactin concentrations after induction of anaesthesia. This became significant before insufflation of carbon

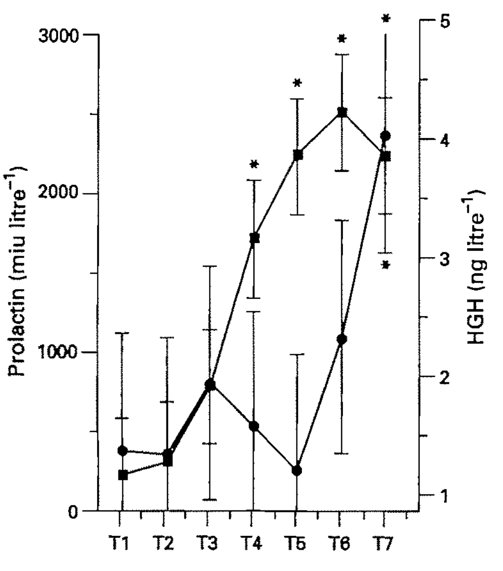

Figure 4 Mean (SD) changes in plasma concentrations of human growth hormone (HGH) (●) and prolactin (■) (normal range 50–300 miu litre^{-1}). Times T1–T7 as in figure 1. Significant difference ($*P < 0.05$) in: prolactin from T1 to T4, T5, T6 and T7; HGH from T1, T2, T3 and T4 to T7.

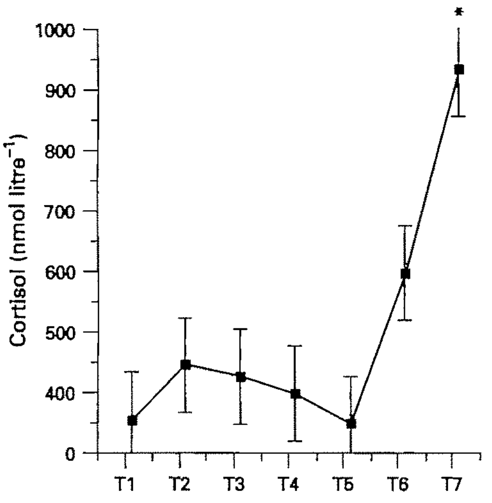

Figure 5 Mean (SD) changes in plasma concentrations of cortisol (normal range 300–700 nmol litre^{-1}). Times T1–T7 as in figure 1. $*P < 0.05$ compared with T1, T2, T3, T4, T5 and T6.

dioxide ($P = 0.003$) and remained increased for the rest of the study. Human growth hormone remained relatively stable after induction of anaesthesia and showed a significant increase after exsufflation of carbon dioxide ($P = 0.01$) (fig. 4).

Plasma concentrations of cortisol increased threefold after exsufflation of carbon dioxide ($P = 0.0002$) (fig. 5).

There was a linear correlation between changes in MAP and plasma concentrations of renin and aldosterone ($r = 0.97$ and 0.85, respectively) after pneumoperitoneum and reverse Trendelenburg positioning.

Discussion

The sequential effects of anaesthesia, positioning (20° reverse Trendelenburg), and mechanical and neuroendocrine effects of pneumoperitoneum and absorbed carbon dioxide combine to produce a characteristic haemodynamic response [4]. A biphasic pattern of initial reduction in cardiac index with subsequent recovery after pneumoperitoneum has been described [4]. In this study, we demonstrated that peritoneal insufflation of carbon dioxide to an intra-abdominal pressure of 14 mm Hg induced characteristic increases in MAP but no acute ECG ST segment changes in a series of healthy, non-obese patients, free from cardiac disease, undergoing elective laparoscopic cholecystectomy.

In patients with mild heart disease or those with clinically severe systemic disease (ASA III–IV), the pattern of changes in cardiac index, MAP and SVR is qualitatively similar to that observed in series of healthy patients [9–11]. The most striking features are the considerable initial reductions in cardiac index occurring simultaneously with large increases in MAP and SVR, followed by recovery of cardiac index, as described in healthy patients. This study suggests that acute haemodynamic changes during pneumoperitoneum and changes in position in healthy patients do not provoke ECG ST segments changes characteristic of myocardial ischaemia. Such changes were observed in only two patients, in one case associated with an episode of hypotension and bradycardia after induction of anaesthesia and in the other during peritoneal exsufflation.

Continuous ambulatory electrocardiographic (CAECG) monitoring has been developed as a non-invasive method of detecting perioperative myocardial ischaemia [12]. A variety of independent measures of ischaemia, including abnormalities of myocardial perfusion, regional left ventricular dysfunction, and pulmonary and left ventricular changes have been correlated with transient ST segment changes [13]. Little information is available, however, on the diagnostic accuracy of CAECG monitoring in patients with no known history of coronary heart disease, especially in those patients with a relatively low pre-test probability of the disease [12]. Studies in normal subjects without coronary artery disease (CAD) have demonstrated a very low incidence of such ECG changes. Current consensus does not support the use of continuous ST segment monitoring as a screening tool for detecting CAD [12]. In our series of 16 patients, free from cardiac disease, only one patient developed acute ST segment changes during deflation of the pneumoperitoneum. There were no postoperative sequelae, as detected by clinical assessment, serial ECG and cardiac enzymes.

The effects of abdominal distension with carbon dioxide are complex and may combine direct mechanical compressive effects, neurohumoral responses and changes induced by the absorbed carbon dioxide. Possible mediators of the initial and delayed changes in CI, MAP and SVR observed in this and other studies include catecholamines, prostaglandins, the renin–angiotensin system and vasopressin [5]. Joris and Lamy [8] documented significant vasopressin release after pneumoperitoneum that paralleled the time course of the increase in SVR. In this study, plasma concentrations of adrenaline, renin–aldosterone and prolactin increased considerably after pneumoperitoneum and change in position. Of particular importance was the time course of the increase in renin–aldosterone. The plasma concentration–time course profile of renin–aldosterone paralleled that of changes in MAP, suggesting a possible cause–effect relationship. Increased abdominal pressure associated with pneumoperitoneum may reduce venous return, compress the abdominal capacitance vessels, reduce cardiac output and renal blood flow. These factors may combine to activate the renin–aldosterone system. Even though prolactin increases in response to stress, the time course of its changes suggests an interaction with the opioid fentanyl [14]. The peak HGH and cortisol responses reflect the postoperative stress response and parallel the ischaemic experience in patient No. 8.

Considerable systemic absorption of carbon dioxide occurs during prolonged insufflation [15]. Hypercapnia may contribute to the delayed recovery of cardiac index and may attenuate the adverse haemodynamic affects of intra-abdominal pressure. Hypercapnia may also contribute to the documented changes in MAP and plasma concentrations of adrenaline observed in this and other studies [16, 17]. Deflation of the induced pneumoperitoneum is associated with acute increases in plasma concentrations of noradrenaline and cortisol. These may be secondary to a combination of factors, including the drugs used in reversal, the patient's return to consciousness or as a result of the patient experiencing pain.

Comparison of the effects of urapidil and sodium nitroprusside on haemodynamic state, myocardial metabolism and function in patients during coronary artery surgery

J. G. VAN DER STROOM, H. B. VAN WEZEL, I. VERGROESEN, J. E. KAL, J. J. KOOLEN,
J. P. DIJKHUIS, A. SWAAN, M. PORSIUS, H. A. J. KLEINJANS AND P. A. VAN ZWIETEN

Summary

We have compared, in an open randomized study, the effects of sodium nitroprusside (SNP) and urapidil on haemodynamic state and myocardial function and metabolism in two groups of patients undergoing elective coronary artery surgery. Sixty patients were allocated randomly to one of two groups: group SNP ($n = 29$) received SNP at an initial rate of 1–2 μg kg^{-1} min^{-1}; group URA ($n = 31$) received one or more bolus injections of urapidil 25 mg and an i.v. infusion at an initial rate of 11–21 μg kg^{-1} min^{-1}. Baseline measurements were obtained 10 min after introduction of an echotransducer into the oesophagus. Subsequently, vasodilator therapy was started in both groups. Infusion rates were adjusted to maintain systolic arterial pressure at 80–120% of baseline values (or mean arterial pressure < 100 mm Hg). Additional measurements were obtained 10 min after the start of vasodilator therapy and after sternotomy when the pericardium was opened. At each measuring time a complete haemodynamic profile, coronary sinus blood flow (CSBF) curves, transoesophageal echocardiographic images, and arterial and coronary venous blood samples were obtained. Arterial pressure was controlled adequately in both groups. After sternotomy, heart rate and cardiac index increased in both groups. At that time, there was a significant increase in myocardial oxygen consumption and CSBF in group URA ($P < 0.05$). However, the ratio between myocardial oxygen demand and oxygen supply remained unchanged and there was no difference in the number of ischaemic episodes between the groups (*Br. J. Anaesth.* 1996; **76**: 645–651).

Key words

Surgery, cardiovascular. Cardiovascular system, effects. Heart, myocardial function. Pharmacology, urapidil. Pharmacology, sodium nitroprusside.

Sodium nitroprusside (SNP) is a classic drug for the management of perioperative hypertension. However, SNP is known to induce several undesirable side effects, including reflex tachycardia, intrapulmonary and intracoronary shunting, tachyphylaxis and cyanide toxicity [1–4]. At present, calcium channel blockers, ketanserin and urapidil are common alternatives for the treatment of perioperative hypertension. Urapidil (URA) may be characterized pharmacodynamically as a selective α_1 adrenoreceptor antagonist causing a reduction in peripheral vascular resistance and hence a reduction in arterial pressure [5]. Additionally, it exerts an agonistic effect on central 5-HT$_{1A}$ receptors in the ventral medullary region [6–8]. Reflex tachycardia does not occur, probably as a result of reduced sympathetic outflow and vagal stimulation [9]. This pharmacodynamic profile suggests the possible usefulness of this agent in the management of patients with coronary artery disease (CAD) developing hypertension in the perioperative period.

Urapidil, administered i.v., has been shown to be effective for the control of arterial pressure in patients undergoing coronary artery surgery (CAS) [10, 11]. However, the effect of this agent on myocardial metabolism and coronary sinus blood flow (CSBF) in surgical patients is unknown. Therefore, in this study we compared the effects of urapidil and SNP on haemodynamic state, myocardial function, global myocardial metabolism and CSBF in patients undergoing CAS.

Patients and methods

After obtaining approval from the local Medical Ethics Committee and written informed consent, we studied 60 patients undergoing elective CAS. Exclusion criteria were patients with left ventricular (LV) end-diastolic pressure > 18 mm Hg, LV ejection fraction < 35%, atrioventricular conduction defects, unstable angina pectoris, severely impaired liver function (AST, ALT > 80 u. litre^{-1}), impaired renal function (men: creatinine > 110 μmol litre^{-1}; women: creatinine > 80 μmol litre^{-1}), acute rhythm

disturbances and those undergoing additional surgical procedures, such as valve replacement or aneurysmectomy.

Patients were allocated randomly to one of two groups: group SNP ($n = 29$) received SNP at an initial rate of 1–2 μg kg^{-1} min^{-1} and at a maximum maintenance infusion rate of 8 μg kg^{-1} min^{-1}; group URA ($n = 31$) received one or more bolus injections of urapidil 25 mg. In addition, urapidil was given at an initial infusion rate of 11–21 μg kg^{-1} min^{-1} and at a maximum maintenance infusion rate of 40 μg kg^{-1} min^{-1} [12]. All infusions were administered via a syringe pump. Polypropylene syringes and infusion cannulae were used throughout. Yellow syringes and infusion cannulae were used for SNP, as this vasodilator undergoes rapid decomposition when exposed to light.

In the operating room, two peripheral infusions and an 18-gauge radial artery cannula were inserted during local anaesthesia. A triple-lumen thermodilution pulmonary artery catheter (Baxter) and a coronary sinus catheter (Wilton-Webster Laboratories, Altadena, CA, USA, type CCS-7U-90B) were introduced via the left subclavian vein. The coronary sinus catheter was advanced into the coronary sinus by means of imaging intensification, fluoroscopy and injection of contrast medium (Hexabrix), so that the external thermistor lay 1–1.5 cm from the ostium. The coronary sinus catheter was connected to a Wilton Webster Wheatstone bridge. Coronary sinus thermodilution signals were recorded with a multichannel amplifier/recorder system. Catheter calibration factors provided by the manufacturer were used. The absence of right atrial admixture in coronary sinus blood (coronary sinus reflex) was checked by injection of cold saline into the right atrium, while coronary sinus thermodilution curves were recorded simultaneously [13, 14]. Infusion rates were verified by timed volume collection, and flow calculations reflected the indicator infusion rate that was used.

All oral medication, with the exception of calcium antagonists, was continued until the morning before surgery. Lorazepam 4 or 5 mg orally, was given as premedication, 2 h before surgery. After preoxygenation, pancuronium 2 mg was given, followed by fentanyl 100 μg kg^{-1} i.v. over 3–5 min and midazolam 5 mg. When the patient became unresponsive to verbal commands an additional dose of pancuronium 6 mg was given; ventilation was assisted and then controlled manually. After intubation of the trachea, the lungs were ventilated with air–oxygen ($F\text{I}_{\text{O}_2} = 0.5$). Ventilation was adjusted to maintain the end-tidal carbon dioxide concentration at 4–4.5 %.

Baseline measurements (measurement I) were obtained at least 10 min after introducing an oesophageal echotransducer (5-MHz Hewlett–Packard omniplane or biplane, Boblingen, Germany). Subsequently, vasodilator therapy was started in both groups and a bolus of urapidil 25 mg i.v. was given in group URA. Infusion rates were adjusted to maintain systolic arterial pressure (SAP) at 80–120 % of baseline values. Furthermore, mean arterial pressure (MAP) was maintained less than 100 mm Hg at all times. Additional measurements were obtained 10 min after the start of vasodilator infusion (measurement II) and after sternotomy when the pericardium was opened (measurement III). At each measurement time, a complete haemodynamic profile, electrocardiographic tracing (leads II and V5), CSBF curves and transoesophageal echocardiographic (TOE) images (videotaped for off-line analysis) were obtained. CSBF was measured by continuous thermodilution [15]. Simultaneous blood samples were obtained from the radial artery and coronary sinus for measurement of oxygen tension and saturation, haemoglobin and whole blood lactate concentrations.

Cardiac output was measured by the single bolus thermodilution technique. Cardiac output measurements were repeated until three consecutive measurements with less than 10 % variability were obtained. Derived haemodynamic variables were calculated according to standard formulae. Oxygen saturation was measured by means of an OSM-II haemoximeter (Radiometer, Copenhagen) and $P\text{o}_2$ by an ABL-III (Radiometer, Copenhagen). Lactate concentration was measured using standard enzymatic techniques [16].

Myocardial metabolic indices were calculated according to standard formulae.

Arterial oxygen content ($C\text{a}_{\text{O}_2}$):

$$C\text{a}_{\text{O}_2}(\text{ml } 100 \text{ ml}^{-1}) = 1.39 \times \text{Hb} \times S\text{o}_2 + 0.003 \times P\text{o}_2$$

where Hb = haemoglobin (g 100 ml^{-1}), $S\text{o}_2$ = arterial oxygen saturation and $P\text{o}_2$ = arterial oxygen tension (kPa).

Myocardial oxygen supply ($M\text{o}_2$):

$$M\text{o}_2 \text{ (ml min}^{-1}) = C\text{a}_{\text{O}_2} \text{ (ml dl}^{-1}) \times \text{CSBF (ml min}^{-1})/100$$

Myocardial oxygen consumption ($M\dot{V}\text{o}_2$):

$$M\dot{V}\text{o}_2 \text{ (ml min}^{-1}) = \text{CSBF} \times (C\text{a}_{\text{O}_2} - C\text{c}_{\text{O}_2})$$

where $C\text{c}_{\text{O}_2}$ = coronary sinus oxygen content and $C\text{a}_{\text{O}_2}$ = arterial oxygen content.

Myocardial lactate extraction (MLE):

$$\text{MLE}(\%) = \frac{\text{lactate}_{\text{art}} - \text{lactate}_{\text{cs}}}{\text{lactate}_{\text{art}}} \times 100$$

Coronary vascular resistance (CVR):

$$\text{CVR (mm Hg ml}^{-1} \text{ min}^{-1}) = \frac{\text{MAP} - \text{RAP}}{\text{CSBF}}$$

where RAP = right atrial pressure.

TRANSOESOPHAGEAL ECHOCARDIOGRAPHY

Echocardiographic data were obtained with a standard Hewlett Packard 5-MHz omniplane or biplane phased array transducer. After tracheal intubation the echotransducer was introduced in the oesophagus and connected to a Hewlett–Packard Sonos 1500 echocardiograph. The transducer was positioned at the level of the papillary muscle. Cross-sectional echocardiograms were recorded on videotape at the measuring times mentioned above. Quantitative analysis of echocardiograms was performed using a computer-aided contouring system (Digisonics). The peak of the R wave of the simultaneously displayed electrocardiogram was used to select end-diastolic stop-frames. End-systolic stop-frames were defined as the minimal cross-sectional area of the left ventricle. End-diastolic and end-systolic areas were calculated. In all images the endocardial outlines were confirmed by playing through preceding and succeeding beats in real-time, slow motion and stop-frame format. The LV (left ventricular) percentage area reduction, defined as

$$\mathrm{PAR}(\%) = \frac{\text{diastolic area} - \text{systolic area}}{\text{diastolic area}} \times 100$$

was calculated using a floating axis analysis system [17, 18], and used as a variable characteristic for myocardial contractility. LV percentage area reductions in three consecutive heart beats were analysed and averaged. Endocardial contouring was performed by an experienced observer who was blinded to patient data. Regional myocardial function was assessed semi-quantitatively.

Electrocardiographic myocardial ischaemia was defined by a horizontal ST-T segment shift of at least 0.1 mV at 80 ms beyond the J point of at least 1 min duration. Myocardial ischaemia detected by echocardiography was defined as the occurrence of new regional wall motion abnormalities.

Myocardial lactate production was used as a metabolic marker of myocardial ischaemia.

Creatine phosphokinase isoenzyme MB (CK-MB) concentrations were measured immediately on arrival in the intensive care unit and at 3-h intervals during the first 9–12 h after operation. If there was still an increase in CK-MB concentrations after 12 h, additional measurements were performed at 3-h intervals until CK-MB concentrations decreased. The measurements were performed using radio-enzymatic techniques [19]. Myocardial infarction was diagnosed when CK-MB concentrations increased to > 70 u. litre^{-1}.

STATISTICAL ANALYSIS

Statistical analysis was performed using the Wilcoxon, Mann–Whitney U test (two-sided) with a correction according to Bonferroni–Holm. $P < 0.05$ was considered significant. Results are reported as mean (SD).

Results

Before operation, the two groups of patients were comparable in age, weight, body surface area, left ventricular end-diastolic pressure, degree of coronary artery disease and oral medication (table 1).

We studied 60 patients. In nine patients no reliable coronary sinus thermodilution signal was recorded or coronary sinus blood sampling was impossible (group SNP, five patients; group URA, four patients). Data obtained at that time are not reported. In two patients urapidil was combined with SNP to obtain acceptable control of arterial pressure. Because of this combination of antihypertensive agents, the data obtained in these two patients are not reported. In two patients in group SNP, arterial pressure did not respond adequately. In these two patients, however, no additional antihypertensive therapy was used and therefore all data obtained in those patients were included in the final analysis.

Accordingly, the results of 24 patients treated with SNP and 25 patients treated with urapidil are described.

Table 1 Patient characteristics, degree of coronary artery disease and preoperative medication (mean (SD or range) or number). SNP = Sodium nitroprusside; URA = urapidil; BSA = body surface area

	SNP	URA
n	29	31
Age (yr)	60 (36–74)	58 (35–74)
Weight (kg)	76 (10.0)	81 (12.1)

Preoperative medication (n)		
β Adrenergic blockers	20	23
Long-acting nitrates	18	21
Ca^{2+} antagonists	21	23

Table 2 Mean (SD) infusion rates and duration of infusion in the sodium nitroprusside (SNP) and urapidil (URA) groups

		Infusion rate (μg kg^{-1} min^{-1})		
Group	n	Drug + 10 min	Post-sternotomy	Duration of infusion (min)
SNP	24	1.2 (0.8)	1.4 (0.7)	59 (45)
URA	25	16.0 (8.8)	17.9 (11.9)	60 (47)

DOSES USED

The mean infusion rate administered during the first 10 min and after sternotomy are shown in table 2. Mean infusion rates during the entire study were 12.6 (6.6) μg kg^{-1} min^{-1} (range 4.8–34.6 μg kg^{-1} min^{-1}) for urapidil and 1.0 (1.0) μg kg^{-1} min^{-1} (0.1–2.6 μg kg^{-1} min^{-1}) for SNP. The mean total bolus dose of urapidil administered during the entire study was 98.2 (41.8) mg.

HAEMODYNAMIC VARIABLES

Measured and calculated haemodynamic variables at the three measuring times are shown in table 3. Baseline variables in the two groups were not significantly different. At measurement time II, both SAP and MAP decreased significantly in group URA while in group SNP only SAP decreased significantly compared with baseline. At measurement time III, SAP, DAP and MAP decreased significantly in group URA, and DAP and MAP decreased significantly in group SNP compared with baseline. MAP had to be titrated to less than 100 mm Hg. This could not be achieved in two patients in group SNP and in two patients in group URA.

Table 3 Mean (SD) haemodynamic changes in 60 patients receiving sodium nitroprusside (SNP) or urapidil (URA). Study periods were: I = baseline (before starting vasodilator therapy); II = 10 min after the start of drug infusion; III = after sternotomy when the pericardium was opened. SAP = Systolic arterial pressure; DAP = diastolic arterial pressure; MAP = mean arterial pressure; HR = heart rate; RAP = right atrial pressure; PAP = pulmonary artery pressure; PCWP = pulmonary capillary wedge pressure; CO = cardiac output; CI = cardiac index; SVR = systemic vascular resistance; PVR = pulmonary vascular resistance; LVSWI = left ventricular stroke work index; RVSWI = right ventricular stroke work index; SVI = stroke volume index; SV = stroke volume. HR increased significantly at measurement time III in both groups compared with baseline and measurement time II. Compared with baseline, CI increased, while SVR decreased in both groups at both measurement times II and III.

CORONARY SINUS BLOOD FLOW AND MYOCARDIAL METABOLISM

Coronary dynamics and myocardial metabolic variables are shown in table 4. Baseline variables in the two groups were not significantly different. At measurement time III, CSBF and $M\dot{V}O_2$ increased significantly in group URA compared with baseline and time II. There was a significant difference between the groups in the increase in $M\dot{V}O_2$ between measurement interval I–II and measurement interval I–III.

In three patients in group SNP lactate extraction changed to production (table 5), in two patients after 10 min of vasodilator therapy (measurement II) and in one patient after sternotomy (measurement III). One of these patients developed regional wall motion abnormalities during the study and ECG changes after cardiopulmonary bypass. After operation, this patient developed elevated CK-MB concentrations, indicative of myocardial infarction. In one patient in group URA, lactate extraction changed to production. No regional wall motion abnormalities, ECG changes or elevated CK-MB concentrations were found.

ECHOCARDIOGRAPHY

Baseline variables in the two groups were not significantly different. PAR increased significantly at measurement times II and III compared with control values in both groups. In groups SNP and URA, PAR was 67 (10)% and 66 (7)%, respectively, at baseline. After 10 min of drug infusion, PAR increased ($P < 0.05$) to 69 (10)% and 69 (7)%, respectively. At measurement time III, PAR increased ($P < 0.05$) to 71 (8)% and 70 (7)% compared with baseline. Compared with baseline measurements regional wall motion abnormalities developed in one or more segments in one patient in group SNP. This patient developed a perioperative myocardial infarction (elvated CK-MB concentrations). In three patients in group URA wall motion abnormalities occurred but none of these patients developed a myocardial infarction in the perioperative period.

Table 4 Mean (SD) coronary haemodynamic variables and global myocardial metabolism in the sodium nitroprusside (SNP) and urapidil (URA) groups. Study periods were: I = baseline (before starting vasodilator therapy); II = 10 min after the start of drug infusion; III = after sternotomy when the pericardium was opened. Table 5 Ischaemic events during the study (number of patients) in the sodium nitroprusside (SNP) and urapidil (URA) groups

	SNP	URA
ST segment changes (leads II and V5)	0	0
Wall motion abnormalities	1	3
Myocardial lactate production	3	1
Myocardial infarction (CK-MB > 70 u. $litre^{-1}$)	3	0

ELECTROCARDIOGRAPHY

In one patient in group SNP ischaemia developed (ST segment depression in leads II and V5) followed by ventricular fibrillation during weaning from cardiopulmonary bypass (not during the study). This condition was treated successfully with electrical defibrillation (200 W s^{-1}) followed by continuous infusion of lignocaine. In this patient there was already a change from lactate extraction to production at measurement time II, as described above. We observed elevated CK-MB concentrations after operation in this patient (144 u. $litre^{-1}$).

In one patient in URA group there were signs of ischaemia on the ECG associated with hypotension. This condition occurred after cardiopulmonary bypass (not during the study) and disappeared during treatment with nitroglycerine and nicardipine. It seems therefore that coronary spasm had occurred, which was relieved by these vasodilators. In this patient CK-MB concentrations were within normal limits after operation.

CK-MB CONCENTRATIONS

The groups were comparable in duration of aortic cross-clamping (SNP 61 (10) min, URA 59 (9) min). Three patients in group SNP (table 5) developed a myocardial infarction, compared with none in group URA (ns). There were no significant differences between the groups in CK-MB concentrations in the first 12 h after operation.

Discussion

Hypertension, associated with increases in systemic vascular resistance, cardiac filling pressures and HR, frequently develops in patients undergoing CAS, particularly after sternotomy [20–22]. This type of hypertension probably results from activation of the sympathetic nervous system.

Urapidil is a relatively short-acting peripheral α_1 adrenoceptor blocker with an additional stimulating effect on central serotonin $(5\text{-HT})_{1A}$ receptors located in the ventral medullary region [7,23]. The importance of 5-HT receptors and pathways in the central regulation of arterial pressure has been substantiated by the discovery that central 5-HT_{1A} receptors, when stimulated with an appropriate agonist, mediate inhibition of peripheral sympathetic activity and a reduction in HR [8,24,25]. Reflex tachycardia associated with the use of urapidil has not been reported, probably as a result of reduced sympathetic activity and enhanced parasympathetic outflow [9,26]. This pharmacodynamic profile suggests the potential usefulness of urapidil in the management of patients with coronary artery disease (CAD) developing hypertension in the perioperative period [10].

In this study, it was not surprising to find a significant increase in HR in patients treated with SNP. However, patients treated with urapidil also developed tachycardia. Similar increases in HR were reported in patients with CAD given nifedipine, nicardipine or placebo for the treatment of hypertension after sternotomy [21,27,28]. In contrast with our findings, we reported previously that the use of urapidil given after operation, was not associated with significant changes in HR. This was confirmed by several investigators [11,29]. From these combined observations it appears likely that sympathetic activation after sternotomy is more pronounced than stimulation of the sympathetic system after operation. This may (partially) explain the increase in HR found in both groups.

Although urapidil has an inhibiting effect on sympathetic activity there is no published evidence that it has any negative inotropic properties. Wouters and colleagues described the absence of myocardial depression by urapidil in dogs with chronically ischaemic hearts [30]. Lepage and co-workers used radionuclide angiography to demonstrate that urapidil i.v. had no detectable negative inotropic activity in conscious patients with CAD and hypertension [31]. In a study in hypertensive patients after CAS, van der Stroom and colleagues demonstrated that urapidil was an effective and safe antihypertensive agent; its use was associated with a significant increase in PAR [12]. In this study, echocardiographic PAR also increased significantly and to a similar extent in both groups. The changes in PCWP and SVR, reflecting preload and afterload respectively, were of the same order of magnitude in both groups throughout the study. Consequently, our finding that both urapidil and SNP can increase PAR implies that these agents do not exert a relevant reduction in myocardial contractility.

For a better understanding of the changes in CSBF and $M\dot{V}O_2$ reported here, it is important to realize that regulation of coronary blood flow is primarily governed by local metabolic demand (i.e. metabolic flow regulation) [32]. From animal experiments it is known that within each experiment $M\dot{V}O_2$ and coronary oxygen supply are correlated, with an average slope of 1.3–1.6 [33].

Figure 1A shows that SNP did not change $M\dot{V}O_2$ substantially. The ratio of oxygen supply and demand remained normal (i.e. 1.35) and was not changed by the dose of SNP administered. This implies that SNP (in the doses used) did not have a direct coronary vasodilator effect, as all changes in oxygen supply can be attributed to a concomitant change in $M\dot{V}O_2$. This is in keeping with previous studies in patients undergoing CAS, which demonstrated that effective treatment of hypertension with SNP is not associated with changes in CSBF or $M\dot{V}O_2$ [21, 27].

In patients given urapidil, there appeared to be a trend towards the upper right corner (fig. 1B), implying a higher level of $M\dot{V}O_2$ and oxygen supply respectively. This appeared particularly prominent at the time of the highest infusion rate of urapidil, after sternotomy. This increase in $M\dot{V}O_2$ is difficult to explain. Of the determinants of $M\dot{V}O_2$, only HR increased significantly in both groups URA and SNP. Therefore, tachycardia can only partly explain this unexpected finding, as there was no change in $M\dot{V}O_2$ in group SNP. However, in the majority of patients given urapidil, the increase in $M\dot{V}O_2$ was adequately compensated by an increase in coronary oxygen supply, presumably because of metabolic flow regulation. An additional factor may be that block by urapidil of α_1 adrenoceptors in the coronary arterial wall, contributed to the increase in CSBF. Such a mechanism would explain the larger oxygen supply–demand ratio (1.35 for SNP and 1.56 for urapidil) and may also play a role in the absence of serious coronary adverse events in the presence of high levels of $M\dot{V}O_2$.

In summary, this study indicates that in the doses used, urapidil was equally effective and safe as SNP in controlling hypertension during CAS. Although the use of both agents resulted in tachycardia, only urapidil increased $M\dot{V}O_2$. This was associated with an increase in CSBF, without changes in the myocardial oxygen supply–demand ratio.

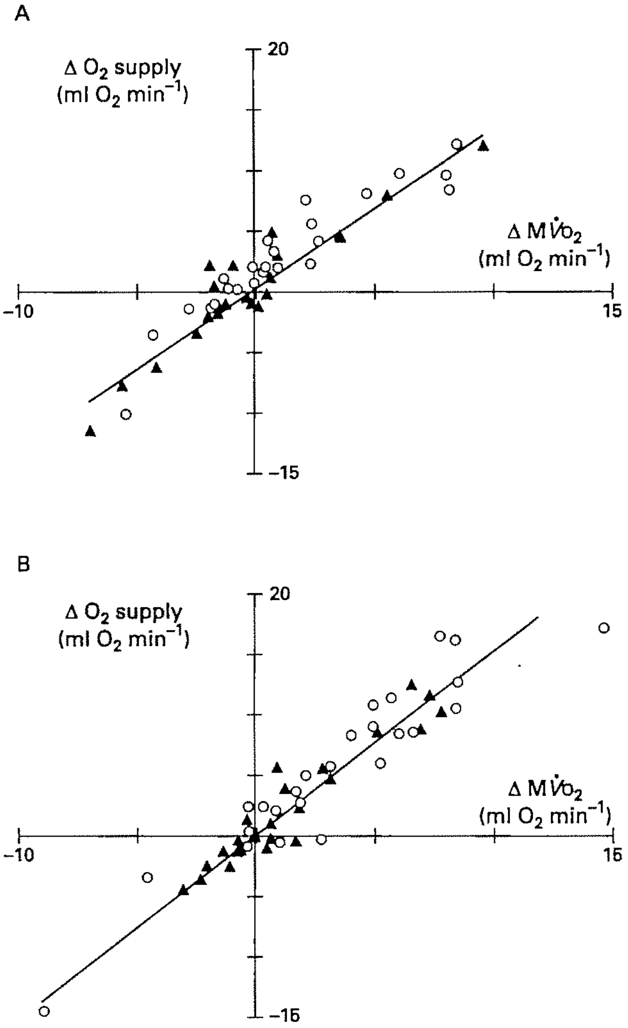

Figure 1 Relationship between oxygen supply (CSBF × Ca_{O_2}) and oxygen demand ($M\dot{V}O_2$) in anaesthetized patients undergoing coronary artery surgery. To be able to estimate the oxygen demand–supply ratio without the influence of the variation in intercepts caused by variation in coronary perfusion pressure and heart weights, the different (Δ) in $M\dot{V}O_2$ and oxygen supply between measurement II and control, and measurement III and control, are plotted for both sodium nitroprusside (SNP) (A) and urapidil (B). ▲ = Difference between measurement II (10 min of drug infusion) and measurement I (baseline) ($r^2 = 0.87$, $y = 1.35x$ for SNP; $r^2 = 0.90$, $y = 1.57x$ for urapidil); ○ = difference between measurement III (post-sternotomy) and measurement I (baseline) ($r^2 = 0.84$, $y = 1.35x$ for SNP; $r^2 = 0.87$, $y = 1.55x$ for urapidil).

Kinetics of methaemoglobin and serum nitrogen oxide production during inhalation of nitric oxide in volunteers

J. D. YOUNG, J. W. SEAR AND E. M. VALVINI

Summary

Inhaled nitric oxide is used increasingly to treat pulmonary hypertension and ventilation/perfusion mismatching in seriously ill patients, but little is known of the pharmacokinetics of its two principal metabolites, methaemoglobin and nitrogen oxides (nitrates and nitrites). We have studied the changes in these metabolites in six healthy volunteers during and after 3 h inhalation of 100 volumes per million of nitric oxide. Mean nitric oxide uptake was 0.49 (SD 0.08) ml min^{-1} at standard temperature and pressure, corresponding to 74% of the inhaled dose. During inhalation, methaemoglobin increased monoexponentially with a time constant of 45.6 (11.1) min by 1.77 (0.47)% of total haemoglobin. Serum nitrogen oxides increased from 36.7 (7.6) to 124 (17) µmol $litre^{-1}$, with a time constant of 172 (91.4) min and a volume of distribution of 331 (104) ml kg^{-1}. The volume of distribution for methaemoglobin calculated from nitric oxide uptake and the increase in methaemoglobin, was, on average, 14.3% less than predicted blood volume, suggesting that most of the absorbed nitric oxide initially forms methaemoglobin. Serum nitrogen oxides declined initially after inhalation ceased but then increased to a second peak between 45 and 180 min later. The cause of the second peak was not determined. (*Br. J. Anaesth.* 1996; **76**: 652–656)

Key words

Gases non-anaesthetic. Pharmacology, nitric oxide. Blood, haemoglobin.

Inhaled nitric oxide is used increasingly to treat acute pulmonary hypertension and improve ventilation/perfusion relationships in critically ill adults and children [1–4]. A large proportion of the inhaled nitric oxide is absorbed [5–7]. Most absorbed nitric oxide probably combines with oxyhaemoglobin, which has an affinity for nitric oxide about 1500 times greater than its affinity for carbon monoxide [8], forming methaemoglobin and nitrates. Methaemoglobin is then converted back to haemoglobin by several intra-erythrocytic enzymes of which NADH–methaemoglobin reductase is the most important [9]. However, direct conversion of nitric oxide to nitrite and subsequent oxidation to nitrate is also possible in biological fluids [10], and nitric oxide can also combine with deoxygenated haemoglobin to form nitrosyl haemoglobin [11]. Nitrate, the final metabolite of nitric oxide by all of these pathways, accumulates during inhalation of nitric oxide [12]. Data on the handling and elimination of nitrates are sparse and little is known about the metabolism of inhaled nitric oxide. In this study, we have determined if all of the absorbed inhaled nitric oxide reacts with oxyhaemoglobin to form nitrates and methaemoglobin or if direct conversion to nitrate also occurs, and investigated the pharmacokinetics of the nitrate produced.

Subjects and methods

The study was approved by the local Ethics Committee, and all subjects gave informed consent. We studied six healthy male volunteers, aged 30–38 yr, weighing 67–105 kg. A 16-gauge cannula was inserted in a forearm vein and blood was obtained for baseline methaemoglobin, total haemoglobin and serum nitrate and nitrite concentrations, measured together as serum nitrogen oxides.

Subjects were fitted with a leak-free face mask connected to a non-rebreathing valve. Nitric oxide was stored as a mixture of 2000 volumes per million (vpm) in nitrogen (BOC Special Gases, Guildford, England) and mixed with medical grade air to achieve a final inspired concentration of 100 vpm. Mixed expired gas was collected in an in-line 10-litre mixing chamber. Inspired and mixed expired nitric oxide concentrations were measured with a chemiluminescence analyser (CLD 700AL, Eco Physics, Dürnten, Switzerland). Inspired minute volume was determined from a dry gas meter fitted to the inspiratory limb of the circuit. Subjects inhaled nitric oxide for 3 h and then room air. Venous blood was obtained before inhalation of nitric oxide and at 15, 30, 45, 60, 90, 120 and 180 min during inhalation of nitric oxide. Blood was also sampled 15, 30, 45, 60, 90, 120, 180, 240, 300, 540 and 1260 min after inhalation ceased. Subjects were asked to avoid

processed meats on the day of the experiment as these may contain added nitrites; no other restrictions were placed on their diet or fluid intake.

Methaemoglobin and total haemoglobin concentrations were determined using an OSM3 co-oximeter (Radiometer, Copenhagen, Denmark). Blood samples for measurement of serum nitrogen oxides (nitrate and nitrite) were centrifuged at 3000 rpm for 15 min and the serum separated and stored at −20 °C for later analysis. Serum was deproteinized with zinc sulphate solution 30 mmol litre^{-1} before analysis and added to hot acidic vanadium (III) chloride which converted the nitrates and nitrites to nitric oxide. This was eluted in a stream of nitrogen and then analysed using chemiluminescence (CLD 700AL). The method is identical to that described by Brahman and Hendrix [13]. All analyses were performed in duplicate and the mean value used. The inter-sample coefficient of variation of the assay was 2% and the inter-day coefficient of variation 10%. Samples were analysed in random order. Data were analysed using an analysis/graphics package (Kaleidagraph, v3.0.2, Abelbeck Software) on an Apple Macintosh "Quadra 950". Results are given as mean (SD).

For each subject the inspired and expired nitric oxide concentrations and minute volume were corrected for temperature, ambient pressure and water vapour, and used to calculate nitric oxide uptake ($\dot{V}$NO) at STPD (standard temperature and pressure dry). Methaemoglobin production during inhalation of nitric oxide at a fixed inspired concentration follows simple first-order kinetics [14] and therefore the methaemoglobin concentration at time t can be described by the equation:

$$\text{Methaemoglobin concentration at time } t = B+A\times(1-e^{-t/\tau}) \quad (1)$$

where B = initial (baseline) methaemoglobin concentration (as a percentage of the total haemoglobin), A = plateau concentration of methaemoglobin above baseline that would be reached if inhalation continued for a long time (as a percentage of the total haemoglobin), and τ = time constant in minutes.

This equation was fitted to the methaemoglobin concentration results during inhalation of nitric oxide for each subject using least squares regression. This gave estimates of A and τ. If this equation is differentiated and solved for $t = 0$, the maximum rate of increase in methaemoglobin concentration is obtained. This is given by A/τ and corresponds to the rate of increase of methaemoglobin concentration in the absence of any elimination (i.e. the initial rate of increase of methaemoglobin concentration).

If the rate of production of methaemoglobin and its initial rate of increase are known, an estimate of blood volume can be obtained if it is assumed that all of the nitric oxide absorbed initially forms methaemoglobin:

$$\text{Estimated blood volume (litre)} = \frac{\text{Methaemoglobin production (g min}^{-1}\text{)}}{\text{Initial rate of increase in blood methaemoglobin (g litre}^{-1}\text{ min}^{-1}\text{)}}$$

Thus estimated blood volume is given by:

$$\frac{\dot{V}\text{NO}\times\tau}{1.39\times A} \quad (2)$$

where $\dot{V}$NO = nitric oxide uptake (ml min^{-1}), A is now expressed in grams of methaemoglobin per litre of blood and τ is as before; 1.39 is the affinity of haemoglobin for nitric oxide in millilitres of nitric oxide per gram of haemoglobin.

Mean uptake of nitric oxide and estimates for A and τ were substituted into this equation to give estimated blood volumes. These were compared with other estimates calculated from regression equations using the subjects' heights and weights. Two different equations were used [15, 16] and the mean of the estimates taken. Neither the regression equations nor the calculations based on nitric oxide uptake have a correction for the difference between central and peripheral packed cell volume.

The increase in serum nitrogen oxides during inhalation of nitric oxide could be described by an equation characterizing the behaviour of a one-compartment kinetic model. The volume of distribution was then calculated assuming all inhaled nitric oxide formed nitrogen oxides, and clearance calculated as the volume of distribution divided by the time constant.

Results

The mean inhaled nitric oxide concentration was 100.0 (3.9) vpm and the mean mixed exhaled nitric oxide concentration was 36.0 (5.8) vpm. Mean uptake of nitric oxide was 0.49 (0.08) ml min^{-1} STPD; there were no trends in uptake during the study in any subject. Inspired nitrogen dioxide concentrations (measured in the first subject only) were less than 0.25 vpm. The mean methaemoglobin concentration before inhalation of nitric oxide was 0.87 (0.04)%, and the baseline serum nitrogen oxide concentration was 36.7 (7.6) μmol litre^{-1}. Changes in methaemoglobin and serum nitrogen oxide concentrations during the study are shown in figure 1. The mean peak serum nitrogen oxide concentration was 124.2 (17.0) μmol litre^{-1} and the highest value recorded was 151.1 μmol litre^{-1} in subject No. 6. The

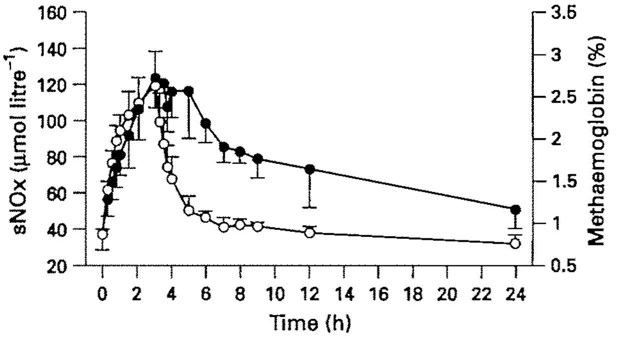

Figure 1 Change in serum nitrogen oxides (sNOx) (●) and methaemoglobin (○) in volunteers breathing inhaled nitric oxide 100 vpm (mean, SD). Nitric oxide was inhaled from 0 to 3 h.

Mean (SD)	172 (91.4)	133 (29.9)	27.6 (11.6)	331 (104)	169 (32.7)	2.15 (0.53)

mean peak methaemoglobin concentration was 2.65 (0.46)% and the highest value was 3.3% in subject No. 5.

Serum nitrogen oxide concentrations showed a double "peak"; an initial peak at the end of inhalation of nitric oxide and a second peak which occurred in all subjects between 45 min and 3 h after cessation of inhalation of nitric oxide.

Table 1 shows the calculated results for methaemoglobin kinetics and blood volumes in all subjects. Blood volume calculated from uptake of nitric oxide was, on average, 14.3% higher than the value estimated from subjects' heights and weights. Table 2 gives the pharmacokinetic variables for nitrogen oxides for all subjects.

Discussion

In this study, two-thirds of the inhaled dose of nitric oxide was absorbed, somewhat less than would be expected from the results of other studies, where up to 95% of inhaled nitric oxide was absorbed during a breath-hold performed to measure the diffusing capacity of the lung for nitric oxide [6, 7]. The fraction of inspired nitric oxide absorbed varies between studies because the limiting factor for pulmonary absorption of nitric oxide is its pulmonary diffusing capacity and therefore uptake is a non-linear function of lung volume, respiratory timing and inspired concentration. The absorbed nitric oxide forms methaemoglobin and nitrates, and possibly a small amount of nitrosyl haemoglobin [11, 17]. It is not known if all of the absorbed nitric oxide initially forms nitrates and methaemoglobin, or if some of the inhaled nitric oxide either combines directly with water to form nitrites and subsequently nitrates [10] or transiently forms nitrosyl haemoglobin, which is converted rapidly to nitrogen oxides [18]. In a previous study to determine the kinetics of methaemoglobin production during inhalation of nitric oxide [14], the maximum rate of methaemoglobin production suggested that nearly all of the inhaled nitric oxide initially formed methaemoglobin, but no exhaled nitric oxide measurements were performed and all of the calculations were based on an assumed uptake of 80–90%. This study was performed with exhaled measurements to determine the fraction of adsorbed nitric oxide that reacts with haemoglobin to form methaemoglobin, and to determine the pharmacokinetics of the serum nitrogen oxides formed during inhalation of nitric oxide.

Measuring blood volume using inhaled gas was first attempted in 1882 [19] with a fixed volume of carbon monoxide and a single measurement of carboxyhaemoglobin; blood volume was assumed to be the same as volume of distribution of carboxyhaemoglobin. The technique we used to determine if nitric oxide initially forms methaemoglobin is essentially determination of volume of distribution of methaemoglobin using continuous inhalation of gas (equation (2) is a variation on the standard equation for calculating volume of distribution for an infused drug [20]). As methaemoglobin is entirely intravascular, this corresponds to blood volume. This technique requires a constant nitric oxide uptake, constant blood volume during nitric oxide inhalation, and that methaemoglobin elimination follows first-order kinetics. We have shown previously that methaemoglobin kinetics are both first order and linear in the range of concentrations studied here [14], that nitric oxide uptake was constant within subjects, and that blood volume would not be expected to change in the 3 h of the study. Ideally blood volume in the subjects should have been measured simultaneously with isotopically labelled red cells, but this was not possible. The agreement between the calculated and measured blood volumes suggests that the majority of the inhaled nitric oxide that is absorbed forms methaemoglobin, although in all cases blood volume calculated from nitric oxide uptake was greater than the expected value, and therefore 14% of the nitric oxide may have been absorbed without forming methaemoglobin. This could be by formation of nitrites and nitrates, or nitrosyl haemoglobin. When nitric oxide reacts with haemoglobin *in vitro*, the ratio of methaemoglobin to nitrosyl haemoglobin formation depends on oxygenation of haemoglobin; oxygenated haemoglobin forms methaemoglobin and nitrates whereas deoxygenated haemoglobin forms nitrosyl haemoglobin [11, 21]. As inhaled nitric oxide is absorbed into blood as it traverses the pulmonary capillary bed, it is reacting with haemoglobin that is 60–100% saturated, and therefore preferential formation of methaemoglobin would be expected. This has been confirmed by Wennmalm and colleagues [17] who could not detect nitrosyl haemoglobin in volunteers inhaling nitric oxide 25 vpm.

Baseline serum nitrogen oxide concentrations measured in this study were close to values reported previously [17, 22, 23]. In the only other published study of inhalation of nitric oxide and nitrates in humans, Wennmalm and colleagues [17] showed an increase in plasma nitrates 26 to 38 μmol litre^{-1} in volunteers inhaling 25 vpm for 1 h. In this study, at 1 h serum nitrogen oxide concentrations were 80.7 (10.7) μmol litre^{-1}, an increase of 44 μmol litre^{-1}. Volumes of distribution, clearances and time constants for serum nitrogen oxides were greater than values given in previous reports where oral doses of nitrate were given to volunteers. Wagner and coworkers [24] showed a volume of distribution of 21.1 litre, total clearance of 48.3 ml min^{-1} and elimination time constant of 429 min. Cortas and Wakid [23] reported nitrate clearance of 25.8 ml min^{-1}, and from their data the volume of distribution of the nitrate was approximately 19 litre and elimination time constant 740 min. These differences may reflect the different routes of administration; oral nitrates may have a different bioavailability than nitrates formed by inhalation of nitric oxide which is equivalent to an i.v. infusion. A reduced bioavailability of nitrates by the oral route would cause an apparent increase in the volume of distribution, but delayed absorbtion would explain the difference in clearances between our study and others. Clearance of nitrogen oxides in this study was close to the expected values for glomerular filtration rate, suggesting that nitrates are filtered but not reabsorbed in the kidney. The kidney is known to be a major elimination pathway for nitrates [24], and serum nitrates increased markedly in a patient with renal failure who received inhaled nitric oxide [12].

The calculated volumes of distribution and time constants assume a simple one-compartment model for nitrate handling. This may be an oversimplification. Although nitrate is a highly diffusible anion that would be expected to distribute throughout the whole body water, several short-term studies indicate this may not be the case. After oral nitrate loading, red cell nitrates are about two-thirds of plasma values [23], and tissue nitrate concentrations in rats given inhaled nitric oxide showed little increase after exposure [25]. Nitrates are probably actively excreted into saliva [18] against a concentration gradient. The volumes of distribution in our study and those cited above indicate a volume of distribution which is greater than the extracellular fluid volume but less than total body water, which is in agreement with the reported tissue to plasma nitrate gradient. The second peak in serum nitrogen oxides found in this study is also difficult to explain in terms of either one or multiple first-order processes. If all of the inhaled nitric oxide formed nitrates, when inhalation of nitric oxide ceased, serum nitrogen oxide concentration would decrease. One possible explanation for this second peak is the presence of a store of nitrogen oxides which are mobilized into the circulation some time after nitric oxide inhalation ceases. This may be related to the experimental procedure; subjects were seated during inhalation of nitric oxide but were free to walk around during the second stage of the experiment, which would both increase cardiac output and alter its distribution to different tissues. The anatomical site of this store of nitrogen oxides is unknown.

The inhaled concentration of nitric oxide used in these studies was greater than used clinically, where a maximum of 40 vpm is more common. The greater dose was used to ensure measurable changes within an acceptable time scale for a volunteer study.

In summary, we have demonstrated that the majority of inhaled nitric oxide reacts with haemoglobin producing methaemoglobin and nitrogen oxides, but up to 14% apparently undergoes direct conversion to nitrogen oxides. The nitrogen oxides produced have a volume of distribution of one-third of body weight and a clearance similar to glomerular filtration rate.

Heart rate variability in patients recovering from general anaesthesia

N. IRELAND, J. MEAGHER, J. W. SLEIGH AND J. D. HENDERSON

Summary

We studied heart rate variability (HRV) using spectral analysis techniques in 58 adult patients recovering from general anaesthesia. The aim was to discover how HRV was affected by a variety of common preoperative, intraoperative and postoperative factors. ECG, respiration, level of consciousness, nausea, pain and arterial pressure were recorded during the first hour of recovery from general anaesthesia. HRV was found to decrease with increased weight, age, complexity of operation, use of reversal agents for neuromuscular block and preoperative beta-block. These effects were not mediated by changes in respiration. HRV was unaffected by administration of morphine. The level of nausea or pain had no effect on HRV except that pain decreased the relative ratio of high frequency to low frequency power within the power spectrum. In the group of patients that did not receive reversal agents, there was an abrupt increase in HRV when patients became responsive to verbal command. (*Br. J. Anaesth.* 1996; **76**: 657–662)

Key words

Anaesthesia, general. Heart, heart rate. Anaesthesia, depth. Memory. Recovery, postoperative.

Analysis of heart rate variability (HRV) has been used widely as a measure of activity in the sympathetic and parasympathetic components of the autonomic nervous system [1–3]. From oscillations in instantaneous heart rate, some information may be obtained on the status of the cardiovascular controlling systems. Spectral analysis of the R-R intervals is used commonly to quantify the components of beat-to-beat variability. The area under the power spectral curve in a particular frequency band is considered to be a measure of the variation in heart rate at that frequency.

From a variety of physiological experiments it has been demonstrated that inspiratory inhibition of vagal parasympathetic tone causes "high" frequency (HF) fluctuations in heart rate which are related to respiration. This effect seems to be mediated centrally via pathways between medullary respiratory and cardiovascular centres, and is well known as "respiratory sinus arrhythmia". The frequency of these oscillations depends on the breathing frequency but is usually 0.15–0.5 Hz. The origins of oscillations in the mid frequency (MF) (0.05–0.15 Hz) range are less well known but are thought to be caused mainly by the vasomotor part of the baroreflex arc [1]. Low frequency (LF) (< 0.05 Hz) fluctuations are believed to be largely the result of thermoregulatory changes in peripheral vascular resistance [1]. However, when HRV is measured in patients undergoing general or regional anaesthesia, the explanation of the observed changes is more difficult to interpret. It is certainly open to debate as to whether HRV is a reliable indicator of autonomic balance [4, 5], and how it is affected by respiration, anaesthetic drugs, illness and surgery [6–8].

Induction and maintenance of general anaesthesia cause a marked reduction in HRV [9, 10], and it has been proposed that monitoring HRV may provide a useful indicator of depth of anaesthesia [11]. All components of the HRV power spectra decrease with general anaesthesia and increase during the recovery period [9]. However, published studies have involved small numbers of patients who were not suffering from chronic diseases and were not receiving long-term medication. These factors have major effects on HRV and therefore may seriously limit its widespread application. With this in mind, an observational study was performed with the aim of understanding the clinical significance of the HRV power spectrum by recording sequential changes in HRV in a cross-section of patients awakening from general anaesthesia. Apart from documenting the changes in HRV that occur as the patient is awakening in the early recovery period, we hoped to identify factors that influence HRV, and study the associations of HRV data with adverse effects experienced during recovery from general anaesthesia. From this we also hoped to gain information on factors that influence the reliability of using HRV as an indicator of arousal and, possibly, awareness.

Patients and methods

DATA COLLECTION

After obtaining regional Ethics Committee approval and written informed consent, we studied 60 randomly selected hospital inpatients undergoing general

anaesthesia for a wide range of surgical procedures. Patients with known arrhythmias and those less than 16 yr of age were excluded. Information was recorded on clinical factors that were thought to possibly influence HRV. These included: preoperative data such as patient age, sex and weight, preoperative medications and significant clinical disease; intraoperative data such as type of surgery and anaesthetic drugs administered. The end of operation was defined as either the time when neuromuscular block was antagonized or when the anaesthetic vapour stopped if spontaneous respiration had been used. An attempt was made to grade the magnitude of surgery using the Resource Utilization System (RUS) score. This is a system that is used routinely in our hospital to grade the complexity of a particular operation for statistical purposes. It classifies operations on an ordinal scale of 1 (minor) to 4 (multiple major); postoperative data, including when the patient entered the recovery room, ECG, respiration and the patient's clinical state for the length of time that the patient was in the recovery room (minimum of 30 min) or until 1 h had elapsed.

ECG and respiratory data were recorded continuously, in serial "runs" of 300 R-R intervals. At the end of each run, the following clinical data were determined: (1) patient's level of consciousness (LOC) using the scale, 1 = alert and orientated, 2 = drowsy but rouses spontaneously, 3 = drowsy, arouses only to verbal command, 4 = asleep, arousable to stimulation, unarousable to verbal command and 5 = anaesthetized, unarousable to pain; (2) level of pain and nausea using the scale, 0 = none, 1 = mild, 2 = moderate and 3 = severe; (3) time of the patient's first response to a verbal command (the patient was requested to give a single hand squeeze) [12]; (4) medications administered and vital signs.

SIGNAL PROCESSING

The patient's ECG was obtained from lead II of a standard ECG monitor. This was fed to a 386DX computer fitted with a 12-bit Keithley DAS-1200 analogue/digital I/O board (Keithley, Taunton, MA, USA), where it was digitized using a sampling rate of 200 Hz. The signal was filtered digitally and processed to extract QRS peaks which determine the R-R intervals [13]. These peaks were then edited semi-manually to remove and interpolate ectopic beat artefacts. Spectral density was then determined by applying Welch's method to 100-s overlapping data segments which were weighted using the Bartlett window and fast Fourier transformed and averaged. Areas under the spectral density curve up to 0.50 Hz were determined by the trapezium rule. Low frequency (LF) (0.02–0.05 Hz), mid frequency (MF) (0.05–0.15 Hz) and high frequency (HF) (0.15–0.50 Hz) bandwidth powers were determined for each 300 R-R interval series.

The respiratory signal was obtained from a respiratory inductance plethysmograph (Respitrace, Studley Data Systems, Oxford). Data were sampled at 20 Hz by the Keithley board (12-bit) and stored on hard disk. The respiratory power spectrum was obtained in a manner identical to that of heart rate. The Respitrace was calibrated using a Wright's respirometer to obtain concurrent tidal volume readings of the first five breaths of the patient. We used the AC output from the Respitrace, without automatic resetting.

The influence of the lung volume signal on the HRV signal was estimated by multiplying the coherence function of the two spectra by the heart rate spectrum. This technique enables HRV power to be partitioned into a proportion that may be attributed to the lung volume signal and a component that is independent of the lung volume signal.

STATISTICAL ANALYSIS

We attempted to discover associations between the dependent HRV indices and the various explanatory "clinical" variables. These explanatory variables comprised preoperative, intraoperative and postoperative data, as described above.

HRV indices consisted of: (i) natural logarithms of absolute LF, MF, HF and total power (LFP, MFP, HFP, TotP); (ii) ratio of HF to LF and MF power (HF/LFMF); (iii) percentage power in each frequency band that could be attributed to respiration (%RHF, %RMF, %RLF, %RTot).

Because power spectral data commonly have a skewed distribution, we followed the example of Kato and colleagues [10] and performed a natural logarithmic transformation on the raw data. After checking for normality using Agostino's Omnibus-K^2 test [14], this allowed the use of parametric statistics for inter-individual comparison and Pearson's statistic for quantifying correlations between HRV indices. All HRV values in this article are therefore reported in $\ln\mathrm{BPM}^2$ units.

Statistical analyses were performed using the NCSS computer package (NCSS 5.01, Kaysville Utah). Initially, we performed an exploratory analysis of the data set looking for associations. The HRV indices were compared pairwise with the various clinical factors; visually using scatterplots and numerically using the Spearman rank correlation measure. Because three HRV power bands are compared with each explanatory variable, $P < 0.02$ was considered significant (giving an overall experimental type I error of $P = 0.056$). Using the NCSS package, it was possible to allow for the effect of other variables (so-called "partial" variables) on the correlation. This is similar to the use of covariates in ANCOVA models. The residual correlation between two variables is determined after a multiple linear regression has subtracted the effect of the partial variables. If the correlation coefficient is unchanged before and after the linear influence of the partial variables is removed, it is suggested that the partial variables are not confounding factors.

For those variables with a binary structure (such as whether or not the patient was receiving preoperative beta-blocker treatment), groups were compared using the *t* test.

From these results it was possible to build a multivariate model to attempt to account for the observed HRV using general linear model (GLM) multiple linear robust regression. The explanatory variables were the various clinical factors. This was done in a "forward stepwise selection" manner by sequentially adding variables to the model. To assess the potential power of HRV to predict wakefulness, a *post hoc* logistic regression was performed and the results presented as area under the receiver operating characteristic curve.

Results

We obtained 420 technically acceptable data records from 58 patients (table 1). Significant correlations between clinical variables and HRV indices are shown in table 2. It can be seen that the correlation coefficients were similar when respiratory-related HRV power was subtracted. This strongly suggests that the mechanisms by which the explanatory variables alter HRV are not mediated via respiratory changes. There was no single variable that was strongly correlated with any of the HRV indices.

The amount of HRV that could be accounted for by changes in lung volume was less than has been found in healthy volunteers, but varied widely between patients. The mean percentage of total power (%RTot) that was correlated with respiration was 46% (interquartile range 30–60%). In the low frequency band (%RLF) it was 43% (interquartile range 24–58%), in the medium frequency band (%RMF) 41% (28–51%) and in the high frequency band (%RHF) 56% (36–74%). The percentage of total power influenced by respiration did not change with increasing time from reversal ($P = 0.9121$).

Table 1 Patient data (mean (range) or number)

Age (yr)	54 (16–65)
Sex (M/F)	25/33
Preoperative disease	
Diabetes	4
Ischaemic heart disease	3
Preoperative medication	
Beta-blockers	11
ACE inhibitors	8
Thyroxine	5
Anaesthetic technique	
IPPV	33
Combined extradural–general anaesthesia	4
Propofol/thiopentone	40/18
Isoflurane/halothane	55/3
Suxamethonium/vecuronium/ pancuronium	2/22/5
Atracurium	6
Operation type	
Laparotomy	15
Thoracic	3
Urological	5
Vascular	4
Body surface	31

There were no significant differences between male and female groups for any of the HRV indices, but our results confirmed the well known negative correlation of HRV with increasing patient age. Of interest, there was a significant, and previously unreported, negative correlation of patient weight with all HRV indices. It appeared to be an independent factor. We repeated the correlation using other factors (age, beta-block, complexity of operation, use of reversal agents, LOC, pain and nausea) as partial correlates, but were unable to identify any confounding factors that might explain this observation. There was also a consistent negative correlation of all HRV indices with the complexity of operation, as estimated by the RUS score. Again, this was unaffected by age, beta-block, reversal agents, LOC, pain or nausea as partial correlates. Patients with diabetes had HRV indices that were low but not statistically different from non-diabetics. Patients who had a combined extradural–general anaesthetic technique had a higher mean TotP than those who received only general anaesthesia ($P = 0.042$).

DRUG EFFECTS

Beta-blocker use ($n = 11$) was associated with a significantly reduced TotP from a mean of 2.15 to 1.40 (SEM 0.12, $P = 0.0001$). This decrease was noted in all frequency bands, but was particularly marked in the MF band. This band also had the strongest negative correlation with beta-blocker use (table 2). Angiotensin converting enzyme (ACE) inhibitor use ($n = 6$) was associated with a slight increase in MFP from −0.10 to 0.58 (SEM 0.31, $P = 0.0197$), and a positive correlation between ACE inhibitor use and HF/LFMF ($r = 0.27$, $P = 0.0006$). There were no differences in HRV attributable to the different induction agents, volatile agents or neuromuscular blocking drugs. The use of reversal agents (neostigmine 2.5 mg and atropine 1.2 mg, $n = 33$) was associated with a significant decrease in HRV (TotP) from a mean of 2.43 to 1.70 (SEM 0.09, $P = 0.0001$). The difference was similar in all frequency bands. It was not possible to separate the effects of reversal

Table 2 Spearman correlation coefficients for respiratory and non-respiratory related HRV spectral power indices. Only correlations for $P < 0.02$ are shown. LF, MF and HF refer to the frequency bands 0.02–0.05, 0.05–0.15 and 0.15–0.5 Hz, respectively. The numbers in parentheses are the correlations after subtraction of the power that is correlated with changes in lung volume and thus is a measure of HRV power independent of respiration

	LFP	MFP	HFP	HF/LF
Age	−0.25 (−0.20)	−0.22 (−0.21)	0.28	
Weight	−0.24 (−0.23)	−0.26 (−0.28)	−0.31 (−0.32)	
Beta-block	−0.16 (−0.16)	−0.26 (−0.26)	−0.17 (−0.19)	
Reversal	−0.22 (−0.19)	−0.35 (−0.33)	−0.23 (−0.21)	
LOC	−0.17 (−0.17)	−0.17 (−0.16)	−0.21	−0.22
SAP	−0.23 (−0.23)	−0.12 (−0.12)	0.26	0.21
Heart rate	−0.22 (−0.29)	−0.13 (−0.20)	−0.22 (−0.26)	
RUS score	−0.17 (−0.17)	−0.19 (−0.24)	−0.17 (−0.18)	

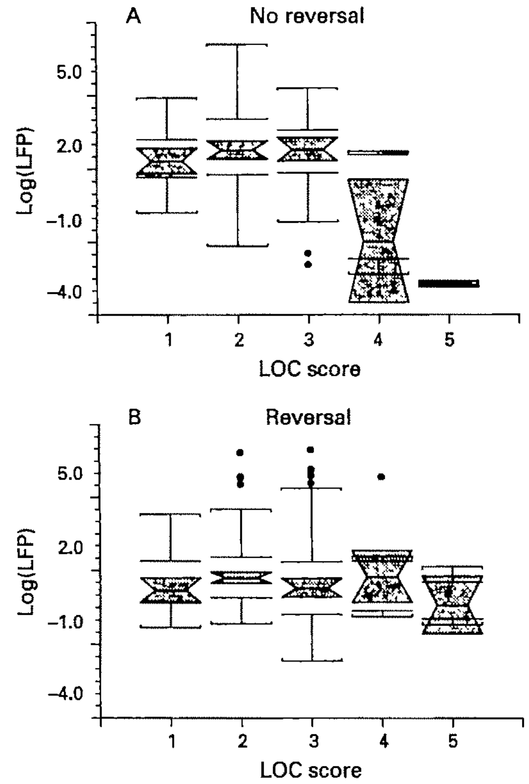

Figure 1 Box plots showing LFP *vs* LOC score in patients who did not have reversal (A) and in those who did (B). Central lines median of the group, with the "notches" showing the 95% confidence intervals of the median. Using this display, it is thus possible to make visual multiple comparisons for non-parametric significant differences between the groups. Outliers are shown as data points outside the (quartile ± 1.5 × interquartile range). Vertical axis is in $\ln BPM^2$ units.

agents from the use of neuromuscular blockers, or positive pressure ventilation, but it seemed likely that the observed effect was largely attributable to atropine.

There were no changes in HRV indices associated with morphine or metaclopramide administration during the recovery period.

PHYSIOLOGICAL CHANGES DURING RECOVERY

As shown in table 2, LOC had a significant negative correlation with LFP and MFP. This effect is shown in figure 1, which also demonstrates that the use of reversal agents eliminated the change in HRV power with LOC. In the group that did not receive reversal agents, there was a large increase in HRV power between LOC grades 3 and 4. This phenomenon occurred before and after patients became responsive to verbal command. If this is taken as a threshold level for consciousness, the area under the receiver operating characteristic curve was 0.91 in the non-reversed and 0.63 in the reversed group. We compared the predictive power of LFP with heart rate (HR) and systolic arterial pressure (SAP) alone, and in combination, using a logistic regression. Only LFP had values significantly different from zero. HR and SAP, either alone or in combination, could not distinguish between awake and asleep groups.

Pain had no significant effect on HRV indices, except for the HF/LFMF ratio which was decreased significantly ($r = -0.18$, $P = 0.02$). Nausea did not appear to have consistent effects on any of the HRV indices except to decrease HFP in the group that had not received reversal agents ($r = 0.21$, $P = 0.0007$).

Table 3 Pearson correlation coefficients among the HRV indices. All are significant ($P < 0.000$). The numbers in parentheses are the correlation coefficients for the subgroup of patients who were receiving beta-blockers

	MFP	HFP	TotP	HF/LFMF
LFP	0.82 (0.41)	0.70 (0.27)	0.96 (0.92)	−0.18
MFP		0.86 (0.69)	0.90 (0.64)	0.06
HFP			0.82 (0.52)	0.36
TotP				0.01

CORRELATIONS WITHIN HRV INDICES

The matrix of correlations between the various HRV indices is shown in table 3. In general the indices demonstrated strong linear correlations. However, as shown by the numbers in parentheses in table 3, the use of beta-blocking drugs appeared to be associated with a reduction in the correlation between the various indices. The use of reversal agents, ACE inhibitors, RUS score, LOC and pain or nausea score resulted in non-significant changes in the correlation coefficients.

MULTIVARIATE MODEL

Eight explanatory variables (age, weight, beta-block, RUS score, reversal, LOC, SAP and beta-block/SAP interaction term) were found to contribute significantly in a robust multiple linear regression model. This model achieved r^2 values of 56% for TotP, 52% for LFP, 63% for MFP and 43% for HFP. If the overall spectral power was partitioned by subtracting the power that was correlated with respiration (% Rtot) from TotP it was possible to derive the amount of spectral power that was independent of lung volume (NR-Tot). When a similar regression was performed, r^2 values of 47% were obtained for NR-Tot, and only 10% for % RTot. Thus about half of the variation in HRV can be accounted for using these predictor variables, none of which appears to act significantly via changes in respiration.

Discussion

This was a descriptive study and therefore interpretation of possible effects is difficult because of the problem of unknown confounding factors which may cause spurious correlations. Notwithstanding, there appeared to be several consistent observations. In this study, approximately 50% of this variability could be explained by a linear multivariate model using clinical variables. Presumably the rest of the interindividual variation was a result of other microscopic and biochemical changes that are not easy to measure. It is difficult to disentangle the relative effects of preoperative morbidity, residual effects of anaesthetic agents and activation of the surgical stress response. However, clearly HRV is correlated negatively with the complexity of the operation and weight of the patient. There is circumstantial evidence that stress hormonal activation may be an important modulator of HRV. Most studies have concentrated on the effects of the autonomic nervous system on HRV, but have ignored the fact that in situations of high sympathetic tone there are commonly coexisting elevations in vasopressin, renin, angiotensin II, corticosteroids and a number of autocoids controlling vasomotor tone [15, 16]. These hormones may act in at least two ways. Vasopressin is known to modulate directly the autonomic outflow from the brain stem by inhibiting vagal tone. Other substances may change peripheral resistance, thus affecting the oscillations in the HR feedback loops that manifest as LFP.

Pain (or nausea) does not appear to be associated with a marked increase in sympathetic power, as shown by an increase in the LFP and MFP bands. There are major problems with the common interpretation of MFP (or LFP) as being an indicator of sympathetic nervous system "tone" [17]. This explanation is based on changes in MFP induced by tilt or negative pressure studies in volunteers. In other hyper-adrenergic states (cardiac failure, exercise and high altitude hypoxia) there is a characteristic pattern in the HRV response, consisting of a decrease in LFP, increase in HR and a relative "switching off" of parasympathetic tone, as evidenced by a decrease in the HF/MFLF ratio. Saul and colleagues [18] compared HRV indices with sympathetic activity, as measured directly from the peroneal nerve, and by plasma noradrenaline concentrations. They found a marked heterogeneity in response. In 50% of their subjects there was a close association with LFP and muscle sympathetic nerve activity, but for the remainder there was no correlation.

Berger, Saul and Cohen [19] performed a canine study in which the cardiac sympathetic nerves were stimulated directly causing some increase in LFP but without effect on MFP. Furthermore, they demonstrated a decrease in LFP with increasing stimulation frequency. Malliani and colleagues [20] found that fluctuations in arterial pressure preceded variations in heart rate. We therefore conclude that it is more accurate to interpret MFP as an index of phasic (not tonic) sympathetic nervous system activity, principally mediated by oscillations in the baroreflex arc. The possible confounding effects of other stress hormones, such as angiotensin and vasopressin, are not mentioned in any of these studies. However, it is of interest to note that ACE inhibitors tend to increase HRV, particularly in the HF band. Hopf and colleagues [21] have compared HRV before and after preganglionic cardiac block using thoracic extradural local anaesthesia. They reasoned that if LFP was dependent on sympathetic activity, then block should result in a decrease in LFP. However, they found that absolute LFP did not decrease when the block was commenced but that HF/LF ratio did decrease with tilt, particularly if the cardiac nerves were not blocked. Interestingly, they reported an increase in vasopressin plasma concentrations in the presence of sympathetic block and tilt.

The effects of beta-block observed were depressant on all frequencies of HRV, but particularly inhibitory on phasic baroreflex activity (MFP). We also showed that beta-block appeared to have the effect of "uncoupling" the usually strong correlations between the different frequency bands in the HRV power spectrum. Beta-blockers have a number of pre- and postsynaptic actions that could affect HRV. Central beta-receptors are known to directly modulate vagal tone, in addition to causing dissociation of sympathetic neural traffic between different organs.

Our findings that LF and HF power are reduced with increasing depth of anaesthesia are consistent with similar studies [9, 10, 11, 22]. Kato and coworkers [10] made the important observation that the reduction in LF power is not related linearly to depth of anaesthesia, as measured by end-tidal volatile anaesthetic concentrations. We have obtained similar results using a relatively coarse clinical scale of arousal. As shown in figure 1, LFP (and HFP) increased abruptly in a stepwise manner at the point at which the patient became responsive to verbal command. This particular end-point may be an important clinical indicator of the possibility of awareness, or at least recall. Dutton, Smith and Smith [12] have studied patients recovering from general anaesthesia. They found that response to command was a useful indicator of anaesthetic depth, as evaluated by memory formation. In their study none of 22 patients who had a brief wakeful response to verbal command had memory formation. In contrast, 13 of 28 patients who could sustain wakefulness long enough to complete four hand squeezes on command had memory formation. On the scale that we used in our study, the transition from LOC grade 4 to 3 would correspond to Dutton's brief wakefulness level. Loss of amnesia starts to occur regularly at the transition from LOC grades 3 to 2. In our study HRV increased markedly when the patient moved from LOC grades 4 to 3. HRV is therefore a conservative marker of consciousness, increasing at the point at which there is a coordinated response to command, but relatively unrelated to the presence or absence of amnesia. We may conclude that a low HRV strongly suggests unawareness and furthermore an increase in HRV is a relatively early warning sign of conscious recall, the patient probably still being amnesic.

Our data tentatively suggest that HRV power may be a useful adjunct in monitoring depth of anaesthesia, but the findings need to be confirmed. In our *post hoc* analysis, if the patient had not received atropine, the LFP correctly categorized wakefulness in 92% of patients in our study. However, this result was biased because most of the patients were rousable by the time they were taken to the recovery area and therefore classified as being "awake". Further work needs to be done to establish accurately the true positive predictive value and appropriate threshold level of HRV. Nevertheless, even if it is not completely reliable, the use of HRV would seem to be a great improvement on the common clinical indicators of awareness. The discriminatory power to detect awareness was not improved if heart rate and systolic arterial pressure were included in the prediction. The predictive power also appeared to be relatively robust to many common medications and illnesses (ACE inhibition and opioids), but allowances in TotP of about -0.1 (lnBPM^2) per decade must be made for age and approximately -1 (lnBPM^2) for the use of beta-block. It was completely obtunded by the use of atropine.

Comparison of sedation with midazolam and ketamine: effects on airway muscle activity†

G. B. DRUMMOND

Summary

Male patients, aged 27–74 yr, without hypertension or overt cardiovascular disease were premedicated with temazepam 20 mg orally and allocated randomly to receive sedation with either midazolam (12 patients) in a dose sufficient to provide light sedation (retained response to loud voice) or ketamine 1 mg kg^{-1} (11 patients). Median midazolam dose was 0.08 (interquartile range 0.02) mg kg^{-1}. The activity of the muscles of the tongue, anterior neck and scalene group was measured with surface electrodes and compared with the awake state. Muscle activity decreased significantly after midazolam in each group of muscles, to median values of 42%, 28% and 33%, respectively, of awake values. Airway obstruction occurred in 10 of 12 patients and during obstruction muscle activity increased significantly to 69%, 73% and 52% of awake values, but in all cases this was insufficient to overcome the obstruction. After ketamine, activity did not change significantly and there were no episodes of airway obstruction. Phasic muscle activity was noted after sedation in 11 subjects but there was no difference in the incidence between the two groups (midazolam, six patients; ketamine, five patients). (*Br. J. Anaesth.* 1996; **76**: 663–667)

Key words

Hypnotics benzodiazepine, midazolam. Anaesthetics i.v., ketamine. Airway, muscles.

Sedation is used frequently in association with regional anaesthesia during surgery [1], and for procedures such as endoscopy [2]. Respiratory function is impaired frequently by sedation [3, 4] and sedation is associated with serious adverse events [5]. Sedative agents such as barbiturates [6] and benzodiazepines [7] cause loss of airway muscle tone and an increase in airway resistance [8]. Ketamine, which is a potential sedative for patients undergoing surgery with regional anaesthesia, appears to have less profound effects on the muscles of the upper airway [9]. In this study, we compared the effects of sedation with midazolam and ketamine on upper airway and respiratory muscles in men undergoing anaesthesia. Men were chosen as they seem to have more problems than women with airway patency in association with sedative use [10, 11]. We also investigated the effects of airway obstruction on airway muscle activity and the incidence of phasic patterns of activity of the muscles.

Subjects and methods

After obtaining approval from the local Ethics of Medical Research Committee and informed consent, we studied male patients undergoing routine surgical procedures under general anaesthesia. Patients were recruited if they had no overt cardiovascular or respiratory disease, and had a normal arterial pressure. Exclusion criteria were age more than 75 yr, body weight more than 120% of that expected for height and weight, obvious risk of regurgitation and those receiving sedative or analgesic medication or treatment for hypertension. Subjects were allocated randomly to receive either midazolam or ketamine by random number tables.

After an overnight fast, premedication comprised temazepam 20 mg orally, 1 h before the patient was studied. The study room was kept warm and quiet and patients were encouraged to relax as much as possible. During local anaesthesia, an i.v. cannula was inserted and a slow infusion of 0.9% saline was started through an infusion set fitted with an extension to allow drug administration without the knowledge of the patient.

Electrocardiograph electrodes were attached and the ECG displayed continuously. Non-invasive arterial pressure measurements were not obtained regularly because they could disturb the patient. The patient lay in the supine position with the head supported in a neutral position in the midline on a single soft pillow. The arms were supported at the sides and the recording apparatus was kept out of the line of vision of the patient.

EMG activity was recorded as in a previous study [6]. Briefly, the skin surface was prepared to obtain an inter-electrode resistance of < 2 kΩ. Disposable pre-gelled silver–silver chloride electrodes were placed with centres 3 cm apart, in the midline posterior to the lower edge of the mandible (tongue), just below the thyroid prominence (neck strap muscles) and over the right scalenus medius (scalene group), and recorded with the ECG using an FM

†Preliminary results of this study were presented to the Anaesthetic Research Society (*British Journal of Anaesthesia* 1989; 62: 230P).

tape recorder. In subsequent analyses the signals were rectified and integrated with a time constant of 100 ms after gating to remove the ECG component [12]. Recordings were made over at least 30 s. Maximum amplitude of the integral during the respiratory cycle was measured. The presence of phasic activity was classified as a variation in amplitude within the respiratory cycle of more than 50 % peak activity, during episodes when airway obstruction was judged to be minimal.

After attaching the electrodes, patients were encouraged to relax for at least 5 min without speaking before measurements were made of resting awake activity. Midazolam was given as an initial bolus of either 2 or 3 mg, according to age, and then in 1-mg or 0.5-mg doses at 3-min intervals to obtain a sedated state where the eyelids were drooping but not shut (the patient would respond either to a voice or light touch to the face) and the eyelash reflex was present.

Ketamine 1 mg kg^{-1} was given as a single dose. After administration the patients were not spoken to unless absolutely necessary, and given no specific instructions either to open or close the eyes. The ambient noise in the room was kept as small as practicable. Measurements were made 3 min after the last dose of midazolam, and at 2 and 4 min after administration of ketamine to provide some indication of the rate of onset of activity of this agent. In patients who received midazolam, further measurements were made during episodes of partial or complete airway obstruction and in some subjects, where possible, after relief of the obstruction by gentle support of the jaw or backward tilting of the head to obtain a clear airway with minimal arousal of the patient. The presence of airway obstruction was judged by clinical criteria, such as changes in gas flow felt at the mouth and nose, noise of breathing and pattern of chest and abdominal motion. In addition, in some patients changes in the movement of mouth and lips were noted. If the obstruction appeared severe, it was always remedied after 1 min. After measurements of muscle activity, administration of oxygen was started and anaesthesia was induced. After induction of anaesthesia and neuromuscular block, another recording of electrical activity was made to allow an exact measure of background electrical activity which was subtracted from the integral values.

Data were analysed using a spreadsheet (Excel v 5.0a) and a statistics package (Minitab release 8.2) using MS-DOS 6.2. Values are given as median (quartiles). Muscle activity, expressed as a percentage of the awake value, was converted to logarithms before statistical comparison; within subjects using the Wilcoxon test and between groups using the Mann–Whitney test. The incidence of phasic muscle activity was compared between groups with Fisher's exact test.

Results

The groups were comparable in age (53, 42–62 *vs* 64, 57–67 yr), height (178, 171–179 *vs* 175, 168–180 cm), weight (71, 63–75 *vs* 67, 61–83 kg) and weight as a percentage of expected weight (95, 90–108 % *vs* 103, 93–114 %) (respective values for midazolam and ketamine).

Table 1 Muscle activity (% of awake values) in the two groups, during periods when airway obstruction was judged to be minimal. Values are median (quartile) values

	Midazolam	Ketamine
Muscle group		
Tongue	42 (20–44)	72 (60–155)
Strap muscles of neck	28 (19–60)	175 (130–213)
Scalene muscle	33 (19–62)	100 (81–311)

The 12 patients who received midazolam were given a median dose of 5 mg (seven patients received 5 mg; dose range 3–8; quartiles 5 and 7 mg). In all patients the required end-points of sedation were reached and no patient was judged to have become oversedated. Airway obstruction occurred in 10 patients sedated with midazolam and patients were either repetitively aroused or the jaw was supported to restore airway patency. In another patient, breathing became noisy but there was no obstruction.

One patient received midazolam 8 mg, which was the largest dose required. If this patient is excluded, there was a significant decrease in dose requirements with age ($P < 0.05$), although the correlation was not strong ($r = 0.4$), indicating considerable variation in dose requirements, independent of age. The relationship between dose and age was less significant if the dose was considered in terms of actual or ideal body weight, although there was no relationship between body weight and age.

There was no difference in muscle activity at 2 and 4 min after administration of ketamine, and the 4-min measurements have been used for presentation and analysis. After ketamine, all patients became quiet and detached. None had clinically apparent airway obstruction.

Sedation with midazolam was associated with a significant reduction in muscle activity in all three muscle groups ($P < 0.01$), whereas there was no significant change in activity after ketamine (table 1).

Partial or complete airway obstruction developed in 10 of 12 patients who received midazolam. In all subjects there were changes in the sounds of airflow, and reductions in gas flow palpable at the airway opening. In six subjects there were changes in the pattern of movement of lips, cheeks, the suprahyoid region of the neck and the chest wall, particularly as the obstruction was prolonged. In patients who received midazolam, measurements during airway obstruction showed progressive increases in muscle activity that were more obvious in the strap muscles of the neck and the scalenes, although there were no significant differences in the increases in the three groups. A typical example is shown in figure 1 and the changes in all subjects are shown in figure 2. During episodes of airway obstruction, activity was phasic in two, six and seven subjects in the tongue, neck strap muscles and scalene muscles, respectively. When the obstruction was relieved, successful recording of activity was obtained in five subjects. In all of these subjects airway muscle activity decreased

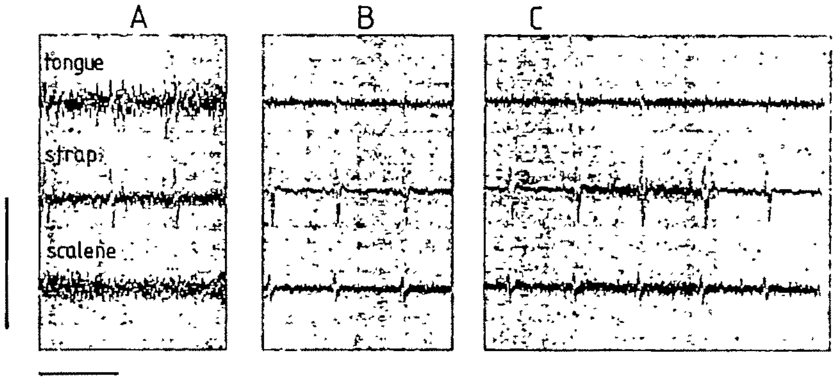

Figure 1 Representative recording of EMG signals in a patient who received midazolam. A = Awake; B = after sedation; and C = during an episode of partial airway obstruction. There is a marked reduction in tonic activity after sedation and an increase in phasic activation in time with inspiration during partial airway obstruction. (Vertical scale marker = 1 mV, horizontal scale marker = 1 s.)

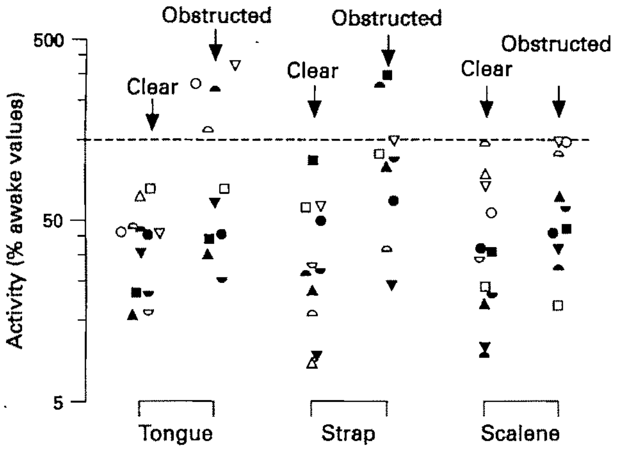

Figure 2 Changes in the activity of the three muscle groups (expressed as percentage of awake values) in patients sedated with midazolam, during episodes of clear breathing (all subjects) and obstructed breathing attempts (10 subjects). The dotted horizontal line indicates the awake activity. Each subject is shown by a different symbol. For subjects with airway obstruction, the increase in activity in each muscle group was significant ($P < 0.05$). Note that obstruction persisted despite activity in some patients being greater than the awake value.

considerably but there were insufficient numbers to allow statistical analysis of sufficient power by the Wilcoxon test.

There was evidence of phasic activity in five patients after ketamine sedation, but in only one subject was phasic activity seen in the tongue signal.

There were no adverse events in the study apart from episodes of airway obstruction, which were corrected promptly. No patient reported unpleasant experiences. The quality of recovery from the subsequent anaesthesia was not altered discernibly.

Discussion

Comparison of sedation with midazolam and ketamine is not simple. In clinical terms, the states of sedation were comparable. However, the ED_{95} for abolition of response to command by ketamine is approximately 0.6 mg kg^{-1} [13], and therefore the dose chosen in this study may have been larger than necessary. In contrast, the end-point of midazolam sedation was deliberately "light" and several patients became aroused by the manoeuvres used to restore airway patency. In patients who received midazolam it is also likely that there was considerable interaction between the drug effect and the sleep state. Such interactions may perhaps explain the discrepancies in previous results where airway obstruction was not observed after the use of similar or greater doses than in the present study [1, 4]. Another factor that complicates comparison between studies is the variation in susceptibility to midazolam with age [14]. The relative potencies of these two agents depend on the measure of effect that is used for comparison as they do not have parallel dose–response relationships [13]. The dose of midazolam relative to ketamine used in this study was less than the equivalent dose in a previous comparison [15], but the patients in that study were less healthy (ASA III or IV). In addition, in our study patients were premedicated with temazepam. This is likely to have had an additive influence on the effects of midazolam. For ketamine, which is a different class of agent, the effects are less easy to predict, but ketamine appears to have additive effects with propofol (which does act in a way similar to that of the benzodiazepines) [16]. Stella, Torri and Castiglioni [13] reported that the ED_{95} of ketamine for abolition of response to command was 0.6 mg kg^{-1} and for diazepam, which is generally considered to be approximately 50% as potent as midazolam, 0.5 mg kg^{-1}, which again suggests that the dose of midazolam used in this study was small in comparison with the dose of ketamine.

Additional measurement of airway or oesophageal pressure would have allowed more exact assessment of the relationship between muscle action, airway pressure and resistance changes. However, such measurements are more invasive and more likely to alter arousal and consequent responses than the presence of external electrodes. On the other hand, inductance band measurements of the rib cage and abdomen would have caused no disturbance to patients and might have confirmed previous observations of the pattern of rib cage movement during sedation with midazolam [17] which have now been recognized as associated with airway obstruction [11].

The pattern of activity in the muscles studied was similar to that found in a previous study [6], although tongue activity was less often phasic than activity recorded using intramuscular electrodes placed via the mouth [18, 19]. Previous workers have reported variations in the pattern of activity depending on the site of measurements [20]. In normal subjects, genioglossus activity is greater in the supine than the sitting position, and greater when breathing via the nose than the mouth [19]. These factors may have a bearing on the present results as from clinical experience and previous observations [6], increasing sedation alters the route of respiration from the nose to the mouth, probably with loss of muscle tone in the soft palate, and a change in the breathing route may contribute to loss of tongue muscle activity. Our observations of scalene muscle activity are also in agreement with previous reports [6, 21–23] but not with a more recent study using intramuscular electrodes [24] in which no activity was found during quiet respiration in the supine position.

In this study, administration of ketamine was not associated with loss of airway patency or with a decrease in airway muscle activity, consistent with previous animal studies [9]. Previous studies in humans with ketamine 1 mg kg^{-1} reported greater resistance to aspiration of radio-opaque markers than with other sedatives such as diazepam [25]. In contrast, there was marked loss of airway muscle activity and airway patency with administration of midazolam. Animal studies in particular indicate the relative importance of the neck muscles in the control of airway patency [26, 27].

Sedation with midazolam 0.1 mg kg^{-1} increases nasal airway resistance in supine subjects [8] and causes a reduction in inspiratory flow and snoring in male, or female, subjects with partial nasal obstruction [11]. The obstruction causes an increase in the relative contribution of the rib cage to respiratory movement [11, 17] which suggests reflex activation of rib cage muscles such as the scalenes, which can contribute to rib cage movement [28–31], and is consistent with our observations. Such abnormalities of movement in sedated patients can be reversed by application of positive airway pressure [32].

The progressive increase in activation of the muscles during obstruction has been noted in previous studies [18] but does not appear to be a universal finding in sleeping patients. The mechanism is unclear. Although there are reflexes associated with upper airway sensation [33–35], and in animals from lung volume feedback [36], there is also a progressive increase which resembles the probable increase in chemical drive. It is possible that arousal from the sedated state might have occurred if the airway muscle activity had been allowed to increase further, as occurs in sleep apnoea [37].

This study suggests that when male patients are sedated with midazolam, even if they remain easily rousable, close attention must be paid to their airway, and airway support is likely to be required. In contrast, ketamine sedation is not likely to reduce airway muscle activity and impair upper airway patency. The results of this study, together with previous studies [11, 17], also suggest that observation of movements of the rib cage may be misleading in the assessment of the presence of airway obstruction, as most observers probably associate breathing difficulty with reduced rib cage excursion.

Accumulation of foreign gases during closed-system anaesthesia

L. VERSICHELEN, G. ROLLY AND H. VERMEULEN

Summary

In a previous study, accumulation of methane was found at the end of closed-system ventilation. As on-line analysis of gas concentrations is now available, we examined the progressive increase in concentrations of methane, carbon monoxide and acetone during modern, closed-system conditions, and their influence on infrared halothane analysis, in 26 non-pregnant, gynaecological patients. A computer-controlled closed-system anaesthesia apparatus (PhysioFlex) was used for ventilation during total i.v. anaesthesia (excluding nitrous oxide or potent inhalation anaesthetics) for gynaecological laparoscopy. Methane, carbon monoxide and acetone concentrations were analysed every 15 min in a photoacoustic infrared monitor and halothane concentrations by built-in infrared spectrometry. Mean methane concentrations increased progressively after 105 min to 941 (SD 1094) ppm, but concentrations of carbon monoxide and acetone did not increase significantly. In 18 patients, the infrared measurement falsely indicated 0.79 (0.52) % "halothane" after 60 min, but no reading appeared in the other eight patients. We conclude that methane accumulated progressively under strict closed-system conditions in higher concentrations than reported previously. In two-thirds of patients it induced false "halothane" readings. (*Br. J. Anaesth.* 1996; **76**: 668–672)

Key words

Equipment, breathing systems. Gases non-anaesthetic, methane. Gases non-anaesthetic, carbon monoxide. Gases non-anaesthetic, acetone. Measurement techniques, spectrometry.

Modern anaesthetic machines permit low-flow or even totally closed-system anaesthesia. It is known that foreign gases accumulate during closed-system anaesthesia, and that methane in particular can be detected in moderate concentrations [1]. Recently, however, we found that methane was present at the end of closed-system ventilation in much greater concentrations than expected [2].

In animals, during total i.v. anaesthesia, expired false "halothane" concentrations of up to 0.8% have been recorded during rebreathing [3]. As herbivores partly expel methane via the lungs [4], it might be that methane affects the infrared measurement of halothane. In human, we unexpectedly found that closed-system ventilation during i.v. anaesthesia was associated sometimes with falsely recorded "halothane" concentrations [2].

As methods for on-line analysis of gases have become available recently, we have examined the progressive increases in concentrations of methane, carbon monoxide and acetone under modern closed-system conditions, and also the influence of methane on infrared analysis of halothane.

Patients and methods

Since 1989, we have routinely used a computer-controlled anaesthetic apparatus, PhysioFlex (Physio, The Netherlands) in clinical practice. The apparatus has been described in detail previously [5]. In brief, it is a closed system with a volume of 3.5 litre, wherein small amounts of oxygen, nitrous oxide (or air) are given by built-in, computer-controlled injection; excess gases are evacuated if necessary (fig. 1). The inspiratory oxygen concentration is measured continuously with a paramagnetic oxygen analyser, whereas concentrations of nitrous oxide, carbon dioxide and volatile anaesthetics are measured with a built-in, non-agent-specific infrared spectrometer (Andros, Berkeley, CA, USA). Measurement of halothane, enflurane or isoflurane can be set at an infrared wavelength of 3.3 µm. If no particular anaesthetic agent is selected for measurement, halothane sensitivity is chosen automatically in the apparatus used by us. If so chosen, liquid anaesthetic is injected by a computer-controlled syringe. Four-membrane chambers are built into the breathing system for the purpose of controlled ventilation. The apparatus can be used for inhalation anaesthesia or for oxygen–air ventilation, as in this study.

Recently, apparatus became available for measuring trace concentrations of gases. Using the Brüel and Kjaer multi-gas monitor 1302 (Denmark), trace concentrations are determined by a photoacoustic infrared method. At chosen moments, samples of 140 ml of breathing gases can be obtained for analysis, which is performed with dedicated, narrow-band optical filters. In this study, concentrations of methane were measured at a wavelength of 3.6 µm, while carbon monoxide and acetone were analysed at 4.7 and 8.5 µm, respectively. To avoid interference

Correspondence to G.R.

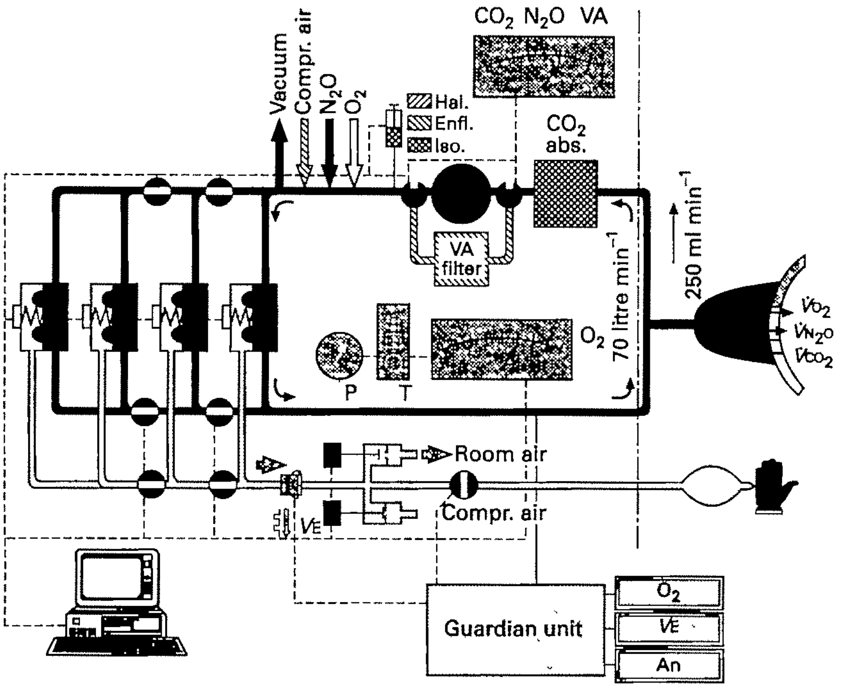

Figure 1 Direction of gases flowing at a flow rate of 70 litre min^{-1} in the circle is shown by the four arrows. No unidirectional valves are present. Inflow of oxygen (O_2), nitrous oxide (N_2O) or compressed air, and eventual injection of liquid halothane (Hal.), enflurane (Enfl.) or isoflurane (Iso.) is shown in the upper part. Excess gases are evacuated by vacuum. The four-membrane chambers are shown to the left. Windows showing carbon dioxide (CO_2), N_2O and volatile anaesthetics, and oxygen concentrations are shown. At the bottom, the Guardian unit is depicted.

at these specific wavelengths, the concomitant use of nitrous oxide and potent inhalation anaesthetics was avoided, and the PhysioFlex apparatus was flushed carefully with oxygen before each use to eliminate any trace of these agents.

After 5 min of closed-system use, and every 15 min thereafter, 140-ml samples of gas were obtained directly at the Y-piece of the breathing circuit via a polytetrafluoroethylene tube and fed into the measuring chamber of the multi-gas monitor, while controlled ventilation was maintained continuously with the PhysioFlex apparatus. Although only oxygen and air were used, and no inhalation anaesthetic was given or selected for measurement, the analyser for halothane is always operational and readings are shown at the appropriate window on the screen. This non-invasive assessment was approved by the Ethics Committee of the hospital.

Total i.v. anaesthesia (TIVA), with oxygen–air ventilation, is used routinely in our department for gynaecological laparoscopy with insufflation of carbon dioxide. TIVA is performed with propofol 1–2.5 mg kg^{-1}, followed by continuous administration at a rate of 10 mg kg^{-1} h^{-1}, and fentanyl (intermittent 0.1-mg boluses as required clinically). Vecuronium 0.1 mg kg^{-1} is used for intubation and surgical neuromuscular block. Controlled ventilation with an $F\text{I}_{O_2}$ of 0.4 is used, with minute volumes to maintain end-tidal $P\text{CO}_2$ at 4.0–4.6 kPa.

Statistical analysis of the data was done using the following tests: Mann–Whitney *U*-test, Wilcoxon signed rank test and Student's *t* test, where appropriate, for comparison of variables at different times within a group and at similar times between groups; ANOVA, Wilcoxon test and Friedman test, where appropriate, for detection of variation in time within a group; and two-way ANOVA for comparison between groups.

Results

We studied 26 ASA I or II, non-pregnant women undergoing routine gynaecological laparoscopy. Mean age, weight and height are shown in table 1, together with the occurrence of "false" halothane readings. Anaesthesia lasted 60–235 min.

A progressive increase in methane concentration was found with time ($P = 0.002$; ANOVA); concentrations of carbon monoxide did not change significantly with time (table 2). A reading for inhalation anaesthetic concentration was present in 18 patients; it did not appear, or occasionally gave the lowest reading possible on the screen, in eight patients. For analysis of the results, patients were therefore allocated to one of two groups according to the presence (group A) or absence (group B) of readings for inhalation anaesthetic values.

Concentrations of methane in the 18 patients in group A were significantly higher than in the eight

Table 1 Patient characteristics in relation to false "halothane" readings (mean (SD or range))

	Presence of "halothane" reading ($n = 18$)	Absence of "halothane" reading ($n = 8$)	Total group ($n = 26$)
Age (yr)	42.7 (29–78)	39.0 (28–77)	41.6 (28–78)
Weight (kg)	62.8 (11.4)	67.6 (10.3)	64.2 (11.0)
Height (cm)	165.1 (7.6)	167.0 (9.0)	165.7 (7.9)

Table 2 Mean (SD) concentrations of methane, carbon monoxide (CO) and acetone measured at progressive times in the total group of 26 patients (overall statistical difference with time was $P < 0.002$ for methane; ns for CO)

	5 min ($n = 26$)	15 min ($n = 26$)	30 min ($n = 26$)	45 min ($n = 26$)	60 min ($n = 26$)	75 min ($n = 20$)	90 min ($n = 13$)	105 min ($n = 11$)
Methane (ppm)	240 (211)	374 (253)	510 (398)	594 (513)	671 (582)	789 (746)	802 (971)	941 (1094)

"Halothane" (%)	0.14 (0.07)	0.27 (0.19)**	0.46 (0.36)**	0.64 (0.44)**††	0.79 (0.52)**††‡‡
Group B					
Methane (ppm)	116 (52)	185 (140)	162 (74)	145 (52)	158 (22)

Table 4 Mean (SD) concentrations of acetone and carbon monoxide (CO) in groups A ($n = 18$) and B ($n = 8$); (no significant difference overall for acetone and CO, both with time and between groups)

	5 min	15 min	30 min	45 min	60 min
Group A					
Acetone (ppm)	36.8 (31.1)	39.7 (38.3)	42.5 (42.1)	41.6 (42.8)	41.5 (44.8)
CO (ppm)	30.1 (35.6)	25.5 (33.8)	23.8 (30.5)	23.4 (27.7)	23.3 (25.8)
Group B					
Acetone (ppm)	20.0 (19.5)	27.1 (26.5)	30.1 (35.2)	32.9 (43.3)	34.7 (40.0)
CO (ppm)	16.9 (9.9)	13.7 (6.1)	13.8 (5.0)	13.5 (3.9)	13.9 (3.5)

patients in group B (table 3). In group A, a progressive increase in methane concentration was noticed ($P < 0.05$ or $P < 0.01$; Wilcoxon signed rank and Friedman's test), as was an increase in the reading for inhalation anaesthetic ($P < 0.01$; Wilcoxon signed rank and Friedman's test). A significant ($P < 0.015$) correlation was found between methane (X) and the anaesthetic reading (Y): "halothane" $\% = (8.5 \times \text{methane (ppm)} \times 10^{-4}) - 0.069$ ($r^2 = 86.10\%$). In group B, there was no statistically significant difference in methane concentration at different times.

Mean values for both carbon monoxide and acetone were higher in group A than group B (table 4). Although no significant changes with time were found for carbon monoxide, concentrations of acetone increased marginally with time.

Discussion

Methane is present in the alimentary tract of animals and humans. It is produced primarily in the distal colon by fermentation of carbohydrates under strict anaerobic conditions by *Methanobacterium ruminatium*. Methane is liberated by reduction of carbon dioxide with hydrogen [6]. Intestinal gas in humans contains up to 26% methane [7]. The main part is excreted in flatus, but a smaller part is taken up in blood. Because of the insolubility of methane in blood relative to air, 90–95% of this gas is cleared in a single passage through the lungs. There are large individual differences: approximately two-thirds of subjects had methane breath concentrations of less than 1 ppm, and one-third concentrations ranging from 1 to 70 ppm [8]; 80% of patients with cancer of the large bowel had detectable levels of methane in their breath [9] and 83% of patients with aorto-iliac disease [10]. Also, patients with extensive ulcerative colitis and colonic polyposis produce high concentrations of methane [11].

Using modern, true closed-system conditions, we have shown that methane not only accumulated in concentrations 10 times higher than reported previously [1], but that the extent of the accumulation was also highly individual. Indeed, two-thirds of our patients had high initial values that increased further with time, whereas one-third had lower values that only moderately and non-significantly increased with time. In one patient a concentration of 4130 ppm was noted, which is more than 15 times the maximum value of 229 ppm found after 72 min by Morita, Latta and Snider [1].

An interesting aspect is that, in our sample of patients, two-thirds were high methane exhalers, whereas in the apparently normal population, two-thirds had only traces of methane excretion [8]. Our patients were women, undergoing laparoscopy for gynaecological reasons. None had ulcerative colitis, aorto-iliac disease or cancer of the large bowel. Even the "low" methane exhalers had pronounced concentrations of gas under closed-system conditions. We cannot explain this but we speculate that laparoscopic pneumoperitoneum induced with carbon dioxide might be a contributing factor. Unfortunately, for technical and practical reasons, baseline measurements of pre-anaesthetic methane excretion could not be made in most of our patients. Allocation of our patients to two groups was made solely on the presence or absence of false "halothane" readings on the PhysioFlex apparatus. Retrospective analysis of the findings for methane shows that, on average, values greater than 150–175 ppm influenced the infrared measurement. However, in three patients, even lower values induced "halothane" readings, whereas in four patients, values up to 389 ppm did not consistently activate the infrared sensor. We therefore speculate that methane was not the only factor disturbing the measurement of inhalation concentration. It has been suggested previously that other hydrocarbons such as acetone might interfere with this [3]. Nevertheless, in our "high" methane exhalers, there was a positive correlation between methane concentration and the false "halothane" concentration on the screen. The highest recorded value was 3.7%, coinciding with a methane concentration of 4130 ppm.

Acetone produced in the liver during metabolism of free fatty acids is excreted partly by the lungs [12]; during fasting there is increased pulmonary excretion [12]. In our study acetone concentrations were, on average, double those found by Morita, Latta and Snider [1], and tended to increase with time, although this was not significant. It has been reported that flushing the system with fresh gas fails to decrease the acetone concentration [1]; this aspect was not analysed here.

Carbon monoxide in alveolar air may be exogenous or endogenous. Cigarette smoke and accidental inhalation of carbon monoxide are examples of the first, whereas endogenously formed carbon monoxide is a by-product of haemoglobin catabolism. Accumulation of carbon monoxide during closed-system anaesthesia was studied as long ago as 1965; values of 0–210 ppm were reported [13], and two-thirds of patients showed an increase in carbon monoxide concentration with time, whereas one-third had no increase or a decrease. In another report, it was stated that concentrations of carbon monoxide decreased in similar circumstances [14]. In this study, values of carbon monoxide of 7.5–164 ppm were found. This last, single, extremely high value influenced greatly the mean in the first group (A). There was no statistically significant difference in carbon monoxide concentrations either between the two groups (A and B) or with time. In three patients an increase and in eight a decrease was seen with closed-system anaesthesia, whereas in 15 patients there was no pronounced change.

The clinical implications of progressively increasing concentrations of methane and acetone are not clear. It has been suggested that with concomitant intake of alcohol, they could reach flammable levels [1]. However, personnel in submarines are often exposed to methane and acetone for months without adverse effects. The concentration limits of the US Navy for acetone and methane for 24 h are 2000 and 5000 ppm, respectively, and it has been argued that concerns about these trace contaminants are unfounded [15]. Although concentrations of acetone measured here were lower than those accepted as toxic, in one patient concentrations of methane were close to toxic levels. However, we never flushed the system deliberately, except before use, and therefore methane concentrations were increased by the chosen method. In normal practice it is customary to flush the system at least every 2 h [14]. Concentrations of methane should be significantly lower during everyday clinical practice with closed-system anaesthesia.

The erroneous influence on the infrared measurement set at 3.3 µm, as used in most inhalation anaesthetic monitors, is disturbing. Our results showed an impressive effect, with a linear relation between methane and the falsely recorded "halothane" concentration. Blindly following the monitored halothane concentration during closed-system or minimal-flow anaesthesia would be hazardous. The false halothane concentration incites lowering of the vaporizer output, with the inherent danger of too light anaesthesia and the possibility of awareness. In the PhysioFlex apparatus, automatic injection of liquid anaesthetic is computer-controlled in a closed loop according to the measured infrared concentrations. Some years ago the use of a feedback loop for halothane was already being questioned, as too low halothane values were recorded by mass spectrometry [16].

Techniques in which potent inhalation anaesthetics are analysed at higher infrared wavelengths (10–13 µm) are not influenced by the presence of methane. These should be preferred during closed-system anaesthesia, or alternatively other techniques, such as mass spectrometry or Raman scattering. Recently, for the PhysioFlex apparatus, an alternative, second method for measuring inhalation anaesthetics (Guardian Unit: piëzo-electrical sensor) has also been built in, the difference between measurements on the two devices providing evidence for the presence of foreign gases such as methane. In the most recent version of the PhysioFlex apparatus, the infrared readout is switched off automatically when no potent inhalation anaesthetic has been selected and used.

A new tracheal tube for difficult intubation

M. R. J. WEST, M. M. JONAS, A. P. ADAMS AND F. CARLI

Summary

We have compared a new Portex tracheal tube with the Oxford tube in performing simulated grade 3 difficult intubations. The Portex tube was modified so that the bevel faced backwards, as in the Oxford tube. A gum elastic introducer was used with both tubes. The time taken and number of attempts needed were recorded, with changes in arterial pressure, heart rate and incidence of sore throat. Both tubes were successful in avoiding the problem of obstruction at the cords, which occurs when a standard Magill tube is used with an introducer. Thus the new tube has the merits of the Oxford tube without the disadvantages of rubber. It is suitable for both easy and difficult intubations with advantages in safety, cost and convenience. An unexpected but important finding was a clear learning effect, despite both investigators being familiar with the technique at the outset. Over the course of the study, intubation time decreased progressively ($P < 0.001$). This provides new evidence of the need for trainees to practise the art of intubation when the cords are not visible. Our estimate of the learning "half-life" was 15 intubations; we conclude that 30 simulated grade 3 intubations would be a reasonable objective for trainees before handling high-risk cases. (*Br. J. Anaesth.* 1996; **76**: 673–679)

Key words

Intubation tracheal. Intubation tracheal, complications. Intubation tracheal, training. Anaesthetist, training. Equipment, tubes tracheal.

Difficult intubation remains a key problem [1] and the value of a flexible introducer (gum elastic or wire) as a first approach is well recognized in the UK and USA [2]. It is the simplest method, effective for all grade 2 laryngoscopies, where at least the arytenoids are visible and most grade 3 laryngoscopies, where the epiglottis can be seen but no part of the glottis. Macintosh initiated the method [3] and also devised the Oxford tube [4] for use with an introducer. When a Magill tube is used with an introducer, it commonly becomes impacted at the cords, but the Oxford tube avoids this problem. However, it is made of rubber which is a disadvantage. This prompted us to see if a plastic version would be as effective as the original.

The Oxford tube also has a feature intended to minimize kinking, that is a reinforced bend, the effectiveness of which was confirmed in 18000 patients [5]. Our study was designed to compare the Oxford tube with a new plastic tube, primarily in relation to these two problems, snagging at the cords and kinking [6].

Patients and methods

The study took place at two hospitals, Guy's and Northwick Park. After obtaining Ethics Committee approval and informed consent, we studied 96 patients. Intubations were carried out by one trainee at each centre (M.M.J. and M.R.J.W.), each of whom had about 2 yr experience of anaesthesia and was familiar with the handling of bougies and the technique of simulated difficult intubation.

Misleading results could occur if, for example, one group had a larger number of edentulous patients, as it would appear to perform better even if the two tubes had identical properties. To avoid this error, patients were selected in pairs, matched roughly for ease of intubation. In practice this implied excluding patients with known stigmata of difficulty. Most were easy cases, converted to difficult intubations by a standard procedure. The pairs were healthy adults, allocated randomly to have a Portex or an Oxford tube. The study could not be performed blind, so the possibility of observer bias was kept in mind; the observers endeavoured to report not what was expected, but what happened. In the measurements recorded there is minimal scope for observer bias.

THE NEW TUBE

Portex Ltd agreed to manufacture a batch of tubes to our specifications. A standard tube was modified so that the bevel faced backwards, as in the Oxford tube. In all other respects it was identical to the widely used Portex Magill cuffed orotracheal tube

(product number 100/166). The plastic has kink-resistant properties, so a reinforced bend was not considered necessary. Resistance to kinking is easily demonstrable *in vitro*, but needed confirmation *in vivo*. The introducer was a standard Eschmann gum elastic bougie (size 15 Ch (5 mm od)) and the laryngoscope was a size 3 Macintosh UK pattern (Penlon Ltd, Abingdon, Oxon, UK).

Premedication comprised lorazepam 2 mg i.m. for females and 3 mg i.m. for males. Anaesthesia was induced with thiopentone 3–4 mg kg^{-1} and maintained with 1–2 % enflurane and 70 % nitrous oxide in oxygen. Neuromuscular block was achieved with atracurium 0.5 mg kg^{-1}.

INTUBATION PROCEDURE

The key feature of a simulated difficult intubation [7] is to intubate while the vocal cords are not visible. Patients' lungs were ventilated for about 3 min with 2.5 % enflurane and 66 % nitrous oxide in oxygen. Laryngoscopy was carried out to expose the glottis, and the blade was deliberately lowered until the epiglottis obscured the cords. Size 8 (females) and size 9 (males) were used, with the introducer projecting 6–8 cm from the tube. Macintosh [4] pointed out that one of the advantages of the introducer is that it prevents the tube blocking the view at the critical moment; it must project far enough for this purpose. The introducer was directed immediately behind the epiglottis, in the mid-line, and advanced together with the tube. The introducer was then removed and the position of the tube verified clinically and by capnography. If the tube was in the oesophagus it was removed and the procedure repeated up to a maximum of three attempts.

Cricoid pressure was applied throughout to provide some indication of how the tubes would perform in emergency cases. The two-handed manoeuvre was used, the assistant placing one hand behind the neck to counteract displacement caused by his other hand. After successful intubation, a record was made of the number of attempts and intubation time, the time lapse between receiving the tube and verifying intubation. Arterial pressure was recorded before and 1 min after intubation.

TEST FOR OBSTRUCTION TO AIRFLOW

Airflow may be blocked by kinking or by the end of the tube becoming opposed to the tracheal wall. Both events cause an increase in airway pressure and both are most likely to occur on flexing the neck. After allowing 10 min for the tube to warm up towards body temperature, the neck was flexed gently to its maximum and the change in airway pressure recorded, using an aneroid manometer.

INCIDENCE OF POSTOPERATIVE SORE THROAT

After surgery, the patient was interviewed. If no complaint was volunteered a specific question was asked about sore throat.

SIGNIFICANCE TESTING

Routine *t* tests were applied to arterial pressure measurements, which were Gaussian; airway pressure was skewed, so Wilcoxon's rank sum test was used. Intubation times were also skewed (fig. 1), but after log transformation, they did not differ significantly from a normal distribution; the one-sample *t* test was used for paired data (comparing tubes) and the two-sample *t* test for unpaired data (comparing observers), both on logged data. Routine linear regression analysis was used to test if the progressive decrease in intubation time resulted from chance.

CURVE-FITTING—UNDERLYING EQUATION

The next step was to fit a more realistic model to the data. Common sense suggests that the true relation cannot be a straight line because that implies that intubation time decreases to zero. Moreover, learning is known to be a non-linear process in which the rate of improvement diminishes steadily, becoming zero when peak performance is reached. Scope for improvement is maximal at the start and zero at the end. If the rate of change is proportional to scope for change, an exponential curve results for reasons clearly explained by Nunn [8]. Learning involves several processes so the true relation is likely to be not a single exponential, but the sum of several.

However, the components of such a process cannot be disentangled realistically when the random error is large. We concluded that the most useful model would be a single exponential decline, such as occurs with radioactive decay. This is a reasonable compromise between the absurdity of a straight line and the ambiguity of a multi-exponential model. The equation of a simple exponential "die-away" curve is:

$$y = y_0 e^{-kn} + y_\infty$$

where y = dependent variable (intubation time) and n = independent variable (serial number of the intubation). There are four constants, the universal constant, e, and three others: y_∞ = "expert time", the time taken by the fully trained anaesthetist, the asymptote (i.e. if $n = \infty$ then $y = y_\infty$); y_0 = additional time required when there is no previous experience, so the "novice time" is $y_0 + y_\infty$ (i.e. if $n = 0$ then $y = y_0 + y_\infty$); k = learning constant, which measures the steepness of the curve, high values of k indicate quick learning $n - p$. (To simply descriptions of radioactivity, physicists have developed the concept of "half-life"; it may help to use the same idea here.)

The "half-life" can be thought of as the number of intubations needed to halve the distance between the novice time and the expert time. It is exactly predictable from k, using this equation:

$$\text{Half-life} = \frac{-\log_e(\frac{1}{2})}{k} = \frac{0.693}{k}$$

If the half-life is 15 then after 15, 30 and 45 intubations the amount of learning still to be done is 1/2, 1/4, 1/8, and so on. Serial numbering starts from 0, not 1, because most descriptions of exponential equations have the independent variable as time, starting at zero time. Thus allowing $n = 0$ for the first intubation leads to an equation identical to the one most commonly used and provides the useful results shown above in parentheses. y_0 can then be thought of as the extra time required when $n = 0$, that is previous experience is zero. Strictly our estimate of y_0 is that for a small n, not for $n = 0$, but that does not affect the other estimates, notably half-life.

CURVE-FITTING—LEAST SQUARES ESTIMATE

In principle the method is exactly the same as familiar linear regression. Gauss argued that the most likely values for slope and intercept are those which produce the smallest average deviation from the line, an idea which certainly appeals to common sense, if the deviations are symmetric. In practice the mathematics is simpler if we minimize not the mean deviation, but the mean squared deviation.

With non-linear processes the position is more complex because the direct route leads to an insoluble equation; that problem is surmounted by starting not from the basic equation, but from a first-order Taylor expansion of it [9]. From then on the route is essentially as mapped out by Gauss for linear regression. The same derivation works for any non-linear equation that can be differentiated. Computers reduce the labour of calculation greatly and make it easy to verify that the results are genuinely "least square". If any of the three constants is altered, up or down, and the variance recalculated, then it is always found to have increased, not a mathematical proof, but an easy and reassuring test.

CONFIDENCE LIMITS OF THE LEARNING CURVE

For linear regression the confidence limits of the slope are found by assuming that, in repeated sampling, the slopes follow a normal distribution and the same approach has been advocated for non-linear functions [10]. Computer simulations enable us to test this, as discussed elsewhere [11]. A program to simulate our study first uses the best fit values of y_0, y_∞ and k, found already, to produce a "perfect" set of y values with no scatter. Next a random number generator superimposes a scatter such that the y values acquire the same residual SD as the clinical observations. Each cycle of the program then yields results similar to the real data, on which a least squares analysis is carried out. The distribution of the variables was found to be highly skewed, particularly k; this invalidates the conventional route to the confidence limits. The modern computer displays the problem very clearly; it can also solve it. The main point of clinical importance is the lower 90% confidence limit of the half-life. To find this we must establish what half-life in the simulation produces exactly 5% of values as large as, or larger than, the best fit value for the real data. This is found by trial and error; after two "bracketing" shots the third estimate, by linear interpolation, is close to the required value, because over narrow ranges the relation is nearly linear.

Results

Patient co-operation was excellent; none declined. Both observers carried out 24 intubations with each tube, giving a total of 96 intubations for analysis (tables 1 and 2).

SUCCESS RATE

Sixty-two of the 96 intubations succeeded the first time, the others at the second or third attempts; the pre-set limit of three failures was never reached. For both tubes, entry to the larynx was smooth with no snagging at the cords. The number of cases in which intubation failed initially was not appreciably different for the two tubes (Oxford 16 of 48, Portex 18 of 48) (ns).

TESTS FOR OBSTRUCTION TO AIRFLOW

For observer 1, neck flexion caused changes in airway pressure with median 0 (range 0–6). For observer 2, the corresponding values were 0 (0–5). P was close to 1 in both.

CHANGES IN ARTERIAL PRESSURE

The mean change in arterial pressure 1 min after intubation was +14% (Oxford) and +12% (Portex) for observer 1 (ns); for observer 2 the values were +14% and +16% (ns). Other studies on routine intubation have shown that the pressor effect is maximal after 1 min and is usually approximately 27%. Thus the simulated difficult intubation drill caused no undue cardiovascular disturbance.

SORE THROAT

The incidence of sore throat was the same for both tubes (33%), which is close to the 34% reported for a similar study [12]. This compares favourably with 56% for routine intubation [13]. Our procedure did not appear to increase the likelihood of sore throat.

INTUBATION TIMES

Oxford tube vs *Portex tube* (n = *24*)

For observer 1, median intubation time was slightly longer for the Oxford tube (27.5 *vs* 21.5 s), while for observer 2 the opposite was true (20 *vs* 25 s). In neither case was the difference significant.

Observer 1 vs *observer 2* (n = *48*)

The (Oxford–Portex) differences did not differ significantly for the two observers and therefore the data were pooled. After pooling, the mean difference between the tubes was 1.3 s (ns), typical of cases

Table 1 Data of observer 1. Column 1 (C1) = serial number of intubation; C2 = intubation time (s); C3 = number of failures; C4 = change in arterial pressure 1 min after intubation; C5 = increase in airway pressure on flexing neck; C6 = postoperative sore throat

where performance was essentially the same. However, a real difference might have been obscured by the scatter. Routine power analysis shows that if there were a real difference of 11.9 s and our study was repeated many times, then P would be less than 0.05 in 80 % of cases. A more rigorous test for, say, a difference of 2 s would need a very large sample. Proving a negative is notoriously difficult when the scatter is large and may not justify the cost.

As neither tubes nor observers differed significantly, all data were pooled ($n = 96$) (fig. 1). Median and interquartile range was 25 (14–40) s.

LEARNING EFFECT

The intubation times showed two distinct populations of data, a larger group in which intubation succeeded the first time and a smaller group with one

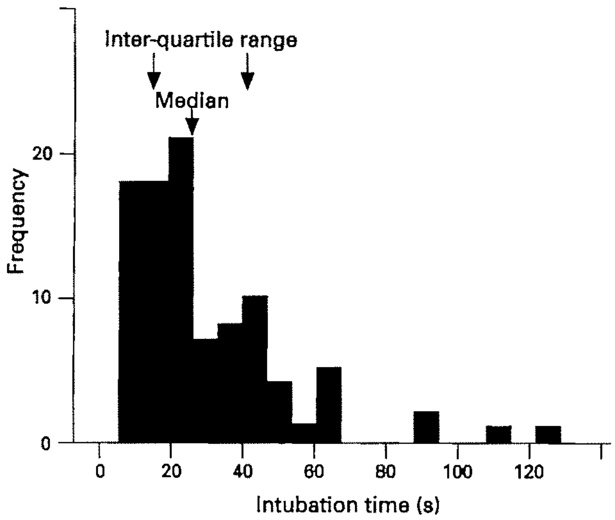

Figure 1 Histogram of intubation times for all 96 intubations carried out. Pooled data for both tubes and both observers.

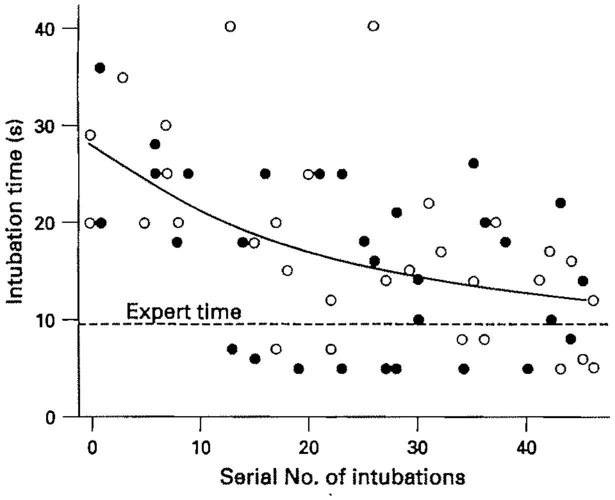

Figure 2 Intubation time *vs* serial number of the intubation for the 62 cases in which intubation was successful at the first attempt. ○ = Oxford tube, ● = Portex tube. (Note the similar performance by the two tubes and the progressive reduction in intubation time over the course of the study. The curve of best fit and its asymptote (expert time) was found by the method of least squares. It is an exponential curve with a half-life of 15 intubations.)

or two failures. Both showed evidence of a learning effect, but it was more clear-cut in the larger group, in particular, the residuals in this group were Gaussian (W' test, $P = 0.07$), as required for least squares analysis [14]. The next section deals with the larger group. Plotting intubation time against serial number of the intubation produced negative slopes for both tubes and both observers (differences between slopes were not significant) and therefore the four data sets were pooled. For the pooled data, the slope was significantly different from zero ($P = 4 \times 10^{-5}$); figure 6 in our abstract [6] shows the line of best fit and its 95% confidence limits. Next a learning curve was fitted. The least square values were : $y_0 = 18$ s, $y_\infty = 9.9$ s, $k = 0.046$, half-life = 15 s. Figure 2 shows the curve of best fit from these values.

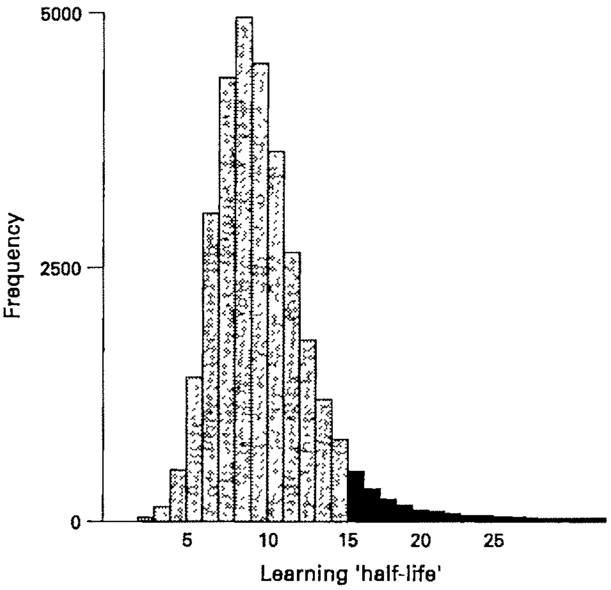

Figure 3 Lower confidence limit of the learning half-life, found by experiment. Computer simulations show what would happen if our study were repeated 30000 times. The variance of the simulated data matched that of the real data, but the half-life was adjusted not to 15, as in the real data, but to 9. The median value in the simulations was 9, but in 5% of cases a value of 15 or more was obtained (the black blocks). It follows that when the best fit value for the real data is 15, its lower 90% confidence limit is 9. This is a confidence limit by counting, as it were, not by calculation. Textbook calculation, assuming a symmetric distribution would clearly give the wrong answer.

LOWER 90% CONFIDENCE LIMIT OF THE LEARNING HALF-LIFE

The conventional lower 90% confidence limit (10.34) provided a first estimate. After entering this value in 30000 simulations, 5% of half-lives (HL) were more than 16.83, which is too high, so a lower value was entered in the next experiment

	HL entered	*Start of upper tail*	*Verdict*
Experiment 1	10.34	16.9	Too high
Experiment 2	8.66	14.6	Too low
Experiment 3	9.12	15.1	Correct

The third experiment gives the required value of 15 (fig. 3)

One advantage of creating an artificial population is that the "true" values, stripped of random variation, are known. In the experiments above, mean and mode differed widely from the true value, but the median agreed extremely well:

	True value	*Median*	*Mean*	*Mode*
Experiment 1	10.34	10.33	10.84	9.84
Experiment 2	8.66	8.67	9.14	8.21
Experiment 3	9.12	9.11	9.58	8.47

The mean is about 5% too high, the mode about 5% too low, but the median has no appreciable error. This supports the view that in a highly skewed population the best estimate of the focal point, as it were, is the not the mean, but the median. Of course for Gaussian populations, mean, mode and median coincide.

Discussion

OBSTRUCTION TO AIRFLOW CAUSED BY KINKING OF THE TUBE

Kinking, which could be a problem with the rubber Magill, occurs rarely with a standard Portex Magill, at least in adults. The modified Portex tube used in this study, even when subjected to maximum likelihood of kinking, never showed evidence of obstruction, which lends weight to the view that this problem has been overcome.

OBSTRUCTION TO AIRFLOW AT THE END OF THE TUBE

The end of the tube may become applied to the wall of the trachea, a blockage which can be relieved with a Murphy eye [15]. Making the bevel face backwards arguably increases the likelihood of this type of obstruction, particularly when there is fixed neck flexion (a notorious cause of difficult intubation). However, maximal neck flexion never caused serious impedance to airflow in our 96 cases. If in a larger sample obstruction did occur, then the simplest solution would probably be to push the tube in further. Blockage is likeliest at the point of maximal curvature of the airway, near the larynx; advancing the tube into the straight part should relieve it. This is not possible with the Oxford tube because of its fixed bend, but would be easy with our tube. If that worked, there would be no need for a Murphy eye.

OBSTRUCTION TO THE PASSAGE OF THE TUBE BETWEEN THE VOCAL CORDS

It is well known that if an introducer is used with a standard Magill tube, the end of the tube commonly becomes impacted at the cords; the Cardiff team [16] reported this in 50% of cases. To prevent this, Cossham [17] advocated rotating the tube 90° anticlockwise to make the bevel face backwards, and two surveys [12, 16] found this manoeuvre to be effective. Macintosh had a different solution, that is to alter the tube so that the bevel faced backwards. Both tubes used in this study had this feature and in all cases this was completely effective in preventing snagging at the cords. When the introducer was in place, entry of the tube was so smooth that it was hard to say at what point it traversed the cords. It is unfortunate that in his original report Macintosh did not explain why he had changed the direction of the bevel; had he done so it seems likely that this simple solution would have been adopted a long time ago. When a standard Magill tube is used with an introducer [12, 16] intubation appears to take longer than with our procedure, but firm conclusions are not possible because of differences in study design. A formal comparison would be instructive. Conclusions need to be confirmed in genuine cases of difficult intubation, but when research is hindered by the paucity of real cases, simulation provides a useful guide.

LEARNING EFFECT

The simulated difficult intubation drill is a straightforward technique that can be carried out by the novice; in some units it has been routine for many years to start teaching it as soon as the trainee is confident with simple intubations. We were surprised therefore to find a definite learning effect, even in those who are familiar with the drill. The case for the simulated difficult intubation drill, when it was originally proposed [7], suffered from the absence of precise data at that time on the incidence of difficult intubation. It is now known [18] that if care is taken with laryngoscopy, approximately 1.3% of cases are grade 3. A recent survey [19] found that anaesthetists generally perform approximately 200 intubations a year, so each will see two or three cases per year, on average. But, because of random variation (Poisson effect [20] 25% of anaesthetists will see 4–7 grade 3 cases in 200 consecutive intubations; at the opposite extreme, 26% will see only one, or none. Clearly those in the second group (the lower tail of the distribution), will have learnt little about difficult intubation in 1 year.

The learning effect that we have detected underlines these conclusions. The objection may be raised that the scatter of our results rules out exact inference. However, even if the true learning half-life were the lower 90% confidence limit of our data (fig. 3), nine intubations would be needed to become half-trained; not even the first group above (the upper tail of the distribution) will see that many grade 3 intubations in a year. The most probable inference from our data is a half-life of 15, which leads to the same conclusion, *a fortiori*.

If training is 50% complete after 15 intubations, then 30 is 75% of the way, and so on. Thirty intubations would seem a reasonable objective for a trainee before handling a high-risk case, such as a possible difficult intubation in a patient with a full stomach. Without such training the failed intubation rate in obstetrics, recently re-analysed [21], is likely to remain high.

Estimates of learning rates based on two individuals may not be typical for anaesthetists in general, but are unlikely to be seriously misleading. The principles underlying this measurement have been described in detail because it may prove useful for further studies. For example, it would be valuable to know if individual tuition increases the rate of learning, as shown for fibreoscopy [22]. With fibreoscopic intubation it is accepted that teaching must be done on patients who do not, strictly speaking, need fibrescopy. Hitherto it has not been obvious that the same applies to the handling of grade 3 cases, but from the evidence cited above any training strategy which relies on their random natural occurrence needs to be re-evaluated.

In summary, simulating the difficult intubation is a well-tried and trouble-free procedure for both training and research. The optimum design of the introducer and similar details require further study, but one factor seems clear, when choosing the right tube for use with an introducer, the new Portex tube is a strong contender. If it proves acceptable for difficult cases, it seems logical to use it for routine cases. There are advantages in safety, cost and convenience if the tube used for difficult intubations is the one we are most familiar with in everyday work.

Failed intubation revisited: 17-yr experience in a teaching maternity unit

L. HAWTHORNE, R. WILSON, G. LYONS AND M. DRESNER

Summary

We have reviewed 5802 Caesarean sections performed during general anaesthesia. Our use of general anaesthesia had decreased from 83% in 1981 to 23% in 1994. Despite this, the incidence of failed intubation has increased from 1 in 1984 to 1 in 250 in 1994. The problems associated with general anaesthesia in the obstetric population are increasing. Asians and African/Afrocaribbeans were represented disproportionately because of the increased use of general anaesthesia in these patients. Exposure of trainees to obstetric general anaesthetics has decreased by one-third. (*Br. J. Anaesth.* 1996; **76**: 680–684)

Key words
Intubation, tracheal. Anaesthesia, obstetric.

Failed tracheal intubation has been an important cause of anaesthetic-related maternal morbidity and mortality. In the North American closed claims study, difficult tracheal intubation and oesophageal intubation comprised 23% of damaging events associated with obstetric general anaesthesia [1]. In the Confidential Enquiries into Maternal Deaths in Great Britain for 1985–1987, four of six deaths directly attributable to anaesthesia were associated with failed tracheal intubation [2], but in the report for 1988–1990, only one of four deaths was a result of problems related to tracheal intubation [3]. Maternal deaths associated with anaesthesia at the beginning of the last decade comprised 13% of all direct maternal deaths, but by the end of the decade this had decreased to 2.2% [3,4]. Maternal mortality related to anaesthesia has probably reached its nadir, and it may be reasonable to suggest that efforts to reduce maternal mortality further might be more effective if directed at the management of haemorrhage. It has been suggested that the decrease in mortality is a result of the declining use of general anaesthesia [5]. In 1981 general anaesthesia was used for 83% of Caesarean sections in this unit, but by 1990 this had decreased to 33% (fig. 1); currently the incidence is 23%. Despite this, we have gained an impression that failure to intubate is no less common today than it was in 1985 when we last reviewed the performance of our unit [6]. Since 1985, we have expanded our data collection, introduced the laryngeal mask, pulse oximetry, capnography and a difficult intubation procedure (fig. 2). It seemed opportune that, at its 10th anniversary, we should revisit this topic, assess the impact of changes in clinical practice and verify our impressions.

Patients and methods

Between 1978 and 1994 we conducted a prospective audit of failure to intubate the trachea in our maternity unit. Failure to intubate was defined as intubation that was not accomplished with a single dose of suxamethonium, and therefore initiated the failed intubation drill (table 1). All women were visited after operation, the anaesthetist involved was interviewed and the information obtained was recorded. At the time of the postoperative visit, appropriate counselling was given, the significance of the incident for future anaesthesia explained and the case notes visibly annotated. The information recorded on our proforma is shown in table 2.

To support the review of these data, we sought additional information on subsequent anaesthetics by retrieval of case notes. The Birth Registers for each year were examined to provide details of the number of Caesarean sections performed, the percentage performed during general anaesthesia, whether the procedure was elective or emergency and time of operation. This was divided into three groups according to time of day and week: group 1, 08:00–17:00; groups 2, 17:00–21:00; group 3, 21:00–08:00 and the weekend. During normal working hours (group 1), theatre staff were designated to the obstetric theatre and consultant anaesthetists were available to oversee the work of trainees. In group 2 (17:00–21:00), theatre staff were available and medical staff cover was provided by the duty doctors for that day. In group 3 (21:00–08:00 and weekends), midwives provided the nursing staff cover, an operating department assistant was available from the general theatres in another section of the hospital and medical cover was again provided by the duty doctors.

Data collected were collated and presented against the background unit activity.

Results

Between 1978 and 1994, 5802 Caesarean sections were performed during general anaesthesia; there

Management procedure

A failed intubation is an intubation that cannot be accomplished with a single dose of suxamethonium

(1) Do not give another dose of suxamethonium
(2) Summon all hands
(3) Turn patient on left side, head down position
(4) Give 100% oxygen
(5) If ventilation is difficult, release cricoid pressure
(6) Summon on-call consultant
(7) Support until spontaneous breathing returns
(8) Discuss further management with consultant

were 23 (0.4%) failures to intubate the trachea. Our incidence of failed tracheal intubation had increased from 1 in 300 general anaesthetics in 1984 to 1 in 250 in 1994. Patient data are shown in table 3. Thirteen (56%) of the patients were white; there were five (22%) Asian patients and five (22%) were of African/Afrocaribbean origin.

Weight (kg)	72.5 (17.1)	[45.6–106]
Height cm	157 (7)	[146–167]

GRADE OF ANAESTHETIST

The grade of anaesthetist was a senior house officer or registrar in 18 (78%) of the 23 incidents, a senior registrar or consultant anaesthetist in three (13%), and in two cases (9%) the anaesthetist was not named. The distribution workload of obstetric general anaesthesia in our unit is summarized in table 4.

TIME OF OPERATION

Sixteen (69%) of 23 failures occurred in group 3; five cases (22%) occurred in group 1, and two (9%) in group 2. This was compared with a typical 12-month period in table 5.

URGENCY

In two instances (9%) surgery was elective, emergency surgery was performed in 20 (87%), and there was one planned emergency (4%). This latter case was performed out of hours on a woman who was booked to have an elective Caesarean section but was

Table 4 Obstetric general anaesthetics from 1987 to 1994 and grade of anaesthetist (expressed as %). Grade of anaesthetist refers to the first anaesthetist. The percentage of consultant general anaesthetics has decreased in recent years as a result of increased teaching of trainees in the performance of obstetric general anaesthetics

Emergency	21 (91%)*	384 (44%)

admitted in labour. Elective operation normally comprises 56% of the total Caesarean sections (table 5).

PREOPERATIVE ASSESSMENT

All patients had been seen by an anaesthetist before operation but difficulty in tracheal intubation was anticipated in only one-third. Of these, two patients were noted to have a short neck and four had a receding jaw, two of whom also had prominent teeth. When recorded, Mallampati score [7] was either grade II or III. In 14 patients (61%) the trachea had been intubated successfully either before or subsequent to this.

LARYNGOSCOPY

At attempted intubation the Cormack and Lehane grade was described as 3 (only epiglottis visible) in 15 patients [8]. In one patient there was severe masseteric spasm and mouth opening was impossible. This patient was referred for muscle biopsy and suspected malignant hyperthermia; unfortunately she failed to attend follow-up appointments and eventually declined further investigation. Laryngeal oedema was reported in six patients; of these two had pre-eclampsia and another two had generalized oedema but were normotensive and had no evidence of proteinuria.

MANAGEMENT

Ventilation with a bag and face mask was described as difficult in seven patients (30%) and impossible in two (9%). Eighteen patients were allowed to waken and a regional technique was used; extradural anaesthesia in 10 (43%), spinal in five (22%) and combined spinal–extradural in three (13%). In three patients a laryngeal mask was inserted; in two the lungs were difficult to ventilate with a bag and face mask. Laryngeal oedema was noted in all three patients, two of whom had pre-eclampsia. Cricoid pressure was maintained and they all resumed spontaneous respiration. In a fourth patient a laryngeal mask was inserted but oxygenation proved impossible. It was removed and ventilation with a face mask was used until the patient resumed consciousness. This patient was a large woman (105 kg) with a short neck; she was oedematous but the cords were not seen.

One patient in whom ventilation was described as impossible had an attempted minitracheostomy which failed and was managed subsequently with a face mask and airway when spontaneous respiration unexpectedly resumed. In another case the patient's trachea was subsequently intubated by the same anaesthetist after the failed intubation drill had been instigated, as a good view of the cords was obtained in the left lateral position.

OUTCOME

Despite the indications being fetal distress in seven cases, outcome was good for mother and baby in all but one patient. In the seventh, the mother's outcome was good but her twins had cerebral damage.

FOLLOW-UP

All patients were visited after operation and examined, with particular reference to head, neck and jaw movements, mandibular size and awkward or prominent teeth. Postoperative examination details were not recorded for four patients. The commonest postoperative finding on examination was the presence of a receding jaw (nine patients) followed by limited mouth opening (seven patients); five patients had both these abnormalities. Prominent or awkward teeth were present in five patients, four of these also had a receding jaw. Limited head and neck movements were found in only three patients, associated with limited mouth opening in each case. One patient had all of these findings.

INVESTIGATIONS

Postoperative investigations included indirect laryngoscopy (six patients) and radiographic examination of the cervical spine (five patients) and mandible (five patients). In recent years we have excluded indirect laryngoscopy and x-rays from our regimen.

Discussion

Failed tracheal intubation is well documented in the obstetric population, with an incidence almost eight times higher than in other groups [9]. Against a relative background of declining use of general anaesthesia, the incidence of failure to intubate has increased in our maternity unit, from 1 in 300 general anaesthetics in 1984, to 1 in 250 in 1994. The working practice in our unit mirrors that of the nation as a whole [10]; an increase in the number of Caesarean sections, an increase in the percentage performed under regional anaesthesia and no change in the total number of obstetric general anaesthetics. The national mortality has decreased to approximately 1 in 100000 Caesarean sections, but in common with most other units, we have no data to compare with this. On the other hand, our series has shown an increase in morbidity (failure to intubate). Whether or not this also reflects a national trend is

Table 6 Number of Asian and non-Asian patients undergoing Caesarean section and method of anaesthesia from 1992 to 1994. Chi-square = 73.14, significant at $P < 0.0001$ (for proportion of Asians undergoing general anaesthesia (GA)

Total	832	867	936

open to question as there are no national data available.

In the Confidential Enquiry into Maternal Deaths for 1976–1978 there was an inference that dark-skinned patients were over-represented [11]. A disproportionately large number (46 %) of patients in our series were Asian or Black, while this group comprised less than 20 % of all patients delivering in our obstetric unit. Since the introduction of pulse oximetry, cyanosis is no longer undetected. In a review of maternal deaths in Michigan, inability to establish airway patency was the main cause of anaesthesia-related death in recent years; 13 of 15 deaths occurred in black patients and the three cases of failed tracheal intubation which resulted in fatality were in this group [12]. Why should Asian and African patients represent such a large proportion in our series? This could be because of a higher incidence of Caesarean section in this group, but we have not found this to be the case. A more likely explanation is the increased use of general anaesthesia. In a recent audit (1994) of the Asian population in our unit, 39 of 89 (44 %) of those undergoing Caesarean section had a general anaesthetic compared with 179 of 847 (21 %) in non-Asians. Asian women were 2.1 (95 % confidence interval 1.8–2.4) times more likely to have a general anaesthetic for Caesarean section in our unit than non-Asians (table 6). Preference for general anaesthesia may be a result of language barriers, although 50 % of these patients were African/Afrocaribbean who tend to be English speaking. Cultural background and peer pressure may also contribute. To reduce the risk of failed intubation in Asians and African/Afrocaribbeans, we must attempt to modify our attitudes to regional anaesthesia.

Potential risk factors known to be associated with difficult tracheal intubation include short neck, obesity, missing maxillary incisors, protruding maxillary incisors, single maxillary incisor and receding mandible [13]. The most frequently occurring anatomical findings in our review were receding jaw and limited mouth opening, followed by awkward or prominent teeth. Despite these findings, it should be noted that in one-third of patients, clinical examination was normal, and nearly two-thirds had undergone intubation successfully on another occasion, therefore acting as their own controls. As bony structures are unchanged from the non-pregnant state, any contributory factor presumably resides with the soft tissues. During pregnancy there is capillary engorgement of the nasopharynx and larynx. Total body water increases and generalized oedema may occur in patients who are normotensive with normal renal function. Oedema is thought to be caused by the effect of oestrogen on the ground substance of connective tissue. Laryngeal oedema has been recorded in patients without pre-eclampsia in whom strenuous physical effort associated with labour has resulted in increased venous pressure in the head and neck [9]. We failed to demonstrate laryngeal oedema as a common contributory factor. This may be because of the fact that patients were referred for an ENT opinion when any oedema had subsided. In our review the commonest finding at laryngoscopy was Cormack and Lehane grade 3.

We have commented on the anatomical and physiological factors that can result in failure to intubate, but there are environmental factors on the labour ward that may contribute. The majority of cases of failed intubation were emergencies, occurring out of normal working hours and involved trainees (senior house officers and registrars) working with "skeleton" theatre staff. Experience of general anaesthesia for Caesarean section is diminishing, especially among trainees. The annual mean individual case load of obstetric general anaesthetics in these grades has decreased in the past decade, from 18 in 1984 to 12 in 1994. In 1984 there were 230 obstetric general anaesthetics performed; this incidence had increased to 258 in 1994. This implies that reduced exposure to general anaesthesia in obstetrics is because of an increased number of trainees rather than a decreased number of general anaesthetics. As we have reported, the commonest Cormack and Lehane grade was 3. Any procedure must teach the management of intubation when Cormack and Lehane grade 3 is found at laryngoscopy. We have aimed to do this, although we have not been able to provide simulation in routine operating lists as suggested [8]. Other factors which may be relevant in the difficult obstetric intubation include thoracic lift from a badly placed wedge and over-enthusiastic cricoid pressure. This probably explains why tracheal intubation was achieved successfully in the left lateral position, but impossible when supine, in one of the patients in our review.

In only one patient was neonatal outcome poor. This may have been secondary to antepartum factors and not associated with the delay in delivery because of failed intubation. In one of the patients in our review, oxygen saturation was recorded as low as 17 %. Despite this, both mother and neonate had a favourable outcome. This is the only documented case of severe hypoxia in our review. We believe that in the event of failure to oxygenate the lungs of the mother, further attempts at maternal resuscitation should persist. There is now evidence to suggest that neonatal outcome is more dependent on chronic hypoxia and other antepartum factors [14] rather than the acute anoxia associated with temporary inability to ventilate the lungs of the mother. Delivery of the neonate should be expedited, however, if maternal cardiac arrest is imminent, as this provides the best chance of neonatal survival and maternal resuscitation is usually impossible with a term fetus *in utero*.

Since the last review of failed tracheal intubations in our unit in 1984, enthusiasm for postoperative investigations has waned. Indirect laryngoscopy was reported as normal in all patients during the past 17 yr. Although cervical spine radiographs yielded abnormalities in two patients in the previous review [6] we now feel that anatomical factors are less important.

In the last review of failure to intubate in our unit, the laryngeal mask airway had not gained widespread use. Recently however, the laryngeal mask airway has been used when intubation has not been possible. It was interesting that all three patients in whom successful use of the laryngeal mask was used had laryngeal oedema. Two of these patients had undergone tracheal intubation on a previous occasion and all three had normal postoperative findings. This would suggest that the use of the laryngeal mask in this clinical situation may be particularly justified. The importance of maintaining cricoid pressure should be emphasized and gastric emptying with a stomach tube should be considered. Although protection against aspiration is not ensured, the laryngeal mask can help maintain oxygenation in patients whose lungs are difficult to ventilate with a bag and face mask or where life-threatening haemorrhage is imminent and surgery must be continued. The successful use of the laryngeal mask for failed intubation in Caesarean section has been reported previously by McClune, Regan and Moore [15] and Chadwick and Vohra [16]. As suggested by Benumof [17], we have introduced a difficult intubation regimen, but we have not seen a reduction in failure to intubate. We have now modified our difficult intubation regimen to include the laryngeal mask airway (fig. 2).

Haemodynamic responses to incision and sternotomy in relation to the auditory evoked potential and spontaneous EEG†

N. A. M. DE BEER, J. C. VAN HOOFF, P. J. M. CLUITMANS, H. H. M. KORSTEN AND R. J. E. GROULS

Summary

We investigated the effect of incision and sternotomy on the auditory evoked potential (AEP) and EEG, to try to predict a haemodynamic response to incision or sternotomy using the AEP and EEG in 41 patients undergoing cardiac surgery during propofol and alfentanil anaesthesia. The AEP and EEG were recorded before incision, between incision and sternotomy, and after sternotomy. Peak latencies and amplitudes of AEP peaks V, Na, Pa, Nb, Pb and Nc were determined. From the EEG the median, spectral edge and peak power frequencies, and percentages of delta, theta, alpha and beta power were calculated. Each patient was classified as responsive, equivocally responsive or unresponsive to incision or sternotomy based on increase in arterial pressure and heart rate on incision and sternotomy. Before incision, Nb and Pb latency and propofol concentration were higher for unresponsive patients but heart rate and median frequency before incision were lower. After sternotomy, Pa and Nb amplitude, peak power frequency and percentage alpha power were higher, and percentage theta power lower for responsive patients. Pa latency was higher after sternotomy for unresponsive patients. Using a combination of heart rate, arterial pressures and features derived from the AEP (all recorded before incision), the occurrence of a response to incision could be predicted in individual patients with a sensitivity of 85%, positive predictive accuracy of 63% and total accuracy of 72%. We conclude that AEP are more sensitive to pain stimuli than spectral features of the spontaneous EEG. In addition, the AEP may help in predicting inadequate anaesthesia. (*Br. J. Anaesth.* 1996; **76**: 685–693)

Key words

Monitoring, evoked potentials. Monitoring, electroencephalography. Cardiovascular system, effects. Surgery, cardiovascular.

The purpose of general anaesthesia is to provide a state of analgesia, unconsciousness, relaxation and homeostasis in the surgical patient. Because different patients may react differently to similar concentrations of anaesthetic agent, an objective measure of analgesia and unconsciousness is desired. Results from previously published studies suggest that features derived from the spontaneous electroencephalogram (EEG) [1, 2] or from auditory evoked potentials (AEP) [3–8] may be useful for monitoring the effects of anaesthesia.

Clinically, adequacy of anaesthesia may be evaluated by observing movement or an increase in arterial pressure or heart rate in response to a noxious stimulus. Attempts to use the EEG to predict such a response showed that features derived from the EEG may predict the presence or absence of movement in response to a noxious stimulus with an accuracy of 77–92% [1, 2, 9]. A study by Thornton and colleagues showed that the effects of anaesthesia on the AEP are reversed by pain stimuli [3], but the effect of surgery on the AEP was not different for patients showing a haemodynamic response compared with those in which no such response was present [10]. Also, no attempt at predicting the occurrence of a response to surgery was made, probably because of the small number of patients in that study.

In this study we have used absence of a haemodynamic response to incision and sternotomy as an indication for adequate anaesthesia. The hypotheses underlying our study are: features in the AEP and EEG are sensitive to pain stimuli, in this case incision and sternotomy; patients who respond to incision, sternotomy, or both, with a haemodynamic response show different AEP and EEG features than patients who do not respond, whereas such a difference does not exist in haemodynamic variables measured before incision or sternotomy; the presence or absence of a haemodynamic response is related to plasma concentrations of the administered anaesthetics; and the occurrence of a haemodynamic response to incision can be predicted using features or a combination of features derived from the AEP

and EEG, together with measurements of heart rate and arterial pressure obtained before incision.

Patients and methods

The study was performed at the Catharina Hospital Eindhoven, after obtaining approval from the local Medical Ethics Committee and informed patient consent. We studied 41 patients (34 male) aged 38–74 yr (mean 59 yr) undergoing cardiac surgery. Two patients were undergoing aortic valve replacement and 39 coronary artery bypass grafting. Patients were premedicated approximately 2 h before surgery with morphine 10 mg s.c. Anaesthesia was induced with a loading dose of propofol 2 mg kg^{-1} i.v. and alfentanil 100 µg kg^{-1} i.v. given over 12 min. After these 12 min, anaesthesia was maintained with propofol 8 mg kg^{-1} h^{-1} and alfentanil 4 µg kg^{-1} min^{-1} for 10 min, then propofol 6 mg kg^{-1} h^{-1} and alfentanil 3 µg kg^{-1} min^{-1} for 10 min and finally propofol 4 mg kg^{-1} h^{-1} and alfentanil 2 µg kg^{-1} min^{-1} for the remainder of the operation. Pancuronium 8 mg was used to facilitate tracheal intubation.

RECORDINGS

The raw EEG was recorded from Cz to A1 and from Cz to A2, each referenced to Fpz. Electrode impedance was maintained below 3 kΩ; typically electrode impedance was 1.5 kΩ (measured at 20 Hz). The EEG was amplified and filtered at 5–1500 Hz (−3 dB cut-off) using a Nicolet HGA-200A preamplifier and a Nicolet NIC-501A amplifier/filter. The EEG was sampled at 5 kHz with a resolution of 12 bit and stored on hard disk, using a LabMaster AD converter and an IBM-type 486 33 MHz personal computer. Auditory stimulation for the evoked potentials was performed with monaural 100-µs rarefaction clicks at 75 dB SpL, and contralateral white masking noise at 45 dB SpL. Clicks and noise were produced using a Nicolet 1007 stimulus controller and delivered to the patient through Nicolet Tip-10 earphones. Clicks were delivered with random interstimulus intervals, according to a Poisson distribution, with an average stimulation rate of 80 clicks per second. An important implication of using this distribution for random presentation of stimuli is that the effects of interfering stimuli are equally distributed over the entire sweep, independent of sweep length [11–13]. This results in a smoothing of the effect of interfering stimuli. For analysis of the AEP, we chose a sweep length of 270 ms to ensure that component Nc could be detected if present.

Auditory evoked potentials were recorded starting 10 min before the first incision until 10 min after sternotomy. After automatic detection and removal of sweeps containing artefacts [14], AEP were averaged over the period starting 10 min before the first incision to the end at incision, from incision to sternotomy and from the start of sternotomy until 10 min after the end of sternotomy. From the resulting averages the latency and amplitude of brain stem peak V and of middle latency peaks Na, Pa, Nb, Pb and Nc were determined. For this purpose, we used a combination of automatic recognition of MLAEP peaks by an artificial neural network [Van Gils and Cluitmans, Locating characteristic peaks in auditory evoked potentials using artificial neural networks, submitted] and evaluation by a human observer. The neural network assessed the location of the peaks, and the visual evaluation consisted of checking if the observer agreed with the choice of the neural network in "difficult" cases. In most cases, this meant checking if an auditory response was present at all. This is because the neural network always provides an answer, even in waveforms where no clear brain stem response is present.

Brain stem peak V was used to check if a response was present: if peak V could not be determined, the entire AEP was not used in further processing. The AEP was also not used in further processing if, because of the occurrence of artefacts, the total number of sweeps in the resulting average was less than 3000 (corresponding to a net recording time of 38 s).

The raw EEG recorded for AEP averaging was also used for spectral analysis, using the CCSA software package developed in our group [15]. Before calculation of the spectra, the EEG was digitally low-pass filtered at 32 Hz, using a 69-point moving average filter. Detection and rejection of epochs containing artefacts was done using the same algorithm as used for detecting artefacts in the AEP. Spectra were calculated from 8-s epochs, using an overlap of 2 s between epochs, and applying a Blackman time window to prevent spectral leakage. Features derived from the calculated spectra were median, 95% spectral edge and peak power frequency, and percentage delta (0–4 Hz), theta (4–8 Hz), alpha (8–14 Hz) and beta (above 14 Hz) power. The resulting spectral features for each recording were averaged over the same period as the AEP, to have one set of EEG features for each set of AEP features. If the occurrence of artefacts caused the total number of epochs included in this averaging to be lower than 6 (corresponding to a net recording time of 38 s), that set of EEG features was not used in further processing.

Because the raw EEG was high-pass filtered at 5 Hz to enhance the quality of the AEP recordings, the calculated spectral features are higher than the values reported in the literature necessary for surgical anaesthesia [16, 17], especially for median and peak power frequency. Percentage delta power is lower in our study. Although the filter removes a large part of the delta activity, we considered it valid to include percentage delta power in the analysis, because the filter is not able to remove all delta activity. This allows for trends in delta power to be observed, but possibly affects the significance of any changes in delta power, because these changes are less clear.

OCCURRENCE OF A RESPONSE TO INCISION AND STERNOTOMY

Values of systolic, diastolic and mean arterial pressures (SAP, DAP and MAP) and heart rate (HR) were obtained 1 min before and after incision, and 1 min before and after sternotomy. Changes in arterial pressure and heart rate (ΔSAP, ΔDAP, ΔMAP, ΔHR) were classified into one of four categories: ΔSAP, ΔDAP, ΔMAP were classified as + + + if the increase was larger than 20 mm Hg, + + if the increase was larger than 10 mm Hg, + for increases larger than 3 mm Hg and − if there was a change smaller than 3 mm Hg or a decrease; ΔHR was classified as + + if the increase was larger than 10 beat min^{-1}, + for an increase larger than 3 beat min^{-1} and − if there was a change smaller than 3 beat min^{-1} or a decrease in heart rate.

Based on the classifications for ΔSAP, ΔDAP, ΔMAP and ΔHR, each patient was classified as responsive (+ +), equivocal (+) or unresponsive (−) to incision or sternotomy according to the following criteria: if either ΔSAP, ΔDAP or ΔMAP was classified as + + +, the patient was classified as responsive; if ΔSAP, ΔDAP and ΔMAP were all classified as + +, the patient was also classified as responsive; if all but one of ΔSAP, ΔDAP and ΔMAP were classified as + +, the remaining pressure was classified as +, and ΔHR was classified as +, the patient was also classified as responsive; if no variable had a classification higher than +, the patient was classified as unresponsive. All other patients were classified as showing an equivocal response. This classification into response groups was done twice for all patients: once for the response to incision, and once for the response to sternotomy. A threshold of 3 mm Hg and 3 beat min^{-1} was chosen to prevent noise in arterial pressure and heart rate measurements from influencing the resulting patient classification. However, choosing a threshold of 0 mm Hg and 0 beat min^{-1} did not change this classification.

For those patients who responded unequivocally to incision, the anaesthetic record was checked to see if and how the anaesthetist had treated this response to incision, because such a treatment may have affected the response to sternotomy.

PROPOFOL AND ALFENTANIL CONCENTRATIONS

Immediately after sternotomy, an arterial blood sample was obtained. These samples were analysed by the hospital pharmacy for concentrations of propofol, using high performance liquid chromatography with fluorometric detection. Plasma concentrations of alfentanil were quantified by a validated radioimmunoassay [18] at the Pharmacokinetics Laboratory of the Janssen Research Foundation, Beerse.

STATISTICAL ANALYSIS

For all comparisons between groups of patients for response to incision or sternotomy, a Kruskal–Wallis test with a significance level of 5% was used. For those features for which the Kruskal–Wallis test indicated a statistically significant difference between groups, groups were compared pairwise. For these pairwise comparisons we used a Wilcoxon test with Bonferroni correction, with a significance level of 5%. This implies that a difference between two groups was considered to be statistically significant if the P value resulting from the Wilcoxon test was smaller than 0.05/(number of comparisons) = 0.025. The number of comparison was two, because we always compared responsive with unresponsive and equivocally responsive patients, or we compared unresponsive with responsive and equivocally responsive patients. We used non-parametric tests, because of the low numbers of observations in the different groups. For comparisons of AEP and EEG features between the three recording periods, we also used a Kruskal–Wallis test, and a Wilcoxon test with Bonferroni correction for pairwise comparisons.

Group means tested for statistically significant differences were: AEP and EEG features for each of the three recording periods, averaged over all patients; propofol and alfentanil concentrations for each of the three patient groups for response to incision and response to sternotomy; AEP and EEG features for each of the three patient groups for response to incision and response to sternotomy, for each recording period; and SAP, DAP, MAP and HR before incision and before sternotomy, for each of the three patient groups for response to incision and response to sternotomy.

PREDICTING THE RESPONSE TO INCISION

A discriminant analysis was used to examine if it is possible to predict the occurrence of a response to incision. Based on observations of arterial pressures, HR, AEP and EEG features, a discriminant function was estimated that optimally separates groups of responsive, equivocally responsive and unresponsive patients. Estimation of the optimal discriminant function was performed several times, using different sets of the available features from all patients. First, we attempted to predict the response to incision using only the available observations for SAP, DAP, MAP and HR measured before incision, because this information is conventionally available to the anaesthetist. In subsequent analyses, more variables were included for estimation of the discriminant function. These added variables were median, spectral edge and peak power frequency, and percentage delta, theta, alpha and beta power derived from the EEG in the second cycle, latencies and amplitudes of peaks V, Na, Pa, Nb, Pb and Nc from the AEP in the third cycle, and finally the variables derived from both the AEP and the EEG in the fourth cycle. In each cycle, the discriminant analysis calculated the best linear combination of features from the total available data set by stepwise selection of variables, to optimally separate the three response groups. The resulting discriminant function was tested after each cycle to see if its predictions agreed with the actual occurrence of a response. Because in this study we have only a limited account of data available, we used the leave-one-out method for cross validation. This implies that, when we have n data points, the discriminant function is calculated from $n-1$ data points and subsequently tested on the one remaining datum point. This is repeated n times so that each datum point is used exactly once for testing.

The performance of the resulting discriminant function in each cycle was assessed in terms of total

Table 1 Schematic representation of the predictions of the discriminant function. The number of cases in actual response group *i* and predicted response group *j* are denoted by X*ij*

	Predicted response		
	0	1	2
Actual response			
0	X00	X01	X02
1	X10	X11	X12
2	X20	X21	X22

accuracy, sensitivity and positive predictive accuracy. Using the schematic representation of the predictions of the discriminant function in table 1, total accuracy is defined as the actual percentage of correct predictions:

$$\text{Accuracy} = \frac{X00 + X11 + X22}{\sum_{i,j} Xij}$$

Sensitivity indicates how well the discriminant function is able to predict the occurrence of a response. The definition we used for sensitivity indicates the probability that the actual occurrence of a response or an equivocal response to incision is not underestimated by the discriminant function:

$$\text{Sensitivity} = \frac{X11 + X12 + X22}{\sum_j X1j + \sum_j X2j}$$

Positive predictive accuracy indicates what percentage of cases predicted to show a response is indeed showing a response. The following definition of positive predictive accuracy gives the probability that the prediction of a response or an unequivocal response to incision is not an overestimation of the actual response:

$$\text{Positive predictive accuracy} = \frac{X11 + X21 + X22}{\sum_i Xi1 + \sum_i Xi2}$$

Results

The first incision occurred at a mean time of 32 (SD 4) min after induction and sternotomy occurred 36 (5) min after induction. We obtained auditory evoked potentials from 39 patients. In 38 of these we also obtained a blood sample immediately after sternotomy. We could not reliably record an AEP in each period in all patients. Before incision the total number of recordings from which both AEP features and EEG spectral features could be reliably obtained was 32. Between incision and sternotomy this number was 6, and after sternotomy we obtained recordings from 32 patients.

The mean values of AEP peak latencies and amplitudes and of EEG spectral features for each of the three measurement periods are presented in figure 1. In this and other figures and tables, only contralateral results are presented. The ipsilateral results are comparable, but we preferred contralateral over ipsilateral because there were more observations available for the contralateral recordings. The amplitudes of peaks Nb and Pb were significantly increased ($P = 0.0464$ and 0.0170, respectively) during the period between incision and sternotomy. Pairwise comparisons between recording periods revealed that the group means of recordings before and after incision were significantly different. There was also a significant effect in median frequency ($P = 0.0421$), but pairwise comparisons revealed no significant differences between recording periods.

Three patients responded unequivocally to the first incision and four patients responded unequivocally to sternotomy. All three patients who responded to incision did not respond to sternotomy. One of these had been given ketensine 5 mg, approximately 1 min before sternotomy. The other two were treated with an increased dose of propofol but, according to the anaesthetic record, only several minutes after sternotomy. Of the four patients who responded to sternotomy, two had equivocally responded to the first incision, the other two had not responded. The number of responsive patients for the different conditions is summarized in table 2.

Table 3 summarizes which variables showed significantly different group means between responsive, equivocally responsive and unresponsive patients. There were no statistically significant differences in AEP and EEG features obtained between incision and sternotomy between patient groups for response to incision, and between patient groups for response to sternotomy. In the next sections the effects on AEP latencies before incision, AEP amplitudes after sternotomy and EEG features in these periods are discussed in more detail.

There were no statistically significant differences in mean SAP, DAP or MAP recorded before incision between patient groups for response to incision. HR before incision was significantly different ($P = 0.0451$) between patient groups: 59.7 (SD 9.6) beat min^{-1} for patients unresponsive to incision, 66.0 (5.0) beat min^{-1} for patients equivocally responsive to incision and 77.0 (12.8) for responsive patients. However, pairwise comparisons revealed no statistically significant differences between groups. There were no statistically significant differences in haemodynamic variables recorded before sternotomy between patient groups for the response to sternotomy.

Mean propofol and alfentanil concentrations for the different response groups are shown in table 4. These were calculated using data only from those patients for whom AEP and EEG data were available. Although concentrations of alfentanil were lower for patients responsive to sternotomy, this effect was not significant. There were also no statistically significant differences in concentrations of alfentanil between patient groups for response to incision. There was a significant overall effect in concentrations of propofol for response to incision ($P = 0.0258$). Pairwise comparisons showed that patients unresponsive to incision had significantly greater propofol concentrations than patients who responded equivocally ($P = 0.0095$). No significant

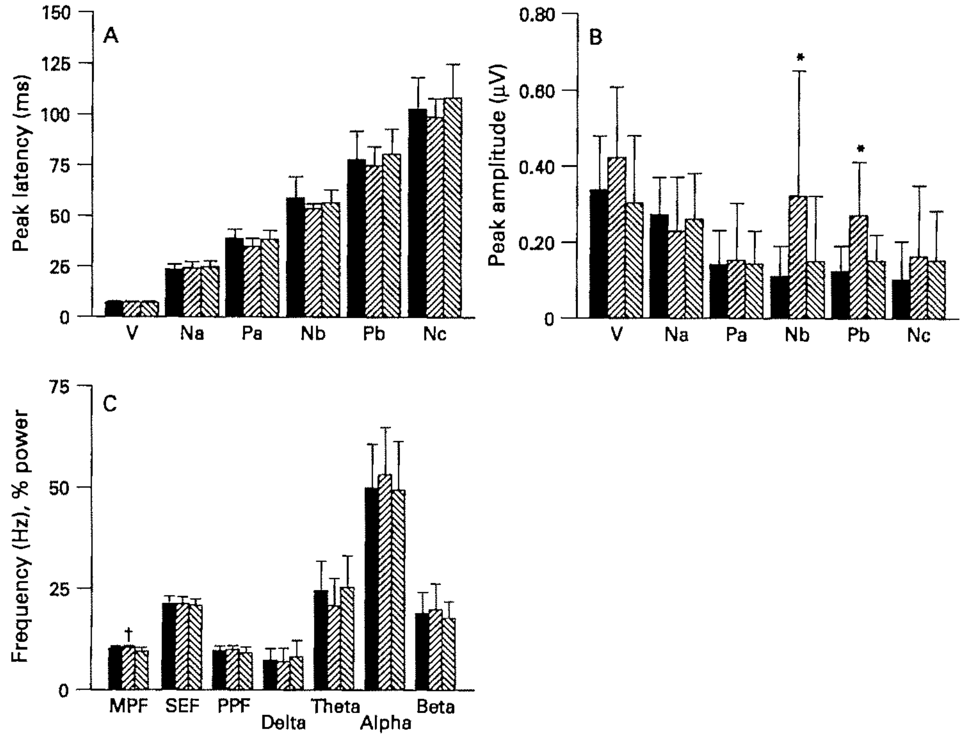

Figure 1 Mean (SD) AEP and EEG features before incision (■) ($n = 32$), between incision and sternotomy (▨) ($n = 6$) and after sternotomy (▧) ($n = 32$), averaged over all patients. Table 2 Number of patients responsive to incision and sternotomy, and number of these patients for which AEP and EEG data were available during the different recordings periods (before incision/between incision and sternotomy/after sternotomy)

Response	No. of patients	AEP and EEG data available
+ + to incision	3	3/—/3
+ to incision	12	10/3/10
− to incision	24	19/3/19
+ + to sternotomy	4	2/3/4
+ to sternotomy	9	5/1/6
− to sternotomy	26	25/2/22

Table 4 Mean (SD) propofol and alfentanil concentrations for patients responsive, equivocally responsive and unresponsive to incision and sternotomy, and number of patients in each group. *Significant difference in mean propofol concentration between unresponsive and equivocally responsive patients (Wilcoxon, $P = 0.0095$)

Response	Propofol ($\mu g\ ml^{-1}$)	Alfentanil ($ng\ ml^{-1}$)	n
− to incision	3.43 (0.95)*	551 (117)	19
+ to incision	2.50 (0.77)*	514 (158)	10
+ + to incision	3.07 (0.58)	555 (182)	3
− to sternotomy	3.03 (1.04)	537 (129)	22
+ to sternotomy	3.10 (0.94)	503 (99)	6
+ + to sternotomy	3.10 (0.85)	462 (168)	4

difference in concentrations of propofol between patients responsive and unresponsive to incision was found, but this could be because of the small number of patients ($n = 3$) in the responsive group. There was no statistically significant difference in propofol concentrations between patient groups for response to sternotomy.

Table 3 Variables that showed significantly different group means between responsive, equivocally responsive and unresponsive patient groups (Kruskal–Wallis, $P < 0.05$)

Measurement period	Classified by response to incision	Classified by response to sternotomy
Before incision	Nb latency ($P = 0.0100$) Pb latency ($P = 0.0197$) median freq. ($P = 0.0336$) heart rate ($P = 0.0451$) propofol ($P = 0.0258$)	theta power ($P = 0.0237$)
After sternotomy		Pa latency ($P = 0.0080$) Pa amplitude ($P = 0.0035$) Nb amplitude ($P = 0.0158$) Peak power freq. ($P = 0.0072$) Theta power ($P = 0.0105$) Alpha power ($P = 0.0456$)

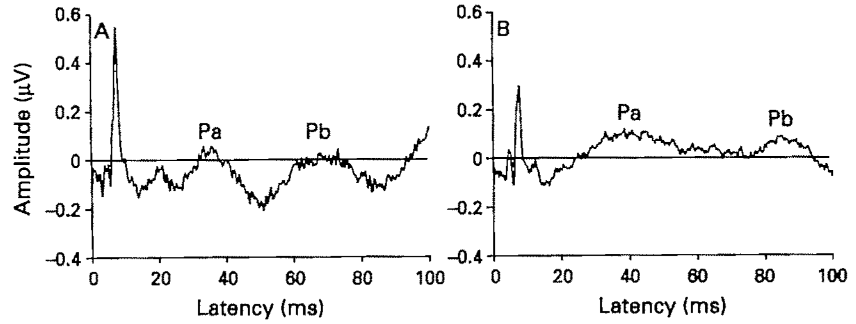

Figure 2 Typical AEP recordings before incision in a patient who was about to respond to incision (A) and in a patient unresponsive to incision (B).

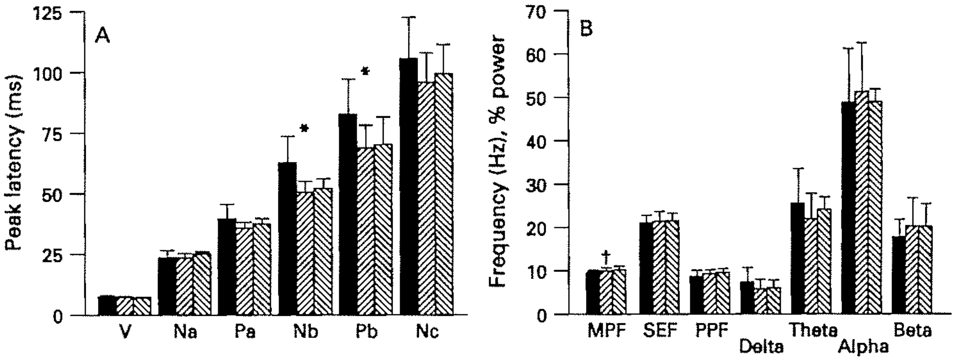

Figure 3 Mean (SD) AEP and EEG features recorded before the first incision, in unresponsive (■), equivocally responsive (▨) and responsive (▧) patients. (A) AEP latencies; (B) EEG spectral features. *Significant difference between group means of patients unresponsive and equivocally responsive to incision (Wilcoxon, $P < 0.025$); †significant overall effect in group means (Kruskal-Wallis, $P < 0.05$).

RESPONSE TO INCISION

Examples of typical AEP recordings for patients responsive and unresponsive to incision are presented in figure 2. Both AEP were recorded before the first incision, in a patient who was about to respond to incision and in a patient unresponsive to incision. In figure 3A, the AEP latencies recorded *before the first incision* are presented for patients responsive, equivocally responsive and unresponsive to the first incision. Latencies of peaks Nb and Pb were significantly longer for patients unresponsive to incision ($P = 0.0100$ and 0.0197, respectively). This effect was statistically significant for the comparison between patients unresponsive and equivocally responsive to incision. The effect was not statistically significant for comparison between patients responsive and unresponsive to incision, but this could be because of the small number of observations ($n = 3$) in the responsive group. In the EEG features recorded before incision presented in figure 3B, there was a statistically significant overall effect ($P = 0.0336$) for the response to incision in median frequency. However, pairwise comparisons revealed no statistically significant differences between any two group means.

Table 5 Performance in terms of sensitivity (Sens.), positive predictive accuracy (Pos. pr.) and total accuracy (Acc.) of different combinations of types of measured variables to predict the occurrence of a haemodynamic response to incision. Chance levels for sensitivity, positive predictive accuracy and total accuracy are 33%

Variable group	Variables selected in discriminant function	Sens. (%)	Pos. pr. (%)	Acc. (%)
Haemodynamic variables	HR, DAP, MAP	69	53	59
Haemodynamic+EEG	HR, median freq., DAP, MAP	62	53	56
Haemodynamic+AEP	Lat. Nb, HR, DAP, MAP, amp. Nc, amp. Na	85	63	72
Haemodynamic+AEP+EEG	Lat. Nb, median freq., HR, DAP, MAP, amp. Na, amp. Nc	85	61	72

RESPONSE TO STERNOTOMY

In figure 4A, the AEP amplitudes recorded *after sternotomy* are presented for patients responsive, equivocally responsive and unresponsive to sternotomy. Amplitudes of peaks Pa and Nb were significantly larger for patients unequivocally responsive to sternotomy ($P = 0.0035$ and 0.0158, respectively), both in comparison with unresponsive and equivocally responsive patients for Pa amplitude. For Nb amplitude only the difference between group means of responsive and unresponsive patients was statistically significant. In figure 4B, EEG spectral features recorded *after sternotomy* are presented for patients responsive, equivocally responsive and unresponsive to sternotomy. The peak power frequency was significantly higher for patients responsive to sternotomy ($P = 0.0072$) compared with equivocally responsive patients. The percentage theta power was significantly lower for patients responsive to sternotomy ($P = 0.0105$) compared with equivocally responsive patients. Before incision, the percentage theta power was also lower in this group ($P = 0.0237$). There was a significant overall effect in percentage alpha power ($P = 0.0456$), but in pairwise comparisons there were no significant differences between group means.

PREDICTING THE RESPONSE TO INCISION

The variables used in the discriminant function and its performance in predicting the responses of individual patients as determined by leave-one-out cross validation are summarized in table 5. Predictions of the best discriminant function using a combination of haemodynamic variables and features from the AEP are summarized in table 6. Predictions of the best discriminant function using a combination of haemodynamic variables and features from both the AEP and EEG are also summarized in table 6. All results were obtained by leave-one-out cross validation. From these results it can be seen that adding features from the EEG to the classifier improved the detection of absence of a response, but also caused overestimation of an equivocal response in one patient. However, overestimation of a response is clinically less relevant than underestimation of a response. Both discriminant functions underestimated an unequivocal response in one of three patients responsive to incision. The presence of an equivocal response was underestimated by both discriminant functions in one of 10 patients equivocally responsive to incision.

Table 6 Predictions of the best discriminant functions using a combination of haemodynamic variables and features from the AEP and a combination of haemodynamic variables and features from both the AEP and EEG. For each combination of actual and predicted response group the total number of observations is shown

Predicted response	0	1	2

Discussion

EFFECT OF PAIN ON THE AEP AND EEG

Our first aim was to determine if AEP and EEG features are sensitive to pain stimuli. It was found earlier by Thornton and colleagues [3] that amplitudes of peaks Nb and Pb increased significantly after the start of surgery. This is consistent with our observation that Nb and Pb amplitudes increased significantly after incision, which indicates that AEP amplitudes appear to be sensitive to pain stimuli. Nb and Pb amplitudes did not increase further and even decreased after sternotomy (when averaged over all patients), but this could be because of the increasing drug concentrations. The last setting in our stepped infusion scheme for propofol and alfentanil was reached on average at incision, but in some patients this last setting was reached only after sternotomy. This explanation for a decrease in Nb and Pb amplitudes after sternotomy is supported by the observed increase in AEP latencies, as indicated in figure 1.

A second observation that supports the hypothesis that AEP amplitudes are sensitive to pain stimuli is the increase in AEP amplitudes after sternotomy for the group of patients responsive to sternotomy. One would also expect an increase in AEP amplitudes after incision for patients responsive to incision, but we did not find such an increase. A possible explanation for this is the low number of observations available during the period between incision and sternotomy for responsive patients.

In the EEG features we found a significant effect only in median frequency between the three recording periods, averaged over all patients. This effect was not found in pairwise comparisons between recording periods. Although median and peak power frequency, and percentages of alpha and beta power tended to increase after incision, and percentages of delta and theta power tended to decrease after incision, these changes were not statistically significant. After sternotomy we observed a decrease in characteristic frequencies and percentages of alpha and beta power, and an increase in percentages of delta and theta power, when averaged over all patients. Similar to the effect in AEP latencies and amplitudes after sternotomy, this could have been because of increasing drug concentrations.

When the EEG features were studied for the different response groups, we found an effect on peak power frequency and percentages of theta and alpha power after sternotomy. However, we cannot be sure that this effect was caused entirely by the painful stimulus of sternotomy, because the difference between response groups in percentage theta power was already present before incision.

PREDICTION OF A RESPONSE TO INCISION

Our second aim was to examine if there were differences in AEP and EEG features between responsive and unresponsive patients, before the occurrence of a response. For AEP features this has not been studied previously. For EEG spectral features, it has been shown that these may predict movement in response to incision, and that EEG spectral features are better predictors for movement in response to incision than haemodynamic variables [2, 9]. In this study, we found Nb and Pb latency to be significantly longer for patients who did not show a haemodynamic response to incision. Moreover, there was no difference in arterial pressures between response groups. The only indication for a possible response was an increased heart rate for patients about to respond to incision, but although there was a significant difference in heart rate between patient groups, mean heart rate for responsive patients was not very high (77.0 (SD 12.8) beat min^{-1}). We found an increased median, spectral edge and peak power frequency in patients about to respond to incision, but only median frequency showed a statistically significant overall effect, and the pairwise comparisons between patient groups were not statistically significant. Thus, if we define adequate anaesthesia as absence of a haemodynamic response to incision, AEP seem more suitable to predict inadequate anaesthesia than EEG features and haemodynamic variables measured before incision.

Although we had expected to find a difference in propofol and alfentanil concentrations between responsive and unresponsive patients, we found a statistically significant difference only in propofol concentrations between patient groups for response to incision. The absence of a significant difference in propofol concentrations between unresponsive and responsive patients in the presence of a significant difference between unresponsive and equivocally responsive patients could be because of the small number of observations in the responding group. This may also explain the absence of a significant effect in alfentanil concentrations, because there was a tendency for alfentanil concentrations to be lower for patients responsive to sternotomy.

Finally, we attempted to predict the response to incision for each patient, using haemodynamic variables recorded before incision, and features from the AEP and EEG recorded before incision. We found that the best prediction of a response to incision was obtained by combining haemodynamic variables with features from the AEP. Including features from the EEG decreased slightly the positive predictive accuracy, that is the probability that a predicted response or equivocal response is not an overestimation of the actual response. The discriminant function thus obtained had a total accuracy of 72%. Although this does not seem very high, it should be noted that using only haemodynamic variables in the discriminant function resulted in a total accuracy of only 59%. Total accuracy on chance level would be 33%, because we used three possible response classes.

CHOICE OF A CLINICAL END-POINT

When monitoring the presence or absence of pain during general anaesthesia, possible clinical end-points are movement or haemodynamic responses to noxious stimulation. The latter option, which we chose to use in this study, has the advantage of providing a graded assessment of the presence or absence of pain. Another consideration is that absence of movement is probably associated with lighter levels of anaesthesia than absence of a haemodynamic response. Because during cardiac surgery relatively deep levels of anaesthesia are needed at sternotomy and sternal spread, we considered absence of movement in response to incision less appropriate than absence of a haemodynamic response to indicate adequate anaesthesia. In addition, movement in response to a noxious stimulus is not a reliable indicator of pain when neuromuscular blockers are administered.

ROUTINE MONITORING OF THE AEP AND EEG

The feasibility of routine AEP and EEG monitoring in the operating theatre is questionable at present, as indicated by our inability to reliably obtain an AEP waveform in all patients during all recording periods. This was partly because of short time between incision and sternotomy in several patients and partly because of the use of electrosurgery during the entire period after incision. Although the algorithm developed in our group for detecting and rejecting this type of artefact appeared to be adequate [14], the remaining amount of signal that was undisturbed by artefacts was not always sufficient to produce a reliable AEP waveform. Using EEG amplifiers with higher input impedances may help in alleviating this problem. Another consideration is the amount of time needed to obtain a reliable AEP waveform. When the AEP, EEG, or both, are used for dynamic monitoring of pain responses, they should be easy to obtain, rapidly. Although the EEG can be obtained more rapidly than the AEP, the EEG itself does not seem to be useful for monitoring pain responses, according to our results. The acquisition times used for obtaining an AEP waveform in this study were relatively long (up to 10 min). Because all AEP waveforms were analysed off-line, this recording time was chosen to compensate in advance for the occurrence of artefacts. The method for random presentation of stimuli used in this study may produce an acceptable AEP waveform within 40–60 s in the absence of artefacts [19]. However, if the AEP is to be used routinely, in an environment where the occurrence of artefacts is to be expected, one would need an on-line assessment of the reliability of the obtained AEP waveform.

We conclude that the AEP is more sensitive to pain stimuli than the EEG. Features from the AEP may provide additional information on the adequacy of anaesthesia, although 100% accurate prediction of the presence or absence of a haemodynamic response to incision was not possible using a combination of AEP and haemodynamic variables.

Double-blind, randomized trial of cessation of smoking after audiotape suggestion during anaesthesia

P. S. MYLES, M. HENDRATA, Y. LAYHER, N. J. WILLIAMS, J. L. HALL, J. T. MOLONEY AND J. POWELL

Summary

We studied the use of intraoperative tape suggestion to improve the rate of cessation of smoking in 363 smokers who wanted to stop smoking. They were allocated randomly to hear a taped message encouraging them to stop smoking or to a blank tape, played during general anaesthesia. Overall 56 patients (15.4%, 95% confidence interval (CI) 11.7–19.1%) had claimed to have stopped smoking at 2 months and 29 patients (8.0%, 95% CI 5.9–10.1%) were confirmed to have stopped smoking at 6 months. There was no significant difference between the groups at either 2 or 6 months (risk ratios 1.06 and 1.09, respectively, $P = 0.78$). A preoperative: postoperative ratio of a visual analogue scale measuring the patient's motivation to stop smoking was not significantly different (control group 1.13 *vs* message group 1.10, $P = 0.55$). This study does not support the hypothesis that intraoperative tape suggestion can change smoking behaviour. (*Br. J. Anaesth.* 1996; **76**: 694–698)

Key words

Anaesthesia: depth. Memory. Complications, smokers.

Smoking is a major health risk, with almost 20% of all deaths in developed countries attributed to tobacco [1]. There have been some reports of successful smoking cessation interventions during the perioperative period, which relied upon auditory "awareness" during anaesthesia [2–4]. However, these studies can be criticized because of major methodological flaws (either unblinded, or absence of confirmation of cessation of smoking at follow-up). Nevertheless, the nature of the surgery and the postoperative period may allow patients to reassess their smoking behaviour.

Awareness during anaesthesia is a major concern for many patients undergoing surgery [5–8]. Awareness commonly involves meaningful sounds or, more rarely, pain perception. It may be conscious (explicit recall) or subconscious (implicit recall), such that implicit recall may not be detected unless under hypnosis or by assessing non-verbal behaviour [5, 8–11]. Cortical auditory evoked potentials are not abolished during general anaesthesia using inhalation agents, despite adequate depth of anaesthesia for surgery [12, 13]. Thus registration of auditory stimuli may occur during routine general anaesthesia. This phenomenon has been reviewed recently [11, 14]. Despite the harmful effects of (unintentional) awareness, a beneficial (intentional) effect on postoperative recovery has been demonstrated with audiotape suggestion [15–17]. An editorial in the *Lancet* suggested that tape recordings could be used with therapeutic "commercial breaks" [18]. Nevertheless, more recent work is conflicting and whether or not intraoperative tape suggestion can effect postoperative behaviour is still in doubt [19, 20].

In this prospective, randomized, double-blind study, we have investigated if tape suggestion during general anaesthesia could be used to promote cessation of smoking in patients who present for elective surgery.

Patients and methods

Patients undergoing elective or semi-elective surgery were enrolled after Ethics Committee approval and written informed consent (which included the fact that they had an equal chance of receiving a blank or message tape). To be eligible for inclusion in the study, patients had to be current daily cigarette smokers (at least two cigarettes per day for at least 21 of the last 28 days) who were sure they wished to stop smoking at that time. Exclusion criteria were pre-existing major medical disorders (major/active malignancy, AIDS, hepatic, renal, cardiac or respiratory disease), a short life expectancy (less than 12 months), cardiac surgery or where the nature of the surgery excluded the use of headphones, hearing deficit, poor English comprehension, history of psychiatric illness, intellectual disability or alcoholism.

All patients were informed briefly about the normal process of general anaesthesia and the nature of subconscious learning or "awareness". They were informed of the accepted health risks of smoking and advised to give up smoking; no other anti-smoking measures were used.

Patients were allocated randomly from a table of random numbers. The treatment group ("message

Correspondence to P.S.M.

group") received the suggestion tape while the control group received the blank tape. Both tapes were indistinguishable and identity was established at completion of the study. The suggestion tape consisted of 3 min of reassurance, explanation and positive encouragement to give up smoking (see appendix). The transcript had been vetted by a clinical psychologist. The tapes were checked for clarity on a regular basis throughout the study and on completion.

After induction of general anaesthesia, the headphones were applied in such a way as to prevent external transmission of sound. The tape was commenced at the first surgical incision and stopped at the end of wound closure while the patient was still anaesthetized. Using a compact portable cassette recorder and headphones (Sony model No. WMFX30), the suggestion tape was played continuously, repeating the 3-min message. Previous testing of this system had excluded external transmission of sound (other than to the patient). Thus theatre personnel and the investigators were blinded to the tape content.

At the preoperative visit, patients were asked to grade their motivation to give up smoking using a 100-mm visual analogue scale (VAS). Details of their smoking history were obtained and the presence of smoking-related diseases noted (ischaemic heart disease, asthma, chronic obstructive airways disease, peptic ulcer). Details of the general anaesthetic were recorded, as was the type and duration of surgery.

After surgery, patients were asked if they had any memory of spoken words during operation and the VAS was repeated. The ratio of the postoperative: preoperative VAS was used as an index of change in motivation to stop smoking. All patients were contacted by telephone (or if uncontactable, by letter) at 2 and 6 months to ascertain their level of smoking.

DEFINITION OF ABSTINENCE

At 2 months, abstinence was defined as patient-reported no cigarette puffs for at least 28 days. At 6 months, patients reporting cessation of smoking were asked to attend hospital for confirmation of their non-smoking status; abstinence was then verified by end-expired carbon monoxide analysis (Bedfont Micro Breathalyser, Southgate, Sydney), defined as carbon monoxide concentration less than 8 ppm.

STATISTICAL ANALYSIS

A preliminary estimate of sample size was based on doubling the expected smoking cessation rate in the treatment group (from 10% to 20%) [3]. With a type I error of 0.05 and a type II error of 0.2, the required total number was calculated at 532 patients (Clinical Trials Design Program V1.0, Biosoft, Cambridge, UK). An unplanned interim analysis was performed after completed follow-up of 240 patients (363 patients enrolled) because of slow recruitment. A smoking cessation rate of 9.6% at 6 months was found. This result supported the conclusion that there was unlikely to be any therapeutic benefit from tape suggestion and the study was therefore stopped [21].

Patient data are presented as proportions, mean (SD) and range. The ratio of postoperative: preoperative VAS for the two groups was compared using the unpaired Student's *t* test (two-tailed). The number of patients who had stopped smoking was analysed using chi-square with Yates' correction. In the outcome analysis, the intention-to-treat principle was applied and patients lost to follow-up were assumed to be still smoking. $P < 0.05$ was considered significant. All statistical analyses were performed using SPSS v4.0 (SPSS Inc, Sydney, Australia).

Results

We enrolled 363 patients in the study, and they averaged 21 cigarettes per day for 19 years. Patient characteristics are shown in table 1; there were no significant differences between the groups. Fourteen patients (seven in each group) were lost to follow-up at 2 months and another 23 patients (10 control group, 13 message group) at 6 months. A total of 56 (15.4%, 95% confidence interval (CI) 11.7–19.1%) patients claimed to have stopped smoking at 2 months and 29 (8.0%, 95% CI 5.9–10.1%) were confirmed to have stopped smoking at 6 months.

Table 1 Patient characteristics in each group (mean (SD) [range] or proportion (%)). * Pack-years = number of years smoked × average number of packets smoked per day

	Control group (*n* = 178)	Message group (*n* = 185)
Age (yr)	37.1 [18–77]	38.0 [18–74]
Sex (M/F) (% male)	119/59 (67%)	119/66 (64%)
No. of cigarettes smoked per day	21.3 (11) [2–60]	20.0 (10) [2–60]
No. of years smoking	18.6 (12) [1–50]	20.1 (13) [1–57]
Pack-years*	21.4 (22) [1–200]	22.1 (19) [1–85]
Smoking-related diseases		
Chronic sinusitis	23 (13%)	16 (8.6%)
Chronic obstructive airways disease	23 (13%)	13 (7%)
Peptic ulcer disease	19 (11%)	23 (12%)
Ischaemic heart disease	4 (2.2%)	6 (3.2%)
Atopic respiratory disease		
Asthma	21 (12%)	25 (14%)
Hay fever	31 (18%)	30 (16%)
Cohabitation with smoker		
Spouse	62 (35%)	64 (35%)
Other	92 (52%)	94 (51%)
Anaesthesia		
Premedication used:	103 (59%)	117 (63%)
(benzodiazepine/opioid/other)	48/25/30	62/27/28
Induction: thiopentone/propofol/other	43/133/2	65/115/5
Maintenance: isoflurane/enflurane/other	123/52/1	121/59/5
Neuromuscular blocker used:	99 (51%)	111 (60%)
(atracurium/vecuronium/other)	59/12/28	67/20/24

Table 2 Change in motivation to stop smoking (VAS) and cessation rates. The cessation rates include those lost to follow-up who were assumed to be still smokers (see text) (mean (SD) or number (%))

	Control group ($n = 178$)	Message group ($n = 185$)	P
VAS ratio (postop:preop.)	1.13 (0.50) ($n = 164$)	1.10 (0.29) ($n = 164$)	0.55
Cessation at 2 months (self-reported)	26 (17.1 %) ($n = 145$)	30 (19.4 %) ($n = 149$)	0.78
Cessation at 6 months (CO-validated)	13 (7.9 %) ($n = 152$)	16 (9.5 %) ($n = 156$)	0.78

Two patients in each group claimed to have heard noises or voices during operation (including one patient in the message group who remembered hearing the tape message before induction of anaesthesia and not afterwards). None of the three other patients could specifically recall a message and none was distressed after operation.

There was no significant difference between the groups in their motivation to stop smoking (VAS) and smoking cessation rates at 2 and 6 months (table 2). Univariate risk ratios for 2 and 6 months were 1.06 (95 % CI 0.81–1.39) and 1.09 (95 % CI 0.77–1.54), respectively.

Discussion

In this study, the largest reported to date, we found no evidence of any benefit in using tape suggestion during anaesthesia to increase smoking cessation after operation or any evidence of effect on patients' motivation to stop smoking. Only 29 patients (8 %) had stopped smoking at 6 months. This is a disappointing result, particularly as this population represents those recovering from a surgical procedure and expected to be more likely to give up smoking. However, it is consistent with other reported rates of spontaneous cessation of smoking [22].

Interestingly, two patients from each group reported auditory awareness during their anaesthetic, although all without explicit memory of surgery or undue anxiety. Explicit recall was therefore very uncommon (1.1 %). It could be argued that because all patients were wearing ear-plugs and that there was no significant difference between the message and control groups, there may not have been specific auditory awareness and such memory may have been non-specific dreaming [11]. It should be appreciated that we did not investigate this issue comprehensively, which would require specialized follow-up, including assessment of non-verbal behaviour and possibly hypnosis [8, 11]. Previous authors have suggested that the content of the tape message is crucial and in this study the tape transcript had been vetted by an experienced clinical psychologist. The identity of the person delivering the message is also considered important, but personalizing such a message is unwieldy for widespread use and previous studies have supported the use of a single speaker.

Can intraoperative tape suggestion change behaviour? Liu, Standen and Aikenhead [19] set out to reproduce a previous study by Evans and Richardson [16] who had demonstrated improved postoperative recovery with tape suggestion. They could find no effect of positive tape suggestion during anaesthesia and concluded that the weight of evidence in favour of a change in postoperative behaviour was questionable, and that a larger study was required to definitively answer this question. Other recent studies have shown similar negative results [23–25]. Nevertheless, evidence for implicit memory formation appears to be stronger, with a clear (negative) relationship between increasing depth of anaesthesia (as measured by auditory evoked potentials) and perhaps type of anaesthetic agent, with implicit recall [13, 26]. It is therefore feasible that the anaesthetic techniques used in this study may have impeded implicit memory formation and therefore the ability to influence postoperative behaviour. But this raises a problem central to intraoperative tape suggestion: if an anaesthetic technique is tailored to enhance implicit memory formation, the risk of inadvertent awareness is probably increased. The only solution is to identify anaesthetic agents that allow implicit memory formation, yet ensure absence of recall; current evidence suggests this would be unlikely.

Successful cessation of smoking after perioperative suggestion was first reported by Aldrete in 1987 [2], after he studied 25 patients and arbitrarily allocated them to one of three groups according to motivation to stop smoking. He then used repeat verbal suggestions before, during and after operation (i.e. patients were sometimes awake). He found that seven of the highly motivated group ($n = 9$) had stopped smoking at 12 months, compared with only two of the moderately motivated group ($n = 7$) and one of the "control" group ($n = 9$). Although encouraging, this study was flawed in its design (small sample, unblinded, not randomized) and interpretation. Similar studies have been published since which support an effect of tape suggestion on smoking cessation [3, 4], but they are also flawed. In particular, cessation of smoking was defined by self-reporting and was not confirmed biochemically [27]. Interestingly, Hughes and colleagues [4] found a significant difference in cessation rates at 1 month, but none of the control group reported cessation of smoking compared with eight in the intervention group ($n = 50$). This conflicts with most smoking cessation studies, which demonstrate a background cessation rate in the control group of about 15–20 % during the early follow-up period (i.e. similar to the intervention group). This supports Millar's explanation of other conflicting studies [20].

Smoking has well-recognized health risks which are often accentuated in the perioperative period [1, 22, 28–32]. The pathophysiological changes that are detrimental to anaesthesia and surgery include increased carboxyhaemoglobin concentrations (and therefore decreased oxygen-carrying capacity), tachycardia and hypertension, increased respiratory secretions and irritability of upper airway reflexes, and decreased immunological function (neutrophil activity, immunoglobulin concentrations, natural killer cells) [28]. Adverse effects have also been documented during the recovery phases, with impaired wound healing [30], respiratory complications [33, 34] and increased length of stay in the recovery room [31]. It is clear that smoking is an important risk factor for anaesthesia and surgery. The original condition leading to hospitalization and surgery may also be associated with smoking [35]. Although the published literature concerning perioperative cessation of smoking is sparse, it appears that patients do not heed such advice given before operation [36]. The time spent in hospital, particularly during recovery after surgery, offers a unique opportunity for medical practitioners to encourage smoking cessation; anaesthetists can share in this role.

Appendix

TRANSCRIPT OF TAPE SUGGESTION

Your operation is going very well.
It is common to hear talking during your operation. There is no need to worry. The doctors are very happy. Your operation is going well.
You would like to give up smoking.
It is a very good idea that you give up smoking.
You will not miss smoking at all.
Smoking is a very dirty and unhealthy habit.
You will succeed in becoming a non-smoker because this is a decision that you have made, because this is something that you choose.
You will experience feelings of pride, and others will notice your change.
You have outgrown your need to smoke to be part of a group. You are confident and assured of your ability to be smoke-free anywhere.
You will find that when you are in a car, or with friends who smoke, you will feel good in knowing that you are a non-smoker.
When offered a cigarette, you will feel proud to say no; you will refuse to smoke.
When you give up smoking you will feel healthier.
When you give up smoking you will live longer.
You will feel proud to be a non-smoker.

Acknowledgements

We thank Dr Steve Gourlay for his constructive advice and Ms Doris Brett, clinical psychologist, for advice on the audiotape transcript. The following also assisted in the study: Drs C. Hawkins, O. Page, J. Monagle, A. Richards, P. Girdlestone, H. Madder, A. Buettner and others. Research funds were provided by the Alfred Hospital Whole Time Medical Specialist's Private Practice Fund.

Recall during intermittent propofol anaesthesia

O. NORDSTRÖM AND R. SANDIN

Summary

We discontinued temporarily an infusion of propofol for surgical reasons in 20 patients undergoing incontinence surgery. The patients, who had not received neuromuscular blockers, were allowed to regain consciousness to a level enabling them to cough on command, open their eyes, and identify and verbally confirm a randomly assigned digit shown on paper. Thereafter, 5–14 min after discontinuation of the propofol infusion, anaesthesia was reinstituted. Memory of the request to cough, a standard conversation and the digit shown was tested 1 h after anaesthesia and on the following day. Only 35% of patients were able to recall one or more of the stimuli presented during wakefulness or were even able to recall having been "awake", and there were very few differences in memory on the day after surgery compared with 1 h after anaesthesia. In comparison with corresponding stimuli given before anaesthesia, memory of material learned during wakefulness was significantly impaired ($P < 0.0001$). Thus patients temporarily capable of cognitive action during propofol anaesthesia may have no subsequent explicit recall of intraoperative events. (*Br. J. Anaesth.* 1996; **76**: 699–701)

Key words

Anaesthetics i.v., propofol. Complications, awareness. Memory. Anaesthesia, depth.

Drug-induced amnesia for events during anaesthesia is often considered beneficial as it is a common belief that post-traumatic neurosis caused by intraoperative cognition during general anaesthesia is more likely after awareness than where there is no explicit recall. However, this assumption is speculative as there are no data, not only on the incidence of significant cognitive capacity during general anaesthesia, but also on the incidence of awareness and subsequent post-traumatic disorders.

In a case report, Ruprecht described a woman who opened and closed her eyes on command during propofol anaesthesia but she had no subsequent recall [1]. Purposeful movements identified by the isolated forearm technique were found in 72% of patients given midazolam and alfentanil, despite the fact that no subsequent recall was evident [2]. Memory impairment for material learned during steady-state propofol infusion in subhypnotic doses has been described previously [3–6]. In the present study, we investigated amnesia for visual and auditory material presented during a period of wakefulness which was preceded, and also followed, by what seemed to be clinically adequate anaesthesia, thus simulating the sequence of events evident in the 14 published cases of awareness during propofol anaesthesia [7–10].

Patients and methods

The study was approved by the Ethics Committee of the University Hospital, Linköping, Sweden. After obtaining informed consent, we studied 20 female patients, ASA I–II, undergoing intra-vaginal sling operation [11]. Median age was 62 (range 49–85) yr, weight 65 (SD 3) kg and height 162 (6) cm.

Preoperative information included the fact that the patients were to be "awakened" during surgery and requested to cough, and also that after anaesthesia they would be questioned about possible memories. No other information on the nature of memory testing was given. Immediately before anaesthesia, the unpremedicated patients were addressed in a standard way and were shown a randomly assigned digit, 0–9 (128 pt Courier font, black on white background). Patients were requested to confirm verbally the digit. Anaesthesia was induced by i.v. infusion of propofol 0.5 mg kg^{-1}, followed by incremental doses of 20 mg every 20 s until loss of response to verbal command and loss of the eyelid reflex. The propofol infusion was continued at 0.17 mg kg^{-1} h^{-1} and subsequently adjusted to clinical needs. Prilocaine 2.5 mg ml^{-1} (100 ml) with adrenaline 2.5 μg ml^{-1} was infiltrated under the symphysis, and 20 ml of bupivacaine 2.5 mg ml^{-1} with adrenaline 2.5 μg ml^{-1} was used for infiltration of the skin over the symphysis. Oxygen 3 litre min^{-1} was administered via nasal cannulae.

In this type of surgery, suspension of the urethra is examined to prevent leakage during coughing but allow voluntary passing of urine. Thus it is necessary for the patient to cough on command. When the first part of surgery was completed (phase 1), the infusion of propofol was discontinued and the bladder was filled with approximately 300 ml of saline. The patient's name, followed by a request to open the eyes was repeated until this was obeyed. Thereafter, the patient was encouraged to cough. After sufficient coughing for evaluation of surgery, the patient was presented with a second randomly assigned digit,

O. NORDSTRÖM, MD, R. SANDIN, MD, PHD, Department of Anaesthesia, Länssjukhuset, S-391 85 Kalmar, Sweden. Accepted for publication: December 22, 1995.

0–9 (not the same as that shown before anaesthesia) and asked to confirm verbally the actual digit. Anaesthesia was again induced and surgery was completed (phase 2).

One hour after surgery patients were asked if they remembered anything immediately before anaesthesia. If this answer did not include the digit shown and the standard conversation, specific questions were asked ("did I show you anything?", "do you remember what I said?"). Thereafter patients were asked if they remembered anything during surgery. If this answer did not include the digit shown, coughing and the standard conversation, specific questions were asked ("did I show you anything?", "did I ask you to do anything?", and—in the event of negative answers—"do you remember having been awake during operation?"). Thereafter patients were asked about dreams during surgery. This questioning was repeated the morning after surgery (approximately 24 h). If at this time patients were unable to recall the stimulus presented, they were given the correct answers and asked if they now could remember.

Until the first memory evaluation 1 h after anaesthesia, no caffeine or drugs other than propofol and local anaesthetics were used on the day of surgery, and only mild non-opioid analgesics were required thereafter.

The incidence of memories for stimuli presented before and during anaesthesia was compared using the Wilcoxon signed rank test. Comparison of doses of propofol and duration of the different phases of anaesthesia in patients who recalled something compared with those who did not was performed by the Mann–Whitney *U* test. $P < 0.05$ was considered significant.

Results

No patient had explicit recall of intraoperative events during propofol infusion. In the period of intraoperative wakefulness, one patient (No 10; table 1) reported having had a bad dream. No other patient reported dreaming.

One hour after surgery, all 20 patients remembered the digit shown before anaesthesia and only one patient could not remember the standard conversation before induction. Seven patients remembered something from the period of wakefulness (table 1). The day after surgery, patient No. 11 had forgotten about the coughing, and the patient who 1 h after anaesthesia could not remember the standard conversation before induction now recalled this. Otherwise, memory testing on the day after surgery was identical to that 1 h after anaesthesia. The reductions in memory for the standard conversation and the digit shown during the period of wakefulness were both significant compared with corresponding types of memory before anaesthesia ($P < 0.0001$). Patients, who during the interview on the day after surgery were unable to remember any of the presented stimuli, were given the correct answers. This did not lead to recall in any patient.

Table 1 Distribution of memory in seven patients who, 1 h after anaesthesia, remembered something from the period of wakefulness

Patient No.	Conversation	Coughing	Digit
5			+
8		+	
10	+		+
11		+	
13			+
19	+	+	+
20			+

Table 2 Doses of propofol for induction, phase 1 (before temporarily discontinuing propofol infusion) and phase 2 (after temporarily discontinuing propofol infusion). Elapsed time from discontinuing the propofol infusion to coughing and verbal confirmation of the digit are shown

	Mean (SD)	Median	Range
Induction dose (mg kg^{-1})	2.3 (0.8)		
Duration phase 1 (min)	40 (17)		
Mean dose phase 1 (mg kg^{-1} min^{-1})	0.21 (0.07)		
Time to coughing (min)		3	0–10
Time to confirming digit (min)		6	2–12
Time to induction 2 (min)		8	5–14
Duration phase 2 (min)	23 (9)		
Mean dose phase 2 (mg kg^{-1} min^{-1})	0.22 (0.02)		

The duration of phase 1, duration of discontinued infusion of anaesthetic (time to induction 2), duration of phase 2, administered doses of propofol and elapsed time from discontinuing the propofol infusion to coughing and verbal confirmation of the digit shown are given in table 2. There were no significant differences between patients with explicit recall and those who could not remember any intraoperative event.

Discussion

In the present study, patients were allowed to regain consciousness and perform cognitive actions during propofol anaesthesia. However, after anaesthesia, 65% of patients were unable to remember having been "awake" and significantly better memory was found for both verbal and visual stimuli when learning occurred immediately before induction compared with that in the period when the propofol fusion was discontinued temporarily.

The true incidence of explicit recall of events experienced during general anaesthesia is not known. Limited data indicate an incidence of approximately 2 per 1000 if neuromuscular block is used in both total i.v. [10, Nordström, unpublished observations] and other types of general anaesthesia [12]. However, most anaesthetics are associated with at least some anterograde amnesia [13] and the question may arise as to whether patients may suffer from intraoperative wakefulness despite a lack of explicit recall. Indeed, as assessed by the isolated forearm technique, Russell found that midazolam and alfentanil, in addition to neuromuscular block, were associated with purposeful movements on command without any subsequent explicit recall in 72% of patients [2]. In a case report by Rupreht, a similar situation was found during i.v. anaesthesia based on propofol (opening and closing of the eyes on command without recall) [1]. Amnesia for visual and verbal stimuli presented during propofol infusion has been described previously. In some of these studies, the amnesic effect for visual stimuli was minimal unless patients were sedated profoundly [3, 5, 6], while Veselis and colleagues found a significant amnesic effect for verbal material that was statistically independent of the degree of sedation [4]. In that study, using subhypnotic doses of propofol, partial amnesia for complex visual stimuli was also evident.

However, in previous studies, amnesia has been tested for material presented during maximal drug concentration, where the period of drug infusion has been preceded, and also followed, by no drug administration. This may not be entirely similar to the situation in which most published cases of awareness during propofol anaesthesia have occurred. In these cases, the induction dose was sufficient for rendering the patient unconscious while subsequent administration of anaesthetics some time thereafter was insufficient to meet the patient's needs because of misjudgement or technical errors. Therefore, we investigated post-anaesthesia recall for visual and auditory stimuli presented to patients capable of cognitive action (coughing and opening eyes on command, verbal confirmation of a digit shown) where the period of wakefulness (in order to mimic awareness during maintenance of "anaesthesia") was preceded, and also followed, by a level of anaesthesia where no response to verbal commands or eyelid reflexes were evident. The present study is not entirely similar to clinical cases of awareness as our patients were not distressed by the experience of being aware and paralysed. However, if distress is important for promoting learning, it should be noted that the rapid filling of the bladder during wakefulness seemed to be invariably unpleasant.

Thus patients may be awake and capable of cognitive action during propofol anaesthesia despite a lack of explicit recall. The fact that 65 % of patients were unable to remember anything during surgery can be interpreted in different ways. First, it is a common belief that prevention of explicit recall in case of cognition and distress during general anaesthesia reduces significantly the risk of post-traumatic neurosis. Thus the amnesic action should be beneficial for the patient's mental outcome. On the other hand, it is unacceptable that patients may suffer during neuromuscular block anaesthesia while being incapable of conveying this.

LABORATORY INVESTIGATIONS

Volatile anaesthetics antagonize nitrous oxide and morphine-induced analgesia in the rat

T. GOTO, J. J. A. MAROTA AND G. CROSBY

Summary

We reported previously that nitrous oxide induces pre-emptive analgesia that is partially antagonized by naloxone and totally antagonized by halothane. The aims of this study were to determine if halothane and isoflurane are similar in this respect and to examine if volatile anaesthetics antagonize the analgesic effect of exogenous opioids. We found that 75% nitrous oxide prolonged tail-flick latency by 37% and this analgesia was dose-dependently inhibited by halothane and, less effectively, by isoflurane. In contrast, morphine 1.25 mg kg^{-1} i.v. also prolonged tail-flick latency by 35% but, unlike nitrous oxide-induced analgesia, this effect was attenuated only by high doses of halothane and was unaffected by isoflurane. Neither halothane nor isoflurane alone altered the tail-flick response. We conclude that both halothane and isoflurane dose-dependently antagonized nitrous oxide analgesia but antagonized morphine-induced analgesia to a lesser extent. (*Br. J. Anaesth.* 1996; **76**: 702–706)

Key words

Anaesthetics gases, nitrous oxide. Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane. Analgesics opioid, morphine. Interactions (drugs). Rat.

The analgesic actions of anaesthetic agents have been studied extensively over the past several years, but interactions between drugs have not been well characterized. We reported previously that 75% nitrous oxide produces pre-emptive analgesia in the rat formalin test which is antagonized partially by naloxone and completely abolished by 0.5 MAC of halothane [1]. Another study using a similar model demonstrated that isoflurane produced modest antinociception whereas the combination of 1% isoflurane and 70% nitrous oxide did not [2], suggesting that nitrous oxide-induced pre-emptive analgesia may also be attenuated by isoflurane.

Based on these data and evidence that nitrous oxide analgesia is mediated at least in part by the endogenous opioid system [1, 3], it follows that these volatile anaesthetics might also antagonize analgesia produced by an exogenous opioid analgesic. In this study we tested this hypothesis by examining and comparing the influence of halothane and isoflurane on antinociception produced by nitrous oxide or morphine. The tail-flick test was chosen to assess analgesia because, as a spinal reflex [4], the tail-flick response is highly resistant to the hypnotic–sedative effects of anaesthetics [5].

Materials and methods

ANIMAL PREPARATIONS

Studies were performed with the approval of the Institutional Subcommittee on Research Animal Care in 81 male Sprague–Dawley rats (Harlan Sprague Dawley, Indianapolis, IN, USA) weighing 300–325 g. Rats were maintained in a 12-h light–dark cycle (lights on at 07:00) and allowed free access to food and water. Animals assigned to receive morphine had an indwelling i.v. catheter inserted before the experiments. For this purpose, rats were anaesthetized with 1% halothane in oxygen and placed in the supine position. After local infiltration with 0.25% bupivacaine 0.2 ml, the skin was incised in the supraclavicular area, 2–3 mm lateral to the midline. The right external jugular vein was exposed and cannulated with a sterile catheter (PE-50 tubing, Clay Adams, Parsippany, NJ, USA) filled with normal saline containing heparin 100 u. ml^{-1}. The catheter was tunnelled subcutaneously and exteriorized to the interscapular area in the back. After operation rats were housed in individual cages and allowed to recover for at least 48 h before they were used for the experiments. To control for known diurnal fluctuations in responsiveness to nociceptive stimuli [6], experiments were performed between the hours of 10:00 and 22:00 in random order.

TAIL-FLICK TEST

Rats were allocated to one of 17 anaesthetic groups as follows: (1) 75% nitrous oxide ($n = 14$); (2) 0.5 MAC of halothane (0.9% inspired concentration; $n = 5$) (3) 0.5 MAC of isoflurane (1.1%; $n = 6$); (4) 100% oxygen without anaesthetic ($n = 5$); (5–7) 75% nitrous oxide with 0.1, 0.2 or 0.5 MAC of halothane ($n = 6$, 4, 5 per group, respectively);

(8–10) 75 % nitrous oxide with 0.1, 0.2 or 0.5 MAC of isoflurane ($n = 6$ per group); (11) morphine 1.25 mg kg^{-1} i.v.; (12–14) morphine 1.25 mg kg^{-1} i.v. with 0.2, 0.5 or 0.7 MAC of halothane; (15–17) morphine 1.25 mg kg^{-1} with 0.2, 0.5 or 0.7 MAC of isoflurane ($n = 5$ per group). The inspired concentrations of halothane and isoflurane were calculated on the basis of reported MAC values in the rat of 0.95–1.11 % for halothane [7–9] and 1.38–1.58 % for isoflurane [7–9], and an estimated ratio of end-tidal to inspired concentration of halothane and isoflurane of 0.5–0.6 and 0.7–0.8, respectively, in spontaneously breathing rats after 20 min [7]. The dose of morphine (1.25 mg kg^{-1} i.v.) was chosen because in preliminary experiments it provided the same degree of analgesia as 75 % nitrous oxide.

Anaesthesia was induced by placing the animals in a plexiglass box prefilled and flushed continuously with 3 litre min^{-1} of the anaesthetic in oxygen. Oxygen 100 % was given to animals that received morphine alone. The concentrations of nitrous oxide (Ohmeda 5200 CO_2 analyzer, Madison, WI, USA), halothane, isoflurane (Datex 222 anesthetic agent analyzer, Puritan Bennett, Tewksbury, MA, USA) and oxygen (Ohmeda 5100 oxygen analyzer), and the temperature inside the box were measured continuously. Animals were left undisturbed for 20 min so that they would reach a steady state of anaesthesia. They were then removed briefly from the box (< 30 s) and the tail-flick test was performed. Immediately after one measurement was made, animals were returned to the box and maintained under anaesthesia for another 3 min. Then the tail-flick test was repeated and these two measurements were averaged to yield the tail-flick latency (TFL) during anaesthesia. In addition, the control tail-flick response for each rat was determined by averaging duplicate measurements made in the pre-anaesthetic awake state.

The tail-flick test was performed by placing the tail of each rat over a slit 1.5 cm from a 150-W focused projector bulb. The end-point of the test was removal of the tail; a cut-off time of 6 s was imposed to avoid permanent tissue damage. The pre-anaesthetic TFL was typically in the range 1.5–1.8 s. Results of the test are expressed as maximum percentage effect (MPE) according to the formula:

$$\text{MPE} = \frac{(\text{TFL during anaesthesia}) - (\text{pre-anaesthetic TFL})}{(\text{cut-off time}) - (\text{pre-anaesthetic TFL})} \times 100(\%)$$

For this part of the study, each animal was used twice with at least a 5-day interval between the first and second experiments.

In order to determine the effect of the anaesthetic regimens on physiological variables such as tail skin temperature, Pa_{CO_2} and arterial pressure that can affect tail-flick latency [10–12], additional rats were prepared with femoral artery and vein catheters during approximately 15 min of 1 % halothane–75 % nitrous oxide anaesthesia. Rats were then partially immobilized with a pelvic plaster cast and allowed at least 3 h to recover from surgery and anaesthesia. Rats subsequently received one of the following anaesthetic regimens: (1) 75 % nitrous oxide ($n = 8$); (2, 3) 75 % nitrous oxide with 0.5 MAC of halothane or isoflurane ($n = 4$ per group); (4) morphine 1.25 mg kg^{-1} i.v. ($n = 8$); (5, 6) morphine with 0.5 MAC of halothane or isoflurane ($n = 4$ per group). At the end of 20 min of anaesthesia, tail temperature, mean arterial pressure (MAP) and arterial blood-gas tensions were measured. For measurement of tail temperature, a hypodermic needle temperature probe (Model HYP2; Omega, Stamford, CT, USA) was inserted 2 mm into the skin between the middle and distal thirds of the ventral aspect of the tail (i.e. the portion of the tail where thermal stimuli were applied during the tail-flick test) and temperature recorded by a microprocessor thermometer (Model HH21: Omega, Stamford, CT, USA). For this part of the study, each animal was used only once.

DATA ANALYSIS

To evaluate the effects of volatile anaesthetics on nitrous oxide or morphine analgesia, a regression line of the log doses of a volatile anaesthetic *vs* tail-flick latency MPE values was first constructed by the least square method for each combination of anaesthetics. The IC_{50} (the inspired concentration of a volatile anaesthetic which produces 50 % attenuation of nitrous oxide or morphine-induced analgesia) and 95 % confidence intervals were then calculated. Analysis of variance (ANOVA) was used to compare the effect of halothane, isoflurane or 100 % oxygen alone on TFL. ANOVA and Dunnett's test were used to compare physiological data from animals that received volatile anaesthetics with nitrous oxide or morphine with data from those that received nitrous oxide or morphine alone. $P < 0.05$ was considered significant.

Results

Nitrous oxide 75 % increased tail-flick latency (mean MPE 37 (SEM 5) %) but 0.5 MAC of halothane or isoflurane did not alter the response (MPE −4.1 (2) % and −1.5 (1) %, respectively; $F = 0.89$, df = 2 and 13, $P > 0.20$). Both volatile anaesthetics dose-dependently antagonized nitrous oxide analgesia (fig. 1A) and halothane was more potent than isoflurane in this regard. Halothane doses as low as 0.1 and 0.2 MAC produced 76 % and 107 % antagonism of nitrous oxide analgesia, respectively; as the antagonism produced by the lowest concentration was greater than 50 %, we could only estimate an IC_{50} of < 0.1 MAC (confidence level 95 %). Isoflurane 0.5 MAC also induced almost complete (85 %) antagonism, but lower doses were less effective (IC_{50} = 0.23 MAC; 95 % confidence interval 0.18–0.30 MAC).

By design, morphine 1.25 mg kg^{-1} alone prolonged tail-flick latency to the same extent as 75 % nitrous oxide (MPE 35 (9) %). Halothane dose-dependently antagonized this morphine analgesia, with 0.7 MAC producing 80 % antagonism (IC_{50} = 0.43 MAC; 95 % confidence interval 0.36–0.51 MAC) (fig. 1B).

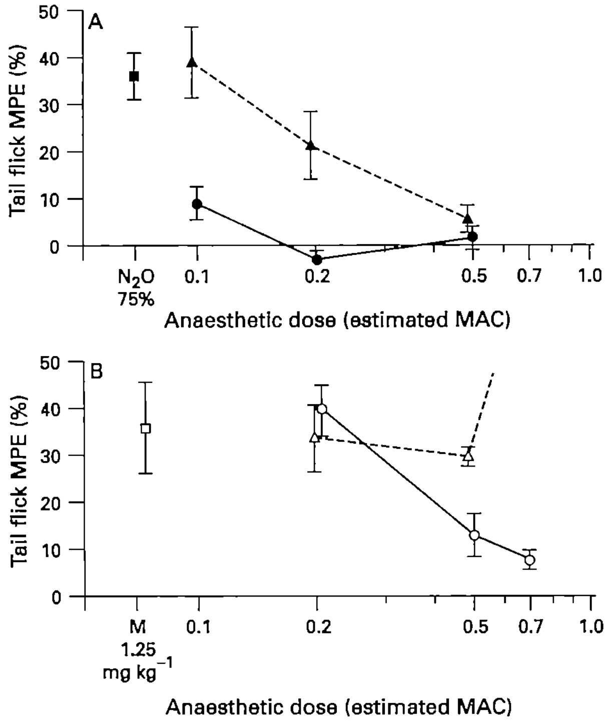

Figure 1 Effect of volatile anaesthetics on nitrous oxide (N_2O) or morphine-induced analgesia. Tail-flick testing was performed twice each before and 20 min after the start of anaesthesia, and the measured latencies were converted to maximum percentage effect (MPE) according to the formula described in the text. (A) N_2O–halothane (●) and N_2O–isoflurane (▲) interactions. (B) Morphine–halothane (○) and morphine–isoflurane (△) interactions. Anaesthetic dose is the dose of volatile anaesthetic added to N_2O or morphine, respectively. The combination of morphine and 0.7 MAC of isoflurane prolonged the tail-flick latency above the cut-off time (i.e. MPE > 100%) in all animals. Data are mean, SEM for 4–14 animals per group (see text).

In contrast, isoflurane did not attenuate morphine analgesia at either 0.2 or 0.5 MAC and, at 0.7 MAC, prolonged tail-flick latency beyond the cut-off time (MPE > 100%; fig. 1B). However, 0.7 MAC of isoflurane combined with morphine also produced some degree of motor dysfunction (i.e. mild flaccidity with some impairment of weight-bearing), suggesting that the prolonged tail-flick response may not be caused entirely by the antinociceptive effects of these agents.

Halothane did not alter tail temperature, whereas isoflurane in combination with nitrous oxide reduced it slightly ($P < 0.05$; table 1). MAP was lower in rats that received a volatile anaesthetic but remained within the physiological range. Morphine-treated rats became hypercapnic and halothane, but not isoflurane, increased Pa_{CO_2} slightly in both nitrous oxide and morphine-treated animals (table 1).

Discussion

We have demonstrated that sub-MAC concentrations of volatile anaesthetics dose-dependently antagonized the analgesic action of nitrous oxide, and that halothane was more potent than isoflurane. In addition, halothane antagonized morphine-induced analgesia in a dose-dependent manner, whereas isoflurane has no effect. As higher doses of halothane were required to antagonize morphine compared with nitrous oxide analgesia, and isoflurane antagonized the effect of nitrous oxide but not morphine, we conclude that nitrous oxide was more sensitive than morphine to analgesic antagonism by volatile anaesthetics.

In previous work using the formalin test to assess nociception [1], we demonstrated that nitrous oxide analgesia can be antagonized by halothane, and these results have been reproduced recently by others [13]. Antagonism between nitrous oxide and volatile anaesthetics has also been reported for MAC in the rat [8, 14] and suppression of learning in humans [15], although interpretation of the MAC studies is a subject of much debate [16–18]. Similarly, a marked morphine–halothane antagonism has been reported for the escape reaction threshold to tail pressure [19] and the cardiac acceleration response to tail clamp [20] in the rat, but the agents were additive in suppressing noxious stimulation-induced purposeful movements [20]. Thus the nature of these drug interactions may vary with the end-point.

It appears unlikely that alterations in physiological variables account for the observed antagonism between the volatile anaesthetics and nitrous oxide or morphine. The isoflurane-induced decrease in tail skin temperature cannot account for attenuation of nitrous oxide analgesia as tail hypothermia has the opposite effect (i.e. prolongs tail-flick latency) [10]. However, the fact that isoflurane, but not halothane, reduced tail skin temperature may be at least partially responsible for the weaker antagonism of nitrous oxide or morphine analgesia produced by isoflurane than halothane. Similarly, moderate hypercapnia (Pa_{CO_2} 8.0–13.3 kPa) prolongs tail-flick latency [11], and therefore slight increases in Pa_{CO_2} produced by the addition of halothane would be expected to intensify, rather than antagonize, nitrous oxide and morphine analgesia. With respect to arterial pres-

Table 1 Physiological data (mean (SEM)) for eight (nitrous oxide (N_2O) or morphine alone groups) or four (combination groups) animals. Data of animals that received the combination of volatile anaesthetic and N_2O or morphine were compared with those that received N_2O or morphine, alone respectively, by ANOVA and Dunnett's test. *$P < 0.05$, **$P < 0.01$

Anaesthesia	MAP (mm Hg)	Tail temp (°C)	pH	Pa_{CO_2} (kPa)	Pa_{O_2} (kPa)
N_2O	138 (1)	28.5 (0.5)	7.42 (0.01)	5.3 (0.1)	16.8 (0.4)
N_2O + halothane	123 (4)**	28.1 (0.6)	7.38 (0.01)*	5.8 (0.1)**	16.7 (0.9)
N_2O + isoflurane	111 (2)**	25.8 (0.2)**	7.43 (0.02)	4.9 (0.4)	17.2 (0.7)
Morphine	136 (2)	26.3 (0.4)	7.36 (0.01)	6.3 (0.1)	60.3 (1.2)

Morphine + isoflurane	110 (2)**	25.7 (0.2)	7.38 (0.01)	6.2 (0.2)	61.9 (1.2)

sure, hypertension is known to produce antinociception [12], but we know of no data on the effect of hypotension. If a mild decrease in arterial pressure were the mechanism underlying antagonism of nitrous oxide and morphine analgesia by volatile anaesthetics, isoflurane should produce greater antagonism than halothane because arterial pressure was lower with isoflurane. This again contradicts our results.

Although neither halothane nor isoflurane alone altered tail-flick latency, these anaesthetics could have intrinsic hyperalgesic properties. In fact, halothane has been reported to slightly decrease the pain threshold to pressure in humans [21]. In our study, the short baseline tail-flick latency caused by intense heat stimuli might have obscured such effects. However, studies with tail-flick testing with a longer baseline latency (5–6 s) have shown that sub-MAC concentrations of halothane and isoflurane modestly prolong tail-flick latency in rodents [22, 23]. In addition, the volatile agents inhibit noxious heat-evoked firing of spinal wide dynamic range nociceptive neurones *in vivo* [24] and suppress electrical stimulation-induced nociceptive transmission in the spinal cord *in vitro* [25]. Hence, it is unlikely that the hyperalgesic properties of the volatile anaesthetics explain the observed antagonism between volatile agents and nitrous oxide or morphine. It is also not likely that volatile anaesthetics possess opioid antagonist properties as, although both morphine and nitrous oxide activate opioid receptors either directly or indirectly [1, 3], halothane does not displace specific binding of radiolabelled ligands to either μ or κ receptor subtypes *in vitro* [26, 27]. We have postulated previously, however, that volatile anaesthetics may antagonize analgesia by a metabolic mechanism [1]. Nitrous oxide and morphine analgesia require active neural processes, including activation of a descending inhibitory pathway [28, 29]. Thus by decreasing the cerebral or spinal metabolic rate, halothane or isoflurane could prevent such neural activation. Although unproved, this hypothesis could explain why nitrous oxide is more susceptible than morphine to antagonism by volatile anaesthetics; spinal transection studies suggest that a descending inhibitory pathway plays a more important role in mediating nitrous oxide than morphine analgesia [28, 29].

Although tail-flick testing is a widely accepted measure of analgesia in animals, extrapolation of these results to the clinical setting requires caution. First, as the MAC of nitrous oxide in rats is 148–235 % [18, 30, 31], we have used only 0.3–0.5 MAC of nitrous oxide, which is lower than that usually administered clinically. It is natural to speculate that the analgesic effect of higher doses of nitrous oxide or morphine may be more resistant to antagonism by volatile anaesthetics. In fact, profound analgesia produced by morphine 10 mg kg^{-1} i.v. (the tail-flick MPE $> 100\%$) was not affected by up to 1 MAC of halothane [unpublished observation]. Second, the tail-flick response is a spinal reflex [4] and such measures are not used clinically to evaluate the adequacy of anaesthesia, analgesia, or both. Third, as discussed previously, the nature of the interaction among anaesthetics appears to vary for different end-points [1, 8, 14, 19, 20]; integrated, complex pain processes may be affected differently than a spinal reflex. Nevertheless, our experiments demonstrate that a simple relationship between anaesthesia and analgesia cannot be assumed because addition of a volatile anaesthetic to nitrous oxide or morphine, while deepening anaesthesia, resulted in less profound analgesia. Thus anaesthesia and analgesia are different end-points and should be considered separately.

Effect of low-dose dopamine on intestinal villus microcirculation during normotensive endotoxaemia in rats

H. SCHMIDT, A. SECCHI, R. WELLMANN, H. BÖHRER, A. BACH AND E. MARTIN

Summary

Hypoperfusion of the gut mucosa is thought to be a factor in the development of gut barrier failure during sepsis and septic shock. Dopamine stimulates DA-1 receptors which mediate regional vasodilatation in the gut. Therefore, we have investigated the effect of low-dose dopamine (3 μg kg^{-1} min^{-1}) on the intestinal villus microcirculation during endotoxaemia in a rat model of normotensive endotoxaemia, using *in vivo* videomicroscopy. Blood flow in and the diameters of central villus arterioles were measured before, immediately after and 60 min after a 1-h continuous infusion of endotoxin 1.5 mg/kg body weight. After baseline measurements were obtained, rats received either an infusion of 0.9% saline (group A; $n = 7$) or a volume-equivalent infusion of dopamine 3 μg kg^{-1} min^{-1} (group B; $n = 7$) throughout the study. Control animals (group C; $n = 7$) received no endotoxin or dopamine. In group A, villus blood flow (mean baseline 8.4 (SEM 0.9) nl min^{-1}) decreased by 29.7 (8.9)% to 5.9 (0.9) nl min^{-1} immediately after endotoxin challenge and by a total of 43.1 (7.3)% to 4.7 (0.7) nl min^{-1} after another 60 min. Simultaneously, villus arteriolar diameters decreased from 7.8 (0.2) to 6.9 (0.3) μm and to 6.5 (0.3) μm, respectively. In group B, villus blood flow (baseline 8.7 (0.4) nl min^{-1}) was unchanged immediately after the 1-h infusion of endotoxin (8.3 (0.4) nl min^{-1}). However, another 60 min later blood flow decreased by 28.8 (8.0)% to 6.1 (0.7) nl min^{-1}. In contrast with group A, the diameters of the central villus arterioles were unchanged despite administration of endotoxin (7.9 (0.2) μm; 8.1 (0.4) μm; 8.2 (0.5) μm). In group C, there were no changes in villus blood flow or arteriolar diameters throughout the study. Our results indicated that low-dose dopamine did not prevent, but delayed and attenuated, the decrease in intestinal villus blood during normotensive endotoxaemia. (*Br. J. Anaesth.* 1996; **76**: 707–712)

The gut mucosa functions as an important barrier preventing translocation of intraluminal bacteria and toxins into the systemic circulation [1]. However, there is an increase in intestinal permeability and translocation during sepsis and endotoxaemia [2–4]. Thus gut-derived endotoxaemia and bacteraemia might be responsible for a self-maintaining process of sepsis and septic shock, and the development of multiple organ failure [5, 6]. Among other pathophysiological mechanisms, hypoperfusion of the gut mucosa has been implicated as an important mechanism contributing to endotoxin-induced mucosal injury [7, 8]. Xu and colleagues [8] described a selective reduction in intestinal blood flow to the distal ileum and caecum by 35–50 % in a rat model of hyperdynamic endotoxaemia which was associated with an increase in small bowel permeability to ^{51}Cr-EDTA.

The development of intestinal hyperpermeability after endotoxin challenge is prevented by maintenance of gut perfusion [9]. In critically ill patients, low-dose dopamine is used for improvement in splanchnic blood flow, particularly to optimize renal perfusion [10]. In patients undergoing gastrectomy, administration of low-dose dopamine (3 μg kg^{-1} min^{-1}) improves portal venous oxygenation suggesting an increase in splanchnic blood flow [11]. In contrast, low-dose dopamine has been demonstrated to exacerbate gut ischaemia during experimental haemorrhagic shock [12]. There are no *in vivo* data during sepsis and septic shock on the influence of low-dose dopamine on the intestinal microcirculation. Therefore, we have investigated the effects of low-dose dopamine on blood flow and arteriolar diameters in intestinal villi in a model of normotensive endotoxaemia in rats.

Materials and methods

ANIMAL PREPARATION

The study protocol was approved by the Governmental Animal Protection Committee. We used male Wistar rats (250–300 g body weight) that were fasted overnight, but received water *ad libitum*. Anaesthesia was induced with sodium pentobarbitone 60 mg/kg body weight i.p. which was supplemented with i.m. injection of 30 mg/kg body weight, 30 min before the start of *in vivo* microscopy. Polyethylene

Correspondence to H.S.

catheters (od 0.8 mm, id 0.5 mm) were inserted into the jugular vein for administration of endotoxin and infusion of dopamine or 0.9% saline, and into the carotid artery for blood sampling and measurement of systemic arterial pressure. Heart rate was derived from the pressure signal. A tracheotomy was performed for airway control. Animals breathed room air. Rectal temperature was maintained at 37 °C using a heating lamp.

Intravital microscopy of the intestinal villus microcirculation was performed according to the method described by Gore and Bohlen [13, 14]. A small segment (2 cm) of the terminal ileum was exteriorized through an abdominal midline incision, opened along its antimesenteric border using electrocautery and placed on a transparent viewing pedestal with the mucosa being upward. After fixation to a frame by four sutures (Ethilon II, 0.7 metric; Ethicon, Germany) the opened bowel segment was placed in a temperature-controlled chamber containing a solution of bicarbonate-buffered Ringer's solution (37.0 °C). The animal was then transferred to the stage of the microscope. The opened mucosal surface was superfused with thermostatically controlled bicarbonate-buffered Ringer's solution that slowly rinsed from the top of the objective of the microscope onto the mucosa. This solution was equilibrated with 5% carbon dioxide in nitrogen to adjust the pH to 7.35, $P\text{O}_2$ to 3.7–4.0 kPa and $P\text{CO}_2$ to 4.8–5.6 kPa. In each rat, 0.5 ml/kg body weight of fluorescent labelled erythrocytes (packed cell volume (PCV) 50%) from donor rats was injected i.v., 30 min before microscopy.

INTRAVITAL MICROSCOPY

The villus microcirculation was observed using transillumination and epifluorescence illumination. Five successive fields of the mucosa were viewed and videotaped for 40 s each. The villus central arterioles were identified according to a descriptive classification [13] and assessment of flow direction in the vessels. The equipment for intravital microscopy consisted of a specially designed intravital microscope (Leitz, Germany) equipped with a ×25 water immersion objective (PL Fluotar 25/0.75 W; Leitz, Germany). Epifluorescence illumination was performed using an epifluorescence illuminator (Leitz; Germany) equipped with an XBO 100 W/2 short arc mercury lamp (Osram, Germany) and an excitation filter (450–490 nm). Transillumination was achieved using a 100 W cold light fountain (KL1500 electronic; Schott, Germany). The microscopic images were transferred to a monitor (PVM/444QM; Sony, Japan) by a low-light camera (CF 8/1; Kappa, Germany) and videotaped for subsequent off-line analysis.

FLUORESCENT LABELLING OF ERYTHROCYTES

Erythrocytes from separate donor animals were labelled with fluorescein isothiocyanate (FITC, Isomer I, No. F-7250; Sigma Chemicals, Germany) using a modified procedure according to Butcher and Weissman [15] and Sarelius and Duling [16]. Erythrocytes were washed three times in a glucose–saline buffer (pH 8.2), resuspended in a bicine–saline buffer (pH 6.8) containing FITC 9 mg ml^{-1} and incubated at 25 °C for 3 h. Labelled cells were then separated from the solution, washed several times until the supernatant was free from fluorescent dye, resuspended in 0.9% NaCl containing 14% citrate–phosphate–glucose (No. C-7165; Sigma Chemicals, Germany) and stored at 1–4 °C in the dark. Using this method, there was no reduction in fluorescence for 7 days. Normal rheological behaviour of FITC-labelled erythrocytes *in vivo* in the rat has been demonstrated by Sarelius and Duling [16]. The *in vivo* stability of FITC-labelled erythrocytes during a 12-h period in rats has been confirmed by Mithöfer and colleagues [17].

DETERMINATION OF INTESTINAL VILLUS BLOOD FLOW AND VILLUS ARTERIOLAR DIAMETERS

Villus blood flow was measured using a combined approach of the methods described by Chun and colleagues [18] for determination of villus red cell flux, and Mithöfer and colleagues [17] for calculation of volumetric blood flow using FITC-labelled erythrocytes. In order to calculate volumetric blood flow in the central villus arteriole, the flux of labelled erythrocytes circulating through the central arteriole near the tip of the villus was determined by videotape replay on a monitor screen during a 30-s period by an observer who was unaware of the identify of the experimental group. The flux of labelled cells (J_{FITC}) per five fields per observation period was averaged in order to rule out time-dependent changes in arteriolar blood flow. Furthermore, at each observation time, arterial blood samples were obtained and the concentration of labelled erythrocytes per unit volume of arterial blood (N_{FITC}) was determined using a Neubauer chamber (Hecht, Germany). Volumetric blood flow in the villus arteriole was calculated from the ratio $J_{\text{FITC}}/N_{\text{FITC}}$. However, because systemic PCV differs from PCV in microcirculatory vessels because of the Fahraeus effect [19], the calculated volumetric blood flow has to be corrected by a factor of 0.76[20]. Therefore, volumetric blood flow (V) in the villus arterioles was calculated as $V = (J_{\text{FITC}}/N_{\text{FITC}})/0.76$ (nl min^{-1}). The diameters of the central villus arterioles were measured using a computerized microcirculation analysis system (Cap image; Zeintl, Germany).

MONITORING

Mean arterial pressure and heart rate were recorded simultaneously with measurement of the intestinal villus microcirculation. In addition, arterial blood samples were obtained to measure PCV (Hematology Analyzer System CP 9000-3; Serono-Baker-Diagnostics Inc., USA) and to perform blood-gas analysis (ABL3; Radiometer, Denmark).

PROCEDURE

The rats were allocated randomly to one of three groups, each group containing seven animals: group A, endotoxin infusion alone (1.5 mg kg^{-1} h^{-1};

Escherichia coli 026:B6; Sigma Chemicals, Germany) from $t = 0$ min to $t = 60$ min; group B, dopamine-treated rats. Endotoxin infusion as in group A, and dopamine infusion (3 μg kg^{-1} min^{-1}) from $t = 0$ min to $t = 120$ min. Dopamine (dopamine hydrochloride; Giulini Pharma, Hannover, Germany) was diluted in 0.9 % saline; group C, control rats. The control rats were given only 0.9 % saline from $t = 0$ min to $t = 120$ min.

During the study all rats received the same amount of fluid, with an infusion rate of 15 ml kg^{-1} h^{-1}. After placing the animals beneath the microscope and injection of fluorescent-labelled erythrocytes, a stabilization period of 30 min was allowed. Videomicroscopy for measurement of villus blood flow, blood sampling for evaluation of PCV and blood-gas analysis, and measurement of haemodynamic variables were performed at $t = 0$ min, $t = 60$ min and $t = 120$ min. Infusion of endotoxin (groups A and B) and dopamine was started after measurement of baseline values ($t = 0$ min).

STATISTICAL ANALYSIS

Data are presented as mean (SEM) unless otherwise indicated. For statistical analysis, the values of five villi were averaged for each animal, and the means were used for further calculations. Differences within and between groups were analysed using two-way ANOVA followed by the Scheffé test. $P < 0.05$ was considered significant.

Results

The age and weight of the animals did not differ between groups. Signs of infection or sepsis were not observed in any of the animals before the experimental procedure.

SYSTEMIC VARIABLES

At the start of the experiment, cardiorespiratory variables did not differ between groups. Mean arterial pressure remained unchanged throughout the observation period in all groups. However, heart rate increased in both groups challenged with endotoxin (groups A and B). Dopamine had no effect on mean arterial pressure or heart rate in group B compared with group A. There were no changes in Po_2 or pH throughout the study in any group. In all groups, there was a reduction in Pco_2 during the study but this was not significant. PCV values showed no difference between the groups at the start of the experiment and were unaffected in all groups throughout the study (table 1).

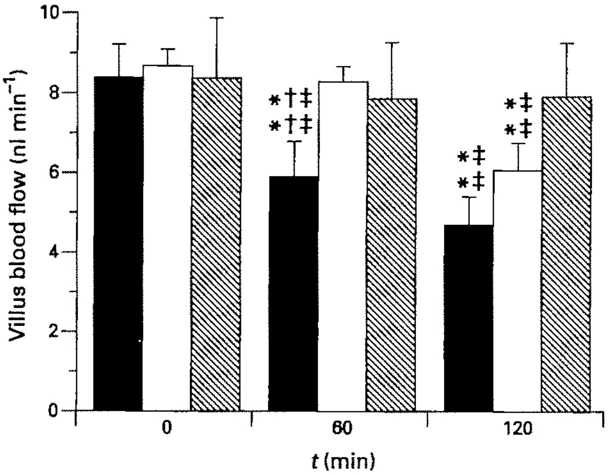

Figure 1 Intestinal villus blood flow at baseline ($t = 0$ min), 60 min ($t = 60$ min) and 120 min ($t = 120$ min) after starting the experiment in group A (■) (endotoxin 1.5 mg kg^{-1} from $t =$ 0 min until $t = 60$ min), group B (□) (endotoxin 1.5 mg kg^{-1} from $t = 0$ min until $t = 60$ min and dopamine 3 μg kg^{-1} min^{-1} from $t = 0$ min until $t = 120$ min) and group C (▨) (0.9 % saline from $t = 0$ min until $t = 120$ min). All data are mean, SEM. ** $P < 0.01$ *vs* baseline, †† $P < 0.01$ *vs* group B, ‡‡ $P < 0.05$ *vs* group C.

ALTERATIONS IN INTESTINAL VILLUS MICROCIRCULATION

Changes in villus blood flow and villus arteriolar diameters are shown in figures 1 and 2. Baseline values of villus blood flow did not differ between groups (group A, 8.4 (0.8) nl min^{-1}; group B, 8.7 (0.4) nl min^{-1}; group C, 8.4 (1.5) nl min^{-1}). Furthermore, there were no differences in the diameters of the villus arterioles between groups at the start of the experiment (group A, 7.8 (0.2) μm, group B, 7.9 (0.2) μm; group C, 7.6 (0.3) μm). Infusion of endotoxin in group A led to a decrease in blood flow in the

Table 1 Mean (SEM) changes in cardiorespiratory variables during the experiments in group A (endotoxin 1.5 mg kg^{-1} from $t = 0$ min until $t = 60$ min), group B (endotoxin 1.5 mg kg^{-1} from $t = 0$ min until $t = 60$ min and dopamine 3 μg kg^{-1} min^{-1} from $t = 0$ min until $t = 120$ min) and group C (0.9 % saline from $t = 0$ min until $t = 120$ min). * $P < 0.01$ *vs* baseline, †† $P < 0.01$ *vs* group C

central villus arterioles to 5.9 (0.9) nl min^{-1} at $t = 60$ min, which was a reduction of 29.7 (8.9)% ($P < 0.01$). Sixty minutes after cessation of administration of endotoxin ($t = 120$), blood flow was diminished by 43.1% from baseline to 4.7 (0.7) nl min^{-1} ($P < 0.01$). This reduction in villus blood flow was associated with a decrease in arteriolar diameters of 11.8 (1.1)% and 15.9 (2.4)%, respectively ($P < 0.01$). In contrast, in the dopamine group (group B) blood flow in the villus arterioles remained unchanged at $t = 60$ min (−2.7 (5.4)%; 8.3 (0.4) nl min^{-1}; $P > 0.05$). However, at $t =$ 120 min blood flow was reduced by 28.8 (8.0)% from baseline (6.1 (0.7) nl min^{-1}; $P < 0.01$). In contrast with group A, there was no vasoconstriction of the villus arteriolar diameters in the dopamine group at any time. Arteriolar diameters in the dopamine group increased significantly at $t = 60$ min and $t = 120$ min compared with groups A and C. In control animals (group C) which received no endotoxin or dopamine, there were no alterations in villus blood flow or arteriolar diameters throughout the study.

Discussion

We found that a continuous infusion of endotoxin resulted in a decrease in intestinal villus blood flow associated with a decrease in central villus arteriole diameter, despite normotensive macrocirculatory conditions. In rats given endotoxin, villus blood flow decreased by 29.7 (8.9)% after 60 min and by 43.1 (7.3)% after 120 min after the start of the endotoxin challenge. This reduction in villus blood flow was associated with vasoconstriction of the central villus arteriole by 11.8 (1.1)% and 15.9 (2.4)%, respectively. These results are in agreement with those obtained by other groups [21, 22] who demonstrated a reduction in segmental mesenteric blood flow which was accompanied by constriction of the previllus microcirculation in the submucosal layer of the bowel wall in a normotensive model of live *E. coli* bacteraemia in rats.

Endotoxin-induced intestinal damage is limited to the mucosa, especially to the villus tips [23, 24]. The preferential sensitivity of the villus tip to hypoperfusion and ischaemic injury is related to its peculiar vascular anatomy. The microcirculation of the intestinal villus is characterized by a central arteriole which branches near the tip of the villus into a subepithelial network of capillaries which drain into venules. Because of the close proximity of the ascending arteriole and the descending venule, a countercurrent arteriovenous diffusion of oxygen occurs resulting in low $P\text{O}_2$ values at the tip of the villus [25, 26]. Using a mathematical model of the countercurrent oxygen exchange mechanism in the intestinal villus, a blood flow-dependent decrease in the villus tip has been demonstrated [27]. Furthermore, the mucosa represents the major site of oxygen consumption in the gut and thus it is to be expected that the mucosa would also be the most susceptible portion of the gut wall to impaired oxygen delivery [28]. Impairment of the mucosal microcirculation characterized by a decrease in villus blood flow during endotoxaemia, as demonstrated in our study, might therefore account for the development of endotoxin-associated mucosal lesions observed in animals with normal blood flow in the mesenteric artery [29].

Maintenance of gut perfusion has been shown to avoid the increase in intestinal hyperpermeability [9] in a model of hyperdynamic endotoxaemia in pigs. Furthermore, increased permeability to large molecules suggesting loss of intercellular tight junction integrity represents the earliest manifestation of splanchnic ischaemia [30].

In humans, improved survival of critically ill patients has been demonstrated when a decrease in gastric mucosal pH is prevented, thus avoiding splanchnic hypoxia [31]. Therefore, maintenance of intestinal mucosal perfusion appears to be important for the prevention of gut-derived mortality in critically ill and septic patients. In critically ill patients, low-dose dopamine is often used to improve splanchnic blood flow, especially to optimize renal perfusion [10, 32]. However, the effects of low-dose dopamine on the mesenteric microcirculation during several pathophysiological conditions are contradictory. On the one hand, administration of low-dose dopamine (3 µg kg^{-1} min^{-1}) during gastrectomy improves portal venous oxygenation suggesting an increase in splanchnic blood flow [11]. In addition, it improves portal flow and gut oxygen delivery during PEEP ventilation in a model of acute lung injury [33]. On the other hand, low-dose dopamine has been demonstrated to exacerbate gut ischaemia in a porcine model of haemorrhagic shock [12]. Furthermore, low-dose dopamine worsens intestinal ischaemia during experimental flow reduction in the superior mesentery artery [34]. Pawlik and colleagues [35] described a reduction in mesenteric blood flow, intestinal oxygen consumption and intestinal capillary density in anaesthetized dogs induced by low (1 μg kg^{-1} min^{-1}), intermediate (5 μg kg^{-1} min^{-1}) and high (20 μg kg^{-1} min^{-1}) doses of dopamine. They suggested from these results that dopamine caused smooth muscle contraction in mesenteric arterioles and precapillary sphincters, thereby reducing total blood flow by constricting arterioles and reducing the nutrient circulation by closing capillaries.

In our study, administration of low-dose dopamine prevented constriction of the villus arteriolar microcirculation during endotoxaemia. The arteriolar diameters in endotoxaemic rats increased during infusion of dopamine even compared with non-endotoxic control animals. Because blood flow in the splanchnic bed is partially under dopaminergic control [36], dilatation of the intestinal villus arterioles can be explained by stimulation of dopamine (DA)-1 receptors. Sixty minutes after the start of the infusion of endotoxin, low-dose dopamine maintained intestinal villus perfusion at baseline levels and prevented the decrease observed during endotoxaemia. However, 120 min after the start of the endotoxin infusion, villus blood flow decreased despite the vasodilator effect of the administered dopamine. This disparity might be explained by simultaneous dilatation of shunt vessels between fourth-order arterioles and fourth-order venules which are located in the previllus, submucosal microcirculation [13]. Thus increased shunting of blood on the previllus level might occur which then does not participate in mucosal perfusion.

In conclusion, our study has demonstrated that low-dose dopamine did not prevent, but delayed and attenuated, the reduction in intestinal mucosal blood flow during normotensive endotoxaemia and exerted vasodilatator properties in the villus microcirculation.

Early effects of total hepatectomy on haemodynamic state and organ uptake of catecholamines in the pig

M. F. M. JAMES, R. HICKMAN, P. JANICKI, B. METS AND J. FOURIE

Summary

In a previous study, we showed that plasma concentrations of catecholamines were increased during the anhepatic phase in pigs. In this study, we investigated if a constant depth of anaesthesia would prevent these changes and, if not, if the changes were caused by impaired extraction of catecholamines. We measured arterial and venous pressures, heart rate and cardiac output in 10 anaesthetized pigs. Hepatic arterial and portal venous flows were measured. Blood for measurement of catecholamines was sampled from carotid and pulmonary arteries and portal, hepatic and renal veins. After a 2-h observation period, the liver was removed and the circulation reconstituted. Measurements were made and samples obtained for another 2 h. Catecholamine concentrations increased 2–10-fold after hepatectomy. Before hepatectomy, noradrenaline was extracted by the lung (mean extraction ratio 23 (SEM 8)%) and the liver (30 (11)%); after hepatectomy, there was extraction by the kidney (24 (12)%) but extraction by the lung (29 (8)%) was unchanged. Before hepatectomy, adrenaline was extracted predominantly by the kidney (73 (5)%) and the liver (70 (6)%), with minimal extraction by the lung; after hepatectomy, extraction by the lung increased (25 (4)%) and decreased slightly in the kidney (56 (6)%). While mean arterial pressure did not change, heart rate increased by approximately 50% and cardiac index declined (ns) within 2 h after hepatectomy. There was a sharp increase in pulmonary vascular resistance after removal of the liver and changes correlated with increases in arterial plasma concentrations of catecholamines. (*Br. J. Anaesth.* 1996; **76**: 713–720)

Key words

Liver, failure. Surgery, hepatic. Sympathetic nervous system, catecholamines. Pig.

Prolonged anhepatic periods of up to 24 h have recently been suggested in patients with fulminant liver failure in order to stabilize biochemical and coagulation abnormalities [1]. Previous reports of the effects of total hepatectomy in animals were discouraging because of numerous complications, and thus in an earlier study we made a preliminary investigation of some of the early effects of total hepatectomy [2]. In that study, we observed a marked increase in plasma concentrations of noradrenaline and adrenaline but it was unclear if the changes were caused by the absence of the liver, or to surgical stimulation and possibly associated haemodynamic changes. In that study the anaesthetic technique was not strictly controlled and haemodynamic or respiratory monitoring was not performed. In this study, a constant partial pressure of inspired anaesthetic gas was maintained, and haemodynamic changes, including blood flow to the liver and lung were monitored carefully. Detailed haemodynamic monitoring was used so that fluid balance could be corrected against measured right and left ventricular preload, and also to allow analysis of the haemodynamic consequences of catecholamine changes. The effects of surgical removal of the liver and the subsequent stabilization period were compared with results obtained during the preceding period of liver mobilization and placement of monitoring devices and the subsequent stabilization period. Blood samples for measurement of catecholamines were obtained across the liver, lung and kidney in order to determine net flux across these organs. Trans-organ extraction of catecholamines was studied in order to assess the extent to which removal of the liver contributed to the previously observed increase in catecholamine concentrations.

Materials and methods

The study was approved by the Animal Research Ethics Committee of the University of Cape Town. We used 10 young Large White Landrace pigs, weighing 23–29 kg (mean 25 (SEM 1) kg) and aged 7–9 weeks. After a fasting period of 16 h, anaesthesia was induced with sodium thiopentone 500–750 mg i.v. and pancuronium 6 mg. The trachea was intubated, a large gauge orogastric tube was passed

and the animals transferred immediately to the operating room while the lungs were ventilated manually. In the operating room anaesthesia was maintained with isoflurane 1.5 kPa and 66 % nitrous oxide in oxygen, delivered from a temperature compensated isoflurane vaporizer (Tec Mark IV, Ohmeda, UK), the accuracy of which had been pre-checked. The lungs were ventilated mechanically using a circle system with carbon dioxide absorption. Normocapnia was monitored by arterial blood-gas analysis and capnography.

POSITIONING OF CATHETERS AND FLOW PROBES (FIG. 1)

On the right side of the neck, size 8-French gauge catheters were introduced into the common carotid artery for monitoring arterial pressure and for blood sampling, and the external jugular vein for infusion of fluid; a 7-French gauge pulmonary artery catheter was floated into the pulmonary artery. Its position was confirmed by characteristic changes in the transduced pressure waveform. Care was taken to ensure that the proximal injection port was beyond the end of the sheath introducer which had been shortened to 9 cm in length. This length had been determined by prior post-mortem dissection of comparable pigs used for other studies.

A midline incision was made from the xiphisternum to the pubis and the bowel enclosed in a large plastic bag to provide exposure and prevent evaporative fluid loss. The ligaments attaching the liver to the diaphragm were divided. Through a left neck incision, a balloon-tipped catheter was advanced via the internal jugular vein into the suprahepatic vena cava and then guided manually into the left lobe of the liver. Within the abdomen, a fine catheter (5-French gauge feeding tube) was advanced via a branch of the splenic vein to lie opposite the outflow of the pancreaticoduodenal vein. Via a groin incision, a catheter (8-French gauge feeding tube) was introduced into the femoral vein and manipulated 10–15 mm into the right renal vein. These are modifications of techniques described previously [3]. The portal vein from the porta hepatis caudad to the confluence of the splenic and mesenteric veins and the common hepatic artery to the same level were dissected free of surrounding tissue and lymph nodes. Pre-calibrated perivascular ultrasonic flow cuffs were placed around the hepatic artery (2 mm) and the portal vein (6 mm), and positioned to ensure measurement of total flow in each vessel using an ultrasonic flowmeter (Transonic Systems Inc., New York, NY, USA, Model T201D) which incorporates a non-occlusive zero facility. The abdomen was closed loosely and observations made, during this pre-hepatectomy phase, immediately after surgery and at hourly intervals over the next 2 h.

I.v. balanced electrolyte solution (Plasmalyte B, Baxter, South Africa) with added 2.5 % glucose was infused at a rate of 10 ml kg^{-1} h^{-1} using a constant infusion pump. This solution resembles lactated Ringer's solution with the exception that the lactate is replaced by bicarbonate, and calcium is excluded. An infusion of 4.2 % sodium bicarbonate 150 ml was given during the period of bypass. Additional fluid was infused through the sheath introducer as needed to maintain a constant pulmonary artery wedge pressure.

Cardiac output and core temperature were measured using a cardiac output monitor (9520A; Edwards Laboratories, CA, USA). Cardiac output measurements in triplicate were performed by injection of 5 ml of normal saline (< 5 °C). Injections were made by a single investigator over a period of less than 4 s at end-expiration.

At the end of the initial observation period, hepatectomy was performed using a modification of previous methods [2]. The abdomen was re-opened and a side-to-side portacaval shunt was established just cephalad to the renal veins and the junction of the splenic and mesenteric veins, using 5-0 non-absorbable sutures. A passive porto-systemic shunt was produced by inserting catheters (22-French gauge) into the splenic vein and the left external jugular vein. For hepatectomy, the infrahepatic vena cava was clamped and the caudal end of the vena cava sutured to one end of a Dacron aortic graft (diameter 12–14 mm). During this time the vena caval and portal circulations passed through the portal vein and the passive bypass. After completion of this anastomosis, the liver was removed definitively and the anastomosis between the suprahepatic vena cava and the end of the graft completed. During this time, the vena caval and portal flows were decompressed partially via the passive shunt. After expulsion of air from the Dacron graft, the clamps were removed and circulation was restored. Total portal and vena caval flow now passed through the graft. The passive shunt was then removed and the orifice in the splenic vein repaired. The abdomen was closed with chromic catgut and nylon sutures. Measurements were made immediately after total hepatectomy and at hourly intervals for the next 2 h.

Blood samples were analysed for acid–base status, Pa_{O_2}, Pa_{CO_2}, and plasma sodium, potassium and lactate concentrations. Plasma concentrations of catecholamines were measured by high pressure liquid chromatography with electrochemical detection using dehydrobenzylamine as the internal standard. The coefficient of variation was 7.9 % for noradrenaline and 8.7 % for adrenaline, and the limit of sensitivity was 10 pg ml^{-1}. Catecholamine extraction ratios (ER) were calculated for the lung, kidney, gut and spleen as:

$$\mathrm{ER} = \frac{(\text{arterial concentration} - \text{venous concentration})}{\text{arterial concentration}} \times 100$$

For the lung, pulmonary venous concentration was assumed to be the same as systemic arterial concentration. For the liver, the formula was:

$$\mathrm{ER} = \frac{(\text{PVconcn} \times \text{PV flow}) + (\text{HAconcn} \times \text{HA flow}) - (\text{HVconcn} \times \text{total flow})}{(\text{PVconcn} \times \text{PVflow}) + (\text{HAconcn} \times \text{HA flow})} \times 100$$

where PV = portal vein, HA = hepatic artery, HV = hepatic vein and concn = concentration.

The total mass of catecholamines extracted by the pulmonary vascular bed and by the liver at each time was obtained by multiplying the difference between inflow and outflow concentration by total organ flow at each time. This was not possible for other organ beds as flow across them was not measured.

Statistical evaluation was performed using Statgraphics (version 5) statistical package on an IBM compatible 386 PC running under MS DOS version 6. All comparisons were against preoperative values unless otherwise stated. Extraction ratios were compared before and after hepatectomy using the paired *t* test. Time-based changes in catecholamine concentrations, extraction ratios, biochemical data and cardiovascular variables were analysed using analysis of variance for repeated measures with individual significantly different groups identified using the 95 % confidence interval multiple range testing method. Changes in haemodynamic variables were compared with changes in catecholamine concentrations in the appropriate vascular bed by regression analysis. Non-normally distributed variables were compared using the Mann-Whitney *U* test. Results are reported as mean (SEM).

Results

The mean time for porto-caval shunt, removal of the liver and replacement with the Dacron graft was 26 (SEM 4) min and the period of portal venous bypass never exceed 11 min. During the 5 h of the procedure, a mean of 2054 (450) ml of fluid were infused i.v. (range 1700–2700 ml). All pigs required additional fluids in excess of 10 ml kg^{-1} h^{-1} to maintain a constant wedge pressure. The mean additional fluid requirement was 33 (5.7) ml kg^{-1} over the 5 h of the procedure, and thus each pig received a mean of 15.8 (1) ml kg^{-1} h^{-1} throughout the experiment. It was noted that the pigs sequestered considerable quantities of fluid into the peritoneal cavity during the study and it was thought that this accounted for the additional fluid requirements. One pig died after hepatectomy.

HAEMODYNAMIC VARIABLES (FIG. 2)

Mean arterial pressure did not change significantly throughout each phase of the experiment. Initial heart rate was 135 (7) beat min^{-1} and increased to 161 (13) beat min^{-1} (ns) during the pre-hepatectomy phase. Two hours after removal of the liver, heart rate reached 184 (11) beat min^{-1} after 2 h ($P < 0.05$ compared with baseline). Cardiac index, expressed as a function of body weight, was 0.120 (0.011) litre kg^{-1} min^{-1} at the start of the study and decreased to 0.079 (0.014) litre kg^{-1} min^{-1} at the end of the study (ns). Weight rather than body surface area (BSA) was used to express cardiac index, as there are no nomograms for BSA in pigs. Pulmonary capillary

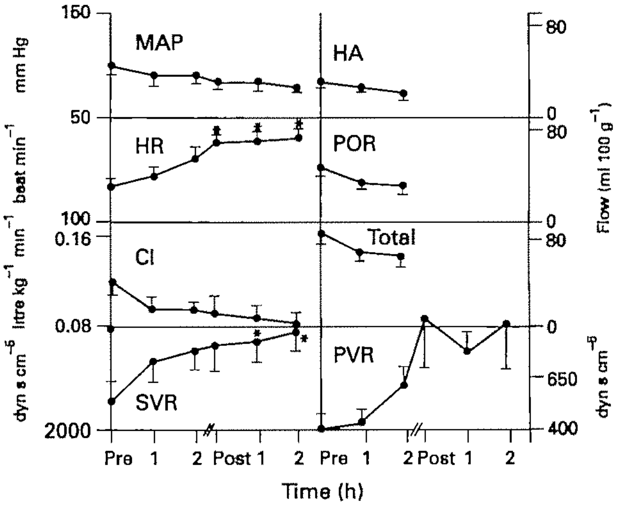

Figure 2 Mean arterial pressure (MAP), heart rate (HR), cardiac index (CI), systemic vascular resistance (SVR), pulmonary vascular resistance (PVR), hepatic arterial (HA), portal (POR) and total liver blood flows (mean, SEM). Measurements were made after positioning of all catheters and flow probes (Pre) and 1 and 2 h thereafter, and again immediately after removal of the liver and restoration of all circulations (Pre) and 1 and 2 h thereafter. * $P < 0.05$ between pre- and post-hepatectomy data.

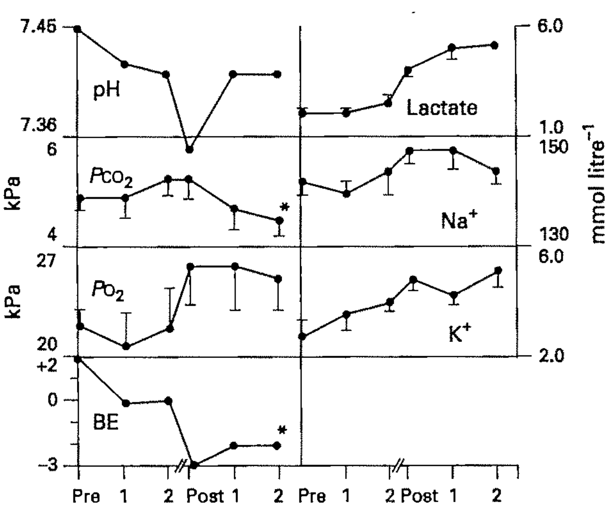

Figure 3 Plasma pH, $P\text{CO}_2$, $P\text{O}_2$, base excess (BE), and lactate, sodium (NA^+) and potassium (K^+) concentrations in arterial blood obtained at intervals described in figure 2. Error bars are not shown for pH or BE as they were too small for accurate depiction. $*P < 0.05$ between pre- and post-hepatectomy data.

wedge pressure was 6 (1) mm Hg and pulmonary arterial pressure was 20 (7) mm Hg at the beginning of the study. These values were not significantly different from values 2 h after hepatectomy (5 (1) mm Hg and 20 (9) mm Hg, respectively). Computation of systemic vascular resistance showed this to be 2378 (321) dyn s cm^{-5} at the beginning and 3473 (341) dyn s cm^{-5} at the end of the study, while pulmonary vascular resistance (PVR) increased slowly from 404 (72) to 630 (82) dyns cm^{-5} (ns) at the end of the pre-hepatectomy phase. There was a sharp 2–4-fold increase in PVR (mean 920 (231) dyn s cm^{-5}) in all animals immediately after removal of the liver which persisted for 2 h after hepatectomy. This was significantly greater than baseline but not significant compared with values immediately before hepatectomy. Changes in PVR correlated well with noradrenaline ($r = 0.73$) and adrenaline ($r = 0.72$) concentrations in the pulmonary artery. None of the other cardiovascular variables correlated significantly with changes in catecholamine concentrations.

All aspects of liver blood flow decreased during the first 2 h of the sham operation but this was not statistically significant. Mean total liver blood flow expressed per liver weight was 90 (8) ml 100 g^{-1} at the beginning of the study which decreased to 68 (9) ml 100 g^{-1} (ns) just before removal of the liver; mean initial portal flow was 49 (5) ml 100 g^{-1} which decreased to 38 (6) ml 100 g^{-1}, while hepatic arterial flow was 37 (3) ml 100 g^{-1} at the beginning of the study and decreased to 25 (5) ml 100 g^{-1} (ns).

BIOCHEMISTRY (FIG. 3)

There was a sharp decrease in plasma pH immediately after removal of the liver but otherwise pH values remained within normal limits. Mean initial Pa_{CO_2} was 4.9 (0.5) kPa which remained unaltered until the first hour after removal of the liver when a decrease was noted which became significant by 2 h after hepatectomy (4.2 (0.4) kPa). Plasma base excess declined from +2 to 0 mmol litre^{-1} before hepatectomy to −3 mmol litre^{-1} immediately and for 2 h after removal of the liver. There was an apparent increase in Pa_{O_2} after hepatectomy (ns).

While mean plasma concentrations of sodium were unaltered during the study, there was a slow increase in plasma potassium from 3.4 (0.3) to 4.6 (0.3) mmol litre^{-1}, 2 h after removal of the liver. There was a sustained but non-significant increase in mean plasma lactate concentrations after removal of the liver from 2–3 to 4–6 mmol litre^{-1}.

ABSOLUTE CATECHOLAMINE CONCENTRATIONS (TABLE 1)

Noradrenaline concentrations remained within the normal range for our laboratory (235–320 pg ml^{-1}) at all sites during the control period. Immediately after removal of the liver, there was a significant 5–10-fold increase in noradrenaline concentrations at all sites. One hour after hepatectomy, all concentrations decreased, with significant reductions from the previous sample in the arterial and renal vein samples. By 2 h after hepatectomy, all concentrations were increased significantly.

(vi)		1393.86 (409.8)		318.26 (172.9)

Concentrations of adrenaline in samples before hepatectomy were unchanged during the control period. After removal of the liver, there was an increase of up to six-fold above baseline in arterial and pulmonary arterial samples but not in those from the renal vein. There was a non-significant decrease 1 h after hepatectomy; at 2 h, concentrations in all circulations were significantly greater than pre-hepatectomy values.

TRANS-ORGAN CATECHOLAMINE CONCENTRATIONS

The majority of individual trans-organ samples showed reductions in effluent catecholamine concentrations (extraction) across individual organs, although there were several samples in which net release of catecholamines occurred.

Pulmonary extraction of catecholamines

Extraction of noradrenaline occurred across the lung in all but seven of the samples, both before and after hepatectomy, and significant noradrenaline extraction was demonstrated at all but one time (table 2). Mean extraction of noradrenaline across the lung was significantly different from zero for both pre- and post-hepatectomy samples ($P < 0.05$). One-third of specimens showed release of adrenaline across the pulmonary circulation during the pre-hepatectomy phase, but only one sample showed release after hepatectomy. However, the mean extraction ratio at each time was always positive (table 2), although not significantly different from zero. Averaged over the three sampling intervals after hepatectomy, the mean extraction ratio was significantly different from zero. After hepatectomy, the total mass of noradrenaline extracted by the pulmonary bed increased 2–4 fold from pre-hepatectomy concentration whereas that of adrenaline increased only 1–2 fold (table 3)

Hepatic extraction of catecholamines

Noradrenaline extraction varied before hepatectomy and only six samples showed release. Overall, there was a mean extraction of noradrenaline which was significantly different from zero ($P < 0.05$) during the pre-hepatectomy period (table 2). Only one sample showed release of adrenaline in the pre-hepatectomy phase and there was a consistently high extraction ratio (table 2). The overall mean extraction of adrenaline by the liver was 66.7 (6.2) %. Despite this high (statistically significant) extraction, the total mass of both catecholamines extracted by the liver was less than that extracted by the lung before hepatectomy (table 3). After hepatectomy the mass of both catecholamines extracted by the lung exceeded that of both the lung and liver combined, before removal of the liver for all times except for adrenaline at time (v) (table 3).

Renal extraction of catecholamines

In the pre-hepatectomy phase, only two-thirds of samples showed extraction of noradrenaline. Consequently, there was no significant net uptake or release of noradrenaline during this period. After removal of the liver only seven of 30 samples showed release of noradrenaline. There was a very high extraction of adrenaline during the pre-hepatectomy phase which persisted at the first sampling interval after removal of the liver but declined thereafter. Only one sample in the entire study showed release, and the concentration of adrenaline released in that sample was at a level within the experimental error.

Gut and splenic (splanchnic) extraction of catecholamines

There was an overall release of noradrenaline from the gut and spleen before hepatectomy but this was not statistically significant. There was significant mean extraction of adrenaline by this vascular bed.

Discussion

This study follows the suggestion of Ringe, Pichlmayr and Luebbe [1] that appropriate liver transplant recipients may be subjected to a prolonged anhepatic phase to allow stabilization of the haemodynamic and biochemical state. Previous studies of anhepatic animals have however, suggested that there may be severe consequences of total removal of the liver, but many of these changes were probably related to the models used [4]. In earlier study, a more stable anhepatic model in the pig was described which would survive at least 12 h and occasionally up to 24 h [2]. In this study, special attempts were made to maintain animals in a steady state. The only significant changes in biochemical measurements were plasma potassium and lactate concentrations. The two-fold increase in mean plasma lactate concentrations was consistent with the findings of Ringe, Pichlmayr and Luebbe who reported a 6–8-fold increase 8 h after hepatectomy in their clinical study of liver transplant recipients [1].

Particular attention was paid in this study to plasma catecholamine concentrations because these had not been measured previously during the anhepatic state in normal animals and because they may have significant early effects on the liver transplant recipient during revascularization of the graft. Catecholamine concentrations increased significantly in all circulations after hepatectomy and the question arises if this was a result of diminished extraction or increased release. Several authors believe that the liver is the major contributor to catecholamine extraction and there are various reports of a clearance ratio of 0.9 [5, 6], an extraction ratio of 62 (5 %) for the hepaticomesenteric sequence [7], clearance by the liver at levels increased fourfold by exogenous administration of catecholamines [8] and significant preferential clearance of noradrenaline by the liver [9] with net removal despite increased sympathetic activity [8]. Korn, Waldhaust and Iratusch-Marrain suggested that the magnitude of hepatic removal correlates with hepatic blood flow [10] although there was no correlation between liver blood flow and extraction ratios in our study. Hepatic removal of catecholamines probably buffers the net release of noradrenaline by the hepatomesenteric sequence, but this effect is seen only in studies in which both portal and hepatic venous blood is sampled [11]. The role of the liver in the removal of catecholamines is also implied in patients with cirrhotic liver disease who manifest very high circulating concentrations, but Silverberg, Shah and Maymond commented that, although it occurs, hepatic inactivation of noradrenaline is only a fraction of the systemic clearance in normal subjects [12].

Our data confirm an important role for the liver in catecholamine extraction, but also show that the lung is a more important site for catecholamine removal. Our results are in agreement with the 25 % pulmonary extraction of noradrenaline reported by Sole and colleagues [13]. Despite the lower extraction ratio for both catecholamines, the lung assumes a major role in catecholamine extraction because the entire circulating blood volume passes through this capillary bed. In the absence of the liver, the mass of catecholamines extracted by the lung more than compensated for the loss of hepatic metabolism.

There appear to be considerable disagreement about the role of the kidney in catecholamine extraction. Release of noradrenaline into the renal circulation has been reported in humans [14] and Oliver and colleagues found that in dogs there was basal release and a correlation between plasma concentrations of noradrenaline and stimulated sympathetic activity [15]. In a recent study, net removal of noradrenaline by the kidney was demonstrated at plasma concentrations midway between our pre- and post-hepatectomy levels [11]. Ring Larsen and colleagues, studying patients with cirrhosis, suggested that increased sympathetic activity in the kidney may be in response to hypotension or decreased peripheral resistance [14] although we did not find evidence of this. Others have reported that extraction occurs after injection of exogenous catecholamines. In this study, adrenaline extraction by the kidney was consistently high, whereas both extraction and release of noradrenaline occurred, which agrees with previous findings [14]. Extraction of adrenaline may, however, be a saturable mechanism, in view of the decrease in the extraction ratio which occurred after the marked increase in adrenaline after hepatic removal. It should be noted that, on the presumption that renal blood flow remained a reasonably constant fraction of cardiac output, the mass of catecholamines extracted by the kidney was probably greatly increased at this time.

The role played by the gut and spleen has only recently been considered [11, 16]. Although many studies have reported on the splanchnic or hepatomesenteric circulations [9, 10, 13, 17] in only one of these studies were transhepatic measurements made [10]. Our data showed equal release or uptake of noradrenaline by the gut and spleen and significant uptake of adrenaline, but studies were not continued after removal of the liver. Preliminary results from further studies suggest that catecholamine release is from the gut, and that the spleen plays little part [unpublished data].

There appear to be very few reports of the influence of anaesthetic technique on haemodynamic monitoring in normal pigs, although Weiskopf and colleagues have published the effects of ketamine and thiopentone [18] or nitrous oxide and halothane [19] in hypovolaemic swine. The initial increase in catecholamine concentrations after hepatic resection could have been in response to the surgical procedure, although the partial pressure of isoflurane with 70% nitrous oxide (equivalent to 2 MAC in humans) should have been sufficient to control autonomic responses. This is supported by the fact that the initial surgical procedure, which should have been at least as stimulating as hepatectomy, particularly as it involved skin incision, resulted in catecholamine concentrations within the normal ranges for pigs in our laboratory and no cardiovascular evidence of sympathetic response. The chosen regimen resulted in a moderately stable state with no significant changes in mean arterial pressure, heart rate, cardiac output and pulmonary or systemic vascular resistance during the first 2 h before hepatectomy. However, heart rate increased gradually throughout the study, and was significantly higher than baseline after hepatectomy, although there was no significant increase from the immediate pre-hepatectomy rate. Subsequent experience with the model has suggested that pigs may require even larger fluid loads than those given in this experiment to maintain intravascular volumes in the face of considerable transudation into the peritoneal cavity. Although pulmonary artery wedge pressure was maintained reasonably constant throughout the experiment, it is possible that the increase in heart rate was because of a relative fluid deficit which was not detected by measurements of wedge pressure alone.

The development of increased pulmonary vascular resistance in the anhepatic and revascularization phases of liver transplantation has been noted previously [unpublished clinical and laboratory observations]. It has been postulated that these changes are related to increased circulating endotoxins, prostaglandins or substance P [20] resulting from the anhepatic state, but increased catecholamine concentrations may also play a role. Our animals were not anticoagulated during the brief period of portal venous bypass, and it is possible that there may have been some clot formation in the graft with pulmonary embolization, although there was no gross evidence of this in terms of occlusion of the bypass catheter. However, the fact that pulmonary vascular resistance correlated well with pulmonary arterial catecholamine concentrations suggests that this observation in the present study was probably a result of the increase in catecholamine concentration or some other simultaneous and parallel event such as an increase in circulating endotoxin. This response of the pulmonary vasculature may be a species-specific effect. Kogure and Suzuki [21] demonstrated an increase in plasma histamine concentrations in portal venous blood after hepatic inflow occlusion. We did not measure histamine concentrations, and this may be an alternative explanation for the increase in pulmonary vascular resistance.

Partial disruption of the circulation at the time of hepatectomy may also have played an important role in the high concentrations of catecholamines. This suggestion is supported by the study of Kogure and Suzuki who showed that hepatic inflow occlusion resulted in significant increases in both portal and systemic plasma concentrations of noradrenaline after 30 min of occlusion time, increasing with time, and that very high concentrations of noradrenaline were associated with poor survival [21]. As the increase was more marked in the portal rather than the systemic circulation, they attributed the increase to splanchnic congestion. In our study, decompression of the portal and vena caval systems through a single bypass was almost certainly inadequate during excision of the liver (±11 min) and some degree of portal congestion would have occurred over this period. Recent evidence of the role of the mesenteric organs in the turnover of noradrenaline supports the possibility that the splanchnic circulation may be an important source of the increased catecholamine concentrations [11, 16].

We conclude therefore that changes in plasma catecholamines and organ extraction are considerable and may be clinically relevant. If these studies are applicable to humans, it would seem likely that an increase in circulating catecholamines may occur during prolonged anhepatic states, but that this increase is not entirely a result of loss of the hepatic metabolism of catecholamines. This study does not shed light on either the source of catecholamine release in the anhepatic phase, or the stimulus which mediated the change. However, the secondary increase in catecholamine concentrations 2 h after surgical manipulation had ceased suggests that the stress of the anhepatic state is at least partially responsible for the increase. These changes may not be reproduced in cirrhotic transplant recipients who may have altered sympathetic tone and abnormal responses to catecholamines [22]. In addition, infusion of catecholamines during anaesthesia produces changes greater than those seen in these experiments. Nevertheless, it is possible that the increased catecholamine concentrations which we have demonstrated could have adverse effects on both hepatic and pulmonary blood flow when a new liver is implanted. Ongoing studies with anhepatic pigs have demonstrated marked attenuation of renal output after removal of the liver, which is probably related to the increase in catecholamine concentrations [unpublished data]. Further studies are being conducted to determine if and how rapidly revascularization of the liver reverses these changes.

Sevoflurane, enflurane and isoflurane have no persistent postanaesthetic effects on the central nervous system in cats

J. KURATA, T. ADACHI, S. NAKAO, M. MURAKAWA, T. SHICHINO, M. SHIBATA AND K. MORI

Summary

Several reports have appeared on postanaesthetic convulsive disorders in humans after enflurane and isoflurane anaesthesia. However, it is controversial if enflurane induces epileptiform electroencephalogram (EEG), abnormal behaviour, or both, lasting for several days after anaesthesia in laboratory animals. We chronically implanted electrodes for EEG recording in the cortex, medial amygdala and dorsal hippocampus, and for reticular multi-unit activity (R-MUA) in the midbrain reticular formation in five cats. Two weeks later they were anaesthetized with 5.0% sevoflurane, 3.5% enflurane or 4.8% isoflurane for 3–4 h. EEG recordings, R-MUA and behaviour were observed for 1–3 h, during both wakefulness and sleep, every day for 5–7 days after anaesthesia. None of the cats showed abnormal behaviour, or EEG or R-MUA abnormalities after any of the anaesthetics, not only during wakefulness but during slow-wave and paradoxical phases of sleep. These results suggest that if seizures occur after anaesthesia, volatile anaesthesia itself may not be the cause. (*Br. J. Anaesth.* 1996; **76**: 721–725)

Key words

Anaesthetics volatile, sevoflurane. Anaesthetics volatile, enflurane. Anaesthetics volatile, isoflurane. Brain, electroencephalography. Complications, convulsions.

Sevoflurane is a new volatile anaesthetic in current popular use in Japan. Using cats with chronically implanted brain electrodes, we have reported that sevoflurane suppresses central nervous system (CNS) background electrical activities and leaves reactive capability relatively unaffected during light planes of anaesthesia but facilitates it in deep anaesthesia to produce an epileptoid state [1]. These neurophysiological properties of sevoflurane are similar to those of enflurane which also induces convulsions in deep anaesthesia [1].

Using cats with chronically implanted brain electrodes, Julien and Kavan reported epileptiform electroencephalogram (EEG) activities and abnormal behaviour after enflurane anaesthesia: the epileptic actions appeared on the second, peaked on the fourth and disappeared by the 16th day after anaesthesia [2]. However, such postanaesthetic neurological sequelae of enflurane were not reproduced in cats and humans by other investigators [3–5]. Nevertheless, the postanaesthetic epileptic effects are controversial in humans because many clinical cases of postanaesthetic seizure have been reported [6–16].

As sevoflurane has an epileptogenic property in deep anaesthesia [1], it is more than scientific interest to examine if sevoflurane has neurological or epileptoid effects in the postanaesthetic period. In this study, we recorded serial EEG before, during and after sevoflurane, enflurane and isoflurane anaesthesia in cats with chronically implanted brain electrodes, and examined the EEG and behavioural effects for 5–7 days after anaesthesia. It is well known that an abnormal EEG becomes manifest during light sleep in epileptic patients and amygdaloid kindled cats [17–22]. Therefore, EEG patterns were compared not only during wakefulness, but during slow-wave and paradoxical phases of sleep.

Materials and methods

Five cats of both sexes, weighing 2.3–4.1 kg, were used in this study, which was approved by our Institutional Animal Research Committee. The anaesthetic agents studied were sevoflurane ($n = 5$), enflurane ($n = 5$) and isoflurane ($n = 3$). At least 2 weeks after implantation of brain electrodes, each anaesthetic was administered to the cats with intervals greater than 4 weeks. EEG activities of wakefulness and sleep were studied before and after anaesthesia. The overall timetable of the experiment on each cat is shown in figure 1.

PLACEMENT OF ELECTRODES

The surgical procedures were performed during pentobarbitone anaesthesia (40 mg kg^{-1} i.p.). Cats were placed on a stereotaxic apparatus and electrodes implanted over the frontal sinus, parietal cortex, occipital cortex and in the amygdala (A:12, L:11, D:−6), dorsal hippocampus (A:2, L:9, D:9) and midbrain reticular formation (A:2, L:±3, D:−2),

according to the atlas of Snider and Niemer [23]. The cortical electrodes were made of stainless steel screws, 2 mm in diameter, and the subcortical bipolar electrodes were made of side-by-side stainless steel wires, 0.2 mm in diameter, insulated with epoxy resin except for the cut-end tips. The distance between the tips was 0.5–1.0 mm. Electrode position in the limbic structures was confirmed by probing the EEG activities: the electrodes were advanced by 1-mm steps until seizure activity appeared on the EEG [1]. This seizure was induced by an injury discharge, typical of the limbic structures [1]. All leads were soldered to a miniature vacuum tube socket, which was fixed to the skull with dental cement. During recording of CNS electrical activities, the socket was connected to the recording devices with a bundle of flexible cables of 5 m in length to allow for free movement of the cats.

ADMINISTRATION OF ANAESTHETICS

Initially the cats were anaesthetized with either 5 % sevoflurane, 5 % enflurane or 5 % isoflurane in oxygen, in a small anaesthesia box. The trachea was intubated without the use of neuromuscular blocking agents. The lungs were ventilated artificially with an animal respirator (SN-480-5, Shinano, Tokyo). The inspired concentration of sevoflurane, enflurane or isoflurane was adjusted to 5.0 %, 3.5 % or 4.8 %, respectively, using the Anaesthetic Gas Monitor (Type 1304, Brüel and Kjær, Nærum, Denmark), and end-tidal carbon dioxide tension was maintained at 4.0–4.7 kPa [24]. These selected concentrations of sevoflurane and enflurane are known to induce EEG seizures [1, 25], and that of isoflurane to induce isoelectric EEG with sporadic spikes [26]. Body temperature was maintained at 37–38 °C with a heated water mattress [24]. Duration of anaesthesia was 3–4 h. After recovery from anaesthesia, the tracheal tube was removed and the cats kept in a EEG recording box (90 × 60 × 70 cm).

RECORDING OF CNS ELECTRICAL ACTIVITIES

Preanaesthetic control and postanaesthetic recordings of EEG and reticular multiunit activity (R-MUA) were made during three behavioural states of wakefulness, and slow-wave and paradoxical phases of sleep. These recordings lasted 1–3 h. The EEG and R-MUA were recorded for 1–3 h, every day, for 5–7 days after anaesthesia. We considered that observation for the first 5 days after anaesthesia would be sufficient to identify any possible neurological abnormality [2]. During the recording, behavioural changes were confirmed by visual observation through a one-way window of the EEG recording box, and EEG changes were correlated with either wakefulness, slow-wave or paradoxical phases of sleep. These CNS electrical activity recordings were performed between 10:00 and 17:00.

Cortical and subcortical EEG were recorded on an eight-channel polygraph (Recti-Horiz-8K, San-ei, Tokyo) at a recording paper speed of 10 mm s^{-1}. The frontal sinus electrode was used as a reference for the cortical EEG. The subcortical EEG were recorded with the bipolar depth electrodes. The time constant was set at 0.1 s and the high-cut filter at 100 Hz.

The R-MUA was measured according to the method described previously [27]. The depth bipolar electrode implanted in the midbrain reticular formation differentially recorded discharge of a population of neurones included in an area with a radius of approximately 1 mm around the tip of the electrode. The wide-band signal obtained was amplified (1205C, San-ei, Tokyo) and then sent to a high-frequency band-pass filter, the peak frequency response of which was centred at 1300 Hz, with 3-dB attenuation at 600 and 2500 Hz. This high-frequency activity was rectified and smoothed with an electronic circuit (envelope detector), with a smoothing time constant of 50 ms, and was expressed as an oscillation of direct current (DC) voltage: the higher the DC level, the greater the firing of a population of neurones. This signal was recorded on a paper recorder (Rectigraph-8K, San-ei, Tokyo) at a speed of 5 mm min^{-1}. The noise level of the recording system was estimated as the distance between the DC level obtained by inserting a 10-kΩ resistor and that obtained by inserting a short across the input in place of the animal. The R-MUA level was measured as the distance from the lower limit of the multi-unit tracing to the 10-kΩ resistor line. The signal-to-noise ratio exceeded 10 in all cases.

Results

Before anaesthesia, all cats showed alternating patterns of typical EEG activities of wakefulness, and slow-wave and paradoxical phases of sleep. Inhalation of the anaesthetics induced EEG activities characteristic of each agent [1, 26]. During enflurane anaesthesia we were able to induce EEG seizures by auditory stimulation by clapping hands [25], but not during sevoflurane or isoflurane anaesthesia.

EEG activities before and after anaesthesia with each anaesthetic did not differ. Characteristic patterns of EEG alternated, coinciding with each of the three phases: wakefulness, slow-wave sleep and paradoxical sleep (fig. 2). These patterns were the same before and for the 5–7 days after anaesthesia. During wakefulness, there were theta waves and high-frequency small amplitude activities in the dorsal hippocampus, desynchronized activities in the cortex and relatively small amplitude activities in

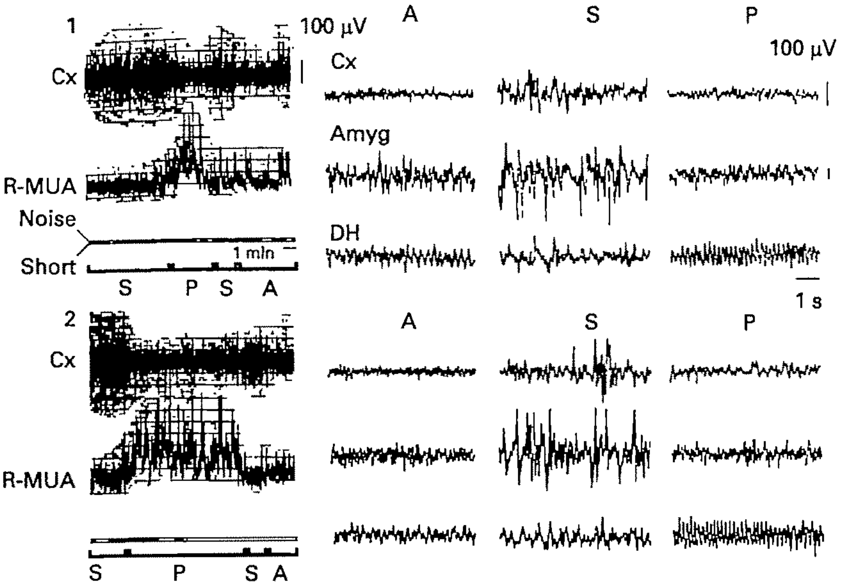

Figure 2 Representative patterns of EEG and reticular multi-unit activity (R-MUA) before (1) and 6 days after (2) sevoflurane anaesthesia. Note that there are three alternating types of states in R-MUA, that is awake (A), slow-wave sleep (S) and paradoxical sleep (P), of variable duration. The characteristic EEG in each state is shown on the right. Cx = Cerebral cortex, Amyg = amygdala, DH = dorsal hippocampus.

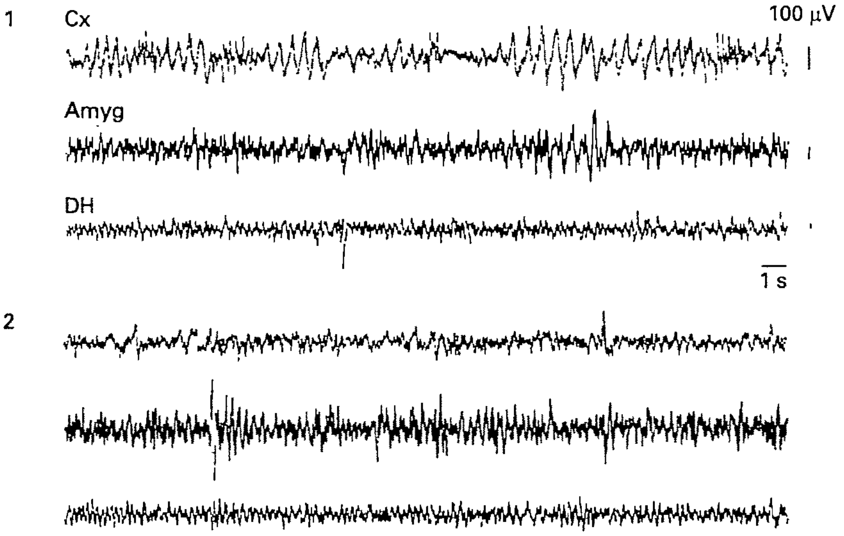

Figure 3 Characteristic EEG of a cat 6 days after sevoflurane anaesthesia when it was grooming (1) or eating (2). Cx = Cerebral cortex, Amyg = amygdala, DH = dorsal hippocampus.

the amygdala. During slow-wave sleep, large amplitude slow waves appeared in all leads and spindle bursts in the cortex. Most characteristics was large amplitude sharp waves in the amygdala but not in the other brain areas. During the paradoxical phase of sleep, small amplitude activities in the dorsal hippocampus disappeared leaving the 4–7 Hz theta waves more prominent, and the EEG of the cortex and amygdala were represented by desynchronized activities.

Large amplitude delta wave bursts sometimes appeared repetitively in the cortex during wakefulness, both before and after anaesthesia, when the cats were either grooming, drinking water or eating (fig. 3). These activities were, however, best understood as movement artefacts. Large amplitude spikes appeared in any lead of the cortex, amygdala and dorsal hippocampus when the cats moved the head in grooming, drinking or eating. These large amplitude spike-like activities did not synchronize with those of the other brain areas.

The R-MUA changed in a characteristic manner according to the three phases stated above: the averaged R-MUA was largest during the paradoxical phase of sleep, smaller during wakefulness, and smallest during slow-wave sleep. Figure 2 shows typical tracings of R-MUA before and after anaesthesia, which did not differ. The intermittent bursts of cortical EEG during wakefulness were usually associated with gross body movements.

The behaviour of the cats was normal and no movements implicating abnormal CNS activities were noted throughout the postanaesthetic period. They remained tame and in good temper as before anaesthesia.

Discussion

This study has confirmed the absence of an abnormal EEG and abnormal behaviour after sevoflurane, enflurane and isoflurane anaesthesia, not only during wakefulness but during slow-wave and paradoxical sleep throughout the postanaesthetic period. The anaesthetic concentrations of sevoflurane and enflurane were in the convulsive range [1, 25]. These findings indicate that these anaesthetics did not induce an epileptoid state after anaesthesia. This is the first study that provides evidence that sevoflurane does not cause persistent postanaesthestic EEG or behavioural abnormalities.

Julien and Kavan first reported the central nervous system effects of enflurane in cats with chronically implanted brain electrodes [2]. They observed residual behavioural and electroencephalographic abnormalities on the second day after anaesthesia and these abnormalities persisted for 14–16 days. Their cats appeared to be frightened, resisted handling and, at the same time, large amplitude spike activities were observed in the cerebral cortex and thalamic nuclei. Such abnormal EEG peaked at day 4, the intensity and frequency of the spike activity decreased by day 8, and the EEG returned to normal by day 16 [2]. Their study was contradicted by a series of other studies. Bassell and co-workers [5] conducted 2 MAC h of enflurane anaesthesia in cats with chronically implanted brain electrodes and observed no abnormal EEG or behaviour for 4 weeks after anaesthesia. Heavner and Amory [4] reported that seizure-inducing thresholds for lignocaine and pentylenetetrazol were not reduced after anaesthesia with 4% enflurane for 2 h over the 4 successive days in cats with chronically implanted brain electrodes. They also reported the absence of behavioural or EEG changes suggestive of long-lasting effects of enflurane exposure [4]. In humans, Burchiel and co-workers were not able to observe *de novo* epileptoid EEG after 9.6 MAC h of enflurane anaesthesia in 12 volunteers for 30 days [3]. However, these earlier studies [3–5], and those of Julien and Kavan on enflurane [2] and isoflurane [28], did not observe EEG during sleep. It is well known that drowsiness and sleep increase the probability of finding epileptiform discharges in the EEG of epileptic patients [17–21], and the EEG of natural or soporific-induced sleep is examined routinely, especially in temporal lobe seizures and nocturnal seizures [20]. In this study we demonstrated the absence of abnormal EEG not only during wakefulness but also during slow-wave and paradoxical phases of sleep after sevoflurane, enflurane and isoflurane anaesthesia.

In the present study, the EEG appeared normal throughout the postanaesthetic period, and large amplitude spike activity was always associated with either slow-wave sleep in the limbic structures or body movements such as grooming, drinking or eating. The large amplitude delta wave bursts, similar to the so-called hypersynchronous delta rhythm, pathognomonic for epilepsy [20], were observed when the cats were grooming, drinking or eating. Such activity is usually provoked by hyperventilation in epileptic patients [20]. This activity resembled the abnormal EEG activities reported by Julien and Kavan [2]. In their experiments no myoclonic movement linked with the abnormal EEG was noted, and movement artefacts might possibly have been misinterpreted as abnormal EEG. In the present study this type of activity appeared even before anaesthesia during head movement, and may be explained by head movement, that is movement artefacts. The cats remained tame, in good temper, with a good appetite and showed no resistance to handling or a frightened appearance such as Julien and Kavan had described [2].

Our experimental conditions were a little different from those of Julien and Kavan [2]. They conducted enflurane anaesthesia during spontaneous ventilation via a face mask with a 2:1 mixture of air and oxygen, while we conducted anaesthesia via a tracheal tube and artificial ventilation with oxygen. They administered 4.5–5.5% enflurane for approximately 30 min, while we gave 3.5% enflurane for 3–4 h. We chose this concentration of enflurane because induction of seizures is known to be easiest with 3.5% enflurane [25]. If the cause of the persistent abnormality of EEG and behaviour in their experiment was the metabolite(s) of enflurane as they suggested, such a metabolite(s) would accumulate more during a longer period of anaesthesia and would tend to induce abnormalities. Therefore, our experimental condition should have been more likely to induce persistent abnormalities in the EEG or behaviour.

Enflurane, during deep anaesthesia, is known to induce an epileptoid state in humans [29, 30] and cats [26], characterized by suppression of background reticular cell firing and augmentation of the reactive capability of the brain [26]. Although there have been several clinical reports of seizures after enflurane anaesthesia [6–15], in this study we may speculate that enflurane itself might not have been the causative agent.

Sevoflurane was confirmed to have similar neurophysiological properties to enflurane in cats [1]. It induces seizures during deep anaesthesia by somatic stimulation, although less frequently than enflurane [1]. In humans, however, a sevoflurane-induced epileptoid state has not yet been reported, and there has been no report of seizure after sevoflurane anaesthesia.

The convulsive property of isoflurane is less potent than that of enflurane in cats [26]. It does not induce seizures even during deep anaesthesia marked by isoelectric EEG with spikes in cats [26] or by isoelectric EEG in humans [31]. Clinically there is only one case report of seizure just after isoflurane anaesthesia, which was characterized by myoclonus [16].

In conclusion, we did not observe abnormal behaviour or epileptic EEG after sevoflurane, enflurane and isoflurane anaesthesia, not only during wakefulness, but also during slow-wave and paradoxical phases of sleep. These results suggest that even convulsant anaesthetics do not produce an epileptoid state after anaesthesia, and if seizures occur after anaesthesia, the anaesthetic itself may not be the cause of the seizure.

REVIEW ARTICLE

Prehospital monitoring of trauma patients: experience of a helicopter emergency medical service

A. P. MORLEY

The Helicopter Emergency Medical Service (HEMS) began operating from the Royal London Hospital in 1989. It remains the only medically staffed helicopter for the retrieval of major trauma victims in the UK. Its aim is to optimize early management and ensure rapid transport to appropriate specialist centres. When necessary, patients are anaesthetized, the trachea intubated and the lungs ventilated manually on scene. Trauma, and ensuing therapy, may be accompanied by significant physiological change. The aims of monitoring are to improve patient safety, increase the likelihood of early, accurate diagnosis, and allow assessment of subsequent treatment.

Monitors for prehospital use

The recommendations of the Association of Anaesthetists for minimal standards of monitoring in anaesthesia are well known. Continuous monitoring of cardiovascular and respiratory function is essential [2]. In addition, a recent working party has produced a report on patient management during helicopter transport, including recommendations for monitoring [6]. Both refer to the uninterrupted presence of an appropriately trained doctor throughout. Table 1 illustrates monitors that HEMS apply on arrival at scene and subsequently in the helicopter, where mechanical ventilation is often commenced. Weight limitations on equipment carried by HEMS in the aircraft and thence to scene has led to the exclusion of some otherwise desirable monitors.

Equipment for use on board aircraft requires Civil Aviation Authority (CAA) approval specific to the type and model of the aircraft in which it is to be used. Each item of monitoring equipment must be tested by a CAA approved organization [11] to exclude any potential hazards, for example fire, smoke, explosion or interference with aircraft communication and navigation systems. While the helicopter is thus unaffected by the monitor, the reverse is not necessarily the case. General monitoring problems encountered in flight, and before this in the field, are summarized in table 2.

Some qualities are desirable in monitors for use in the prehospital environment and in patient transfer (table 3). Portable multimodal monitors are available from several manufacturers, including Siemens, Datascope, Datex and PaceTech. HEMS uses the Propaq 106EL (Protocol Systems, Inc., Beaverton, OR, USA). It measures 16.3 cm by 20.5 cm by 16.8 cm and weighs 3.8 kg. Its minimum battery life is 4 h and it has electrocardiogram (ECG), non-invasive arterial pressure (NIAP), oxygen saturation (Sp_{O_2}), end-tidal carbon dioxide (PE'_{CO_2}) and temperature measurement facilities.

ELECTROCARDIOGRAPHY

ECG monitoring is a fundamental part of most resuscitation procedures. It assists the on scene diagnosis of electromechanical dissociation (EMD), arrhythmias, and myocardial injury and ischaemia. EMD may occur in trauma patients with tension pneumothoraces and hypovolaemia. Myocardial injury from blunt chest trauma may cause arrhythmias or more subtle ST segment deviations, the interpretation of which requires caution. Normal individuals can exhibit ST segment deviation on standard prehospital cardiac monitoring equipment during routine transport [22]. ECG monitoring is prone to mechanical and electrical interference, both on scene and in transit. In addition, adhesive electrodes often become detached in the rain or if blood runs onto the chest.

NON-INVASIVE ARTERIAL PRESSURE

On scene, frequent, automated NIAP monitoring helps in the early detection of hypotension, although this is a late sign of shock in the young. NIAP monitoring enables detection of hypertension accompanying increased intracranial pressure in head injured patients. The efficacy of attempts to obtund the hypertensive response to on scene laryngoscopy and intubation may also be assessed. There are several practical problems with NIAP cuff application in the field. These include lack of access where patients are trapped. Clothing usually needs to be cut and underlying limbs may be injured. When the cuff has been applied, patient movement or vibration from extrication tools may prevent accurate readings.

In helicopter transit, oscillometric readings in critically ill patients are not as reliable as direct invasive monitoring and are, in some instances,

Sunshine	Access
Noise	Electrical interference
Vibration	
Access to patient	
Distraction by events at scene	
Patient-related factors	
Injury preventing monitor application	
Displacement of sensors	
Unco-operative, confused patients	

Table 3 Desirable features in a prehospital monitor

- Accuracy
- Multimodality
- Long battery life with recharging facility
- Durability
- Ease of carriage
- Lightweight
- Reliability in adverse environmental conditions
- Ease of operation by attendant paramedical staff
- Compatibility with equipment at receiving hospitals
- Printer/downloading facility
- Ease of service or part replacement
- Low cost

unobtainable [35]. This may also be because of vibration. In a study by Campbell and colleagues [7] comparing methods of neonatal transport, helicopters in flight were found to produce overall vibration levels of 5.6 m sq s^{-1} in the vertical axis, with least vibration occurring in cruising fixed-wing aircraft (0.04 m sq s^{-1}). During HEMS helicopter transfers, NIAP monitoring is prone to intermittent malfunction. While invasive arterial pressure monitoring may be more accurate and reliable, the aim is to treat and transport casualties as quickly as possible from the scene to the appropriate hospital. Extra time taken attempting roadside arterial cannulation may not be in the patient's best interests.

TEMPERATURE

HEMS uses an aural probe, compatible with the Propaq 106EL, to measure core temperature. This is reasonably well tolerated by conscious patients. It indicates the presence of initial hypothermia and monitors the response to corrective manoeuvres. In trauma patients, core and mean body temperatures are inversely related to severity of injury [34]. For a given level of injury, mortality is increased in trauma patients who develop hypothermia. This is the case whether hypothermia is defined as a core temperature below 34 °C, 33 °C or 32 °C [27]. Patients often sustain injuries outdoors and may suffer prolonged exposure to cold as a result of entrapment in vehicles. Clothing may be cut or removed in order to assess the nature and extent of the injury. Attempts to reduce heat loss at scene include the use of warmed i.v. fluids and reflective insulation blankets. In the helicopter, the cabin is heated by bleeding hot air from the engine compression system. This affects engine performance slightly so heating is not possible during take off or landing.

OXYGEN SATURATION

Pulse oximetry has numerous applications in hospital monitoring and an established place in anaesthesia. Several articles have indicated its usefulness in the prehospital environment, both on scene [36, 50] and in helicopter transfers [49, 54]. Its principal application for the field anaesthetist is detection of hypoxia, which may prompt a decision to induce anaesthesia and intubate the trachea. More controversially, some authors have suggested it has a role in monitoring circulation and assessment of systolic arterial pressure.

Independently, but especially in conjunction with hypotension, hypoxia is recognized as a major extracranial variable influencing outcome in severely head injured patients [10]. Early tracheal intubation of these patients should reduce the likelihood of hypoxia and hypercapnia and may prevent secondary brain injury. In one emergency department study, a group of patients monitored with continuous pulse oximetry while undergoing emergency intubation had a lower likelihood of hypoxic episodes and a shorter duration of severe hypoxia than an unmonitored group [38]. Pulse oximetry has also proved useful in the early detection and management of tension pneumothorax [30], and in other conditions encountered regularly by HEMS, such as severe lung contusions and haemothorax.

Some authors believe that the pulse oximeter is valuable for distal circulatory monitoring in injured limbs. The use of oximetry in the hospital treatment of supracondylar humeral fractures has been reported [5, 40]. However, a prospective study of oximetric monitoring of distal circulation in fractured limbs before and after manipulation showed it had no clear role [15]. In the diagnosis of failing perfusion caused by increased intracompartmental pressure, oximetry is unreliable [37]. This is not surprising. Pulse oximeter signals can be obtained from fingers where Doppler studies indicate only 4% flow [32], suggesting that a plethysmographic trace is no guarantee of effective blood flow to the tissues. This may explain why, while the benefits of oximetry in the management of primary respiratory arrest seem clear, its value in monitoring resuscitation from cardiac arrest is doubtful [51], despite anecdotal reports [39].

As discussed above, there are some circumstances where oscillometric arterial pressure measurement is difficult. The reappearance of a plethysmographic waveform from a distal pulse oximeter probe on deflation of an arterial pressure cuff has been used to measure systolic arterial pressure in hospitalized neonates [31] and it compared favourably with oscillometric measurements. A similar method has also been used with some success in adults [9] and in patients transferred by helicopter [53]. Unfortunately, the accuracy and reliability of the technique used in the last study were not compared with those of the oscillometric method.

Environmental factors affecting pulse oximeter function

Several environmental factors limit the usefulness of pulse oximetry in the prehospital management of trauma patients. While ambient artificial light can cause inaccurate readings [16], the effect of direct sunlight is unknown, although it certainly reduces the visibility of LED display panels. Probe displacement is common. Where this is incomplete, spuriously low Sp_{O_2} readings may occur in normoxic subjects even when heart rate is displayed correctly [29]. In hypoxic subjects, various inaccuracies may result. Importantly, some oximeters display falsely high Sp_{O_2} values at low saturations [3]. Noise on scene may drown the pulse signal. Even in experimental conditions, the change in pitch accompanying desaturation in most oximeters is detected better by some subjects than others [45].

Oximeter readings fail frequently during helicopter transit. A recent study of pulse oximetry in a German air rescue service found that more than 25% of measurement time was subject to interference [23]. Some oximeters incorporate weighted averaging systems to filter out suspect values while enabling a rapid response to changing Sp_{O_2} [56]. By using ECG synchronization, which is a feature of the Propaq 106EL, Helm and colleagues [24] achieved more than an eight-fold reduction in passive motion artefacts in oximetric monitoring during emergency helicopter patient transfer.

Patient factors affecting pulse oximeter function

Trauma victims out of hospital are not prepared in the same way as patients before operation. Although pulse oximeter readings are unchanged by dried blood [42] and most shades of nail polish [14], oximeter failure has occurred in some HEMS patients with fingers covered in oil or bitumen.

Clinical circumstances influence interpretation of oximeter readings. Burns accounted for about 5% of the HEMS workload in 1994 and, at present, there are no facilities for measuring carboxyhaemoglobin (HbCO) on the aircraft. In the presence of HbCO, the fractional oxygen saturation is overestimated by pulse oximetry [41]. Despite absorption spectra differences between oxyhaemoglobin and HbCO, the degree of overestimation is close to the percentage of HbCO in most cases. This has been shown *in vitro* [41], in animal studies [4] and clinically for HbCO values of 1–30% [55].

Blood loss is common in trauma victims. In the presence of normoxia, acute severe anaemia, with haemoglobin concentrations as low as 2.3 g dl^{-1}, does not significantly affect the accuracy of pulse oximetry [26]. However, at an oxygen saturation of less than 80%, anaemia approximately doubles the error of pulse oximeters [46]. HEMS does not carry blood, and patients are resuscitated, where appropriate, with warmed crystalloid or colloid solutions. The resulting haemodilution may exacerbate any decrease in haemoglobin concentration.

Where blood loss and hypothermia coexist, the resulting peripheral vasoconstriction increases the hypotensive failure threshold of pulse oximeters [48]. Under conditions of poor perfusion, a comparison of 20 pulse oximeters showed variable performance, with all but two models failing on occasion. Where readings were obtained, mean differences from corresponding co-oximeter readings were less than 5% [12]. The same group compared the performance of finger, nose, ear and forehead probes, under similar conditions, all of which are carried by HEMS. Their conclusion was that the overall performance of probes in sites other than the finger was worse [13]. Interestingly, there is some evidence that under conditions of profound hypoxia, another clinical state encountered frequently by HEMS, ear probes respond more rapidly and more accurately than finger probes [47].

The accuracy of pulse oximetry may be affected adversely by both patient and environmental factors. The clinical relevance of this may not be immediately apparent, given that 100% oxygen is administered to most trauma victims as soon as ambulance crews or HEMS arrive. However, the first oximetric readings may influence the decision to intubate the trachea or insert chest drains. At present, initial ventilatory frequency, systolic arterial pressure and Glasgow coma scale are used to compile the revised trauma score. This enables the physiological state of trauma victims to be compared and has some predictive value [8]. In future, it is possible that initial oxygen saturation may also be used in this way and accurate measurement will assume even greater importance.

END-TIDAL CARBON DIOXIDE

Portable methods of PE'_{CO_2} measurement are limited to disposable colorimetric devices or in-line analysers, which may be incorporated into multimodal monitors such as the Propaq.

An example of the former is the Easy Cap (Nellcor Incorporated, Hayward, CA, USA). This incorporates metocresol purple as an indicator that changes colour from purple to yellow in the presence of carbon dioxide. A colour scale allows distinction between the following ranges of PE'_{CO_2}; "A" purple, 0.03 to <0.05%; "B" tan, 0.5–2%; "C" yellow, 2–5%. In patients whose tracheas are intubated correctly, the indicator colour cycles from purple (inspiration) to yellow (expiration). The detector has an internal volume of 38 ml, a flow resistance of 3 ± 1 cm H_2O at 60 litre min^{-1} and weighs less than 30 g. It ceases to function if the indicator strip becomes moist. This is a significant limitation in traumatized patients, where the airway may be soiled with blood, sputum, gastric contents, pulmonary oedema or tracheally administered drugs.

On scene capnometry assists confirmation of tracheal intubation, assessment of cardiopulmonary resuscitation, monitoring of deliberate hyperventilation and diagnosis of circuit disconnection.

Reliable confirmation of tracheal intubation is essential in unfavourable prehospital intubating conditions. Before medical staff arrive, the trachea is sometimes intubated by paramedics who may not recognize oesophageal placement [52]. Chest auscultation is often unsatisfactory because of noise, for example extrication equipment, and $P\mathrm{E}'_{CO_2}$ measurement, as in the operating theatre, is the best method. In one hospital study, a disposable device allowed more rapid confirmation of tracheal intubation than capnography. Speed of detection of oesophageal intubation was not significantly different for the two methods, and there were no false positive or false negative results with the colorimetric method [21]. Cautious interpretation is advisable in the field, whichever method is used. Recent ingestion of beer leads to high oesophageal $P\text{CO}_2$ in dogs [19]. In addition, manual bag and mask ventilation by paramedics is common. This produces initial, high "expired" $P\text{CO}_2$ readings where the oesophagus is subsequently intubated [33].

During cardiopulmonary resuscitation, the increase in $P\mathrm{E}'_{CO_2}$ that accompanies the return of spontaneous circulation is detectable with a disposable capnometer [25] and is often the first clinical indicator of the event [20]. The capnograph may herald the onset of circulatory arrest [17] and even indicate the efficacy of external cardiac massage [28]. $P\mathrm{E}'_{CO_2}$ depends on alveolar ventilation and pulmonary circulation. Where the former varies, as might be expected in roadside patients whose lungs are ventilated manually, assessment of pulmonary circulation by $P\mathrm{E}'_{CO_2}$ measurement should not logically be reliable. However, in one hospital study where arrested patients underwent manual ventilation, minimum $P\mathrm{E}'_{CO_2}$ values during CPR were predictive of resuscitation outcome and survival [44].

Capnography may be used to monitor the deliberate hyperventilation of head injured patients, when the trachea has been intubated on scene. Although the accuracy of most capnometers deteriorates even with a relatively modest increase in ventilatory frequency, in-line analysers of the type supplied for the Propaq 106EL are less prone to this than the sampling types [18]. During deliberate hyperventilation, interpretation of $P\mathrm{E}'_{CO_2}$ readings usually relies on the assumption that they accurately reflect arterial partial pressures of carbon dioxide (Pa_{CO_2}). This assumption may be rendered invalid by the physiological state of trauma victims. Askrog and colleagues, for example, demonstrated the increase in $Pa_{CO_2}-P\mathrm{E}'_{CO_2}$ gradient in anaesthetized patients deliberately rendered hypotensive [1]. More significant, perhaps, is a recent study of normovolaemic patients with multiple trauma undergoing mechanical ventilation [43] where the authors established a consistent Pa_{CO_2} to $P\mathrm{E}'_{CO_2}$ correlation across the study population. However, there was no correlation in 22% of individual patients, the frequency of a linear correlation was only 41%, and the ability of $P\mathrm{E}'_{CO_2}$ changes to predict the direction of change of Pa_{CO_2} was in error in 27% of comparisons.

The risk of circuit disconnection in patients undergoing ventilation is greater in the relatively uncontrolled prehospital environment where patients are transferred repeatedly from one site, or mode of transport, to another. Chest wall movements may be obscured, and changes in ventilator tone rendered inaudible by environmental noise. The capnograph is a more reliable indicator of the integrity of a circuit.

Conclusion

Monitors are important in the prehospital management of trauma victims. They may provide information that determines treatment at scene or in transit. Where patients are anaesthetized at scene, the standard of physiological monitoring required does not differ from that in theatre and is approached by some of the recent, portable, multimodal monitors. None of these, however, incorporates an oxygen analyser. Oxygen cylinders frequently run out unnoticed because of the absence of a suitable alarm. Monitoring of equipment used in the field is still suboptimal in this respect.

The accuracy and reliability of monitors may be affected adversely by the prehospital environment and the nature of the patients and their injuries. For the attending physician to interpret monitor readings correctly, familiarity with the equipment, its principles of operation and its limitations is essential.

The principal aim of resuscitation in trauma victims is adequate delivery of oxygenated blood to the tissues. This is difficult to assess in the intensive care unit and even more so at the roadside. Currently available monitors can, at best, provide only a guide. It is hoped that future design modifications will overcome some of the problems with the monitors discussed in this review.

SHORT COMMUNICATIONS

Hydroxyethylstarch compared with modified gelatin as volume preload before spinal anaesthesia for Caesarean section

M. P. VERCAUTEREN, V. HOFFMANN, H. C. COPPEJANS, A. L. VAN STEENBERGE AND H. A. ADRIAENSEN

Summary

We studied 90 patients undergoing elective Caesarean section under spinal anaesthesia who received lactated Ringer's solution 1000 ml with up to 1000 ml of modified gelatin, lactated Ringer's solution 1000 ml with up to 1000 ml of 6% hydroxyethylstarch or only up to 1000 ml of 6% hydroxyethylstarch. Lumbar puncture was performed as soon as 500 ml of the colloid were infused. The incidence of hypotension, number of patients requiring a vasopressor and doses of ephedrine required to restore arterial pressure were significantly lower in favour of those receiving the crystalloid–hydroxyethylstarch combination. In both groups receiving the 2000 ml preload, packed cell volume (PCV) values decreased by more than 20%, which may be of concern in patients already presenting with mild anaemia. In patients who received the colloid without the crystalloid, PCV values decreased by 14% but the risk of severe hypotension was comparable with the crystalloid–gelatin combination. (*Br. J. Anaesth.* 1996; **76**: 731–733)

The risks and benefits of hydration before spinal anaesthesia in obstetrics are subject to much debate. After spinal anaesthesia, even up to 2000 ml of crystalloids may reduce but not eliminate hypotension. During extradural anaesthesia it has been demonstrated that greater volumes of crystalloids (20 ml kg^{-1}) even increase the risk of hypotension compared with lower volumes [1]. This raises doubts, mainly about the usefulness of crystalloid preloading and hydration before (semi-)urgent Caesarean section. However, with colloids, less volumes are required, oncotic pressure may be maintained, but too little attention has been paid to the different properties of the available colloids. The purpose of this study was to compare gelatin with hydroxyethylstarch.

Methods and results

After obtaining approval from the Hospital Ethics Committee and informed consent, we studied 90 term patients presenting for elective Caesarean section, allocated randomly to one of three groups. Sixty patients received lactated Ringer's solution 1000 ml starting in the obstetric ward after which on arrival in the operating theatre they received an additional 16-gauge i.v. cannula for infusion of either modified gelatin (Geloplasma, Merieux, France) or hydroxyethylstarch (HAES-steril 6%, Fresenius, Germany). Another 30 parturients received hydroxyethylstarch 500 ml in the obstetric ward and another 500 ml of the same substance in the operating theatre. Exclusion criteria included patients with pre-eclampsia, hypertension, diabetes, multiple gestation, polyhydramnios, systolic arterial pressure < 100 mm Hg and packed cell volume (PCV) values less than 30% before commencing the anaesthetic technique. Anaesthesia was started during infusion of the second 500-ml volume and comprised a combined spinal–extradural technique using a 26-gauge pencil-point spinal needle (Unisis-corp, Japan). Spinal block was performed with plain bupivacaine 6.6 mg and sufentanil 3.3 µg (i.e. a mixture of 0.5% bupivacaine 2 ml and 1 ml of sufentanil 5 µg ml^{-1}, of which 2 ml were injected) after which an extradural catheter (Perifix Braun, Germany) was inserted for supplementary anaesthesia and relief of postoperative pain. Subsequently, patients were turned to a 15° left lateral tilt. Arterial pressure and heart rate were monitored automatically (Datex AS/3, Helsinki, Finland) every 2.5 min. Ephedrine (5-mg increments) was given when systolic arterial pressure (SAP) decreased to less than 100 mm Hg or to more than 25% (compared with baseline values or at two consecutive measurements), heart rate increase of decreased by 25% (from baseline or at two consecutive measurements) but also in the event of nausea/vomiting or any sense of fainting or non-well-being, even without evidence of haemodynamic instability.

The amount of colloid administered at the moment of spinal injection was recorded. After infusion of 1000 ml of the colloid, a venous blood sample was obtained to measure PCV for comparison with the preoperative value. Measurements and therapy were performed by an anaesthetist unaware of the design of the study.

Table 1 Preloading, anaesthetic and hypotensive data (mean (SEM) or number). *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ compared with the lactated Ringer's (LR)–HES 6 % group

	LR–gelatin ($n = 30$)	LR–HES 6 % ($n = 30$)	HES 6 % ($n = 30$)
Colloid preload (ml)	913.3 (72.2)	756.7 (45.6)	853.1 (33.1)
Height of block (dermatomes > T7)	4.7 (0.4)	4.8 (0.4)	4.3 (0.5)
Lowest SAP (mm Hg	100.5 (3.7)	108.2 (2.7)	94.1 (3.7)*
SAP < 100 mm Hg (*n*)	18*	8	16*
SAP < 90 mm Hg (*n*)	10*	3	12*
Ephedrine dose (mg)	7.6 (1.5)**	2.5 (0.8)	6.2 (1.5)*
Preoperative PCV (%)	35.2 (0.8)	35.5 (0.85)	34.9 (0.6)
PCV after colloid 1.0 litre	28.1 (0.6)	27.9 (0.75)	30.07 (0.6)*
Decrease in PCV (%)	20.3 (1.2)	21.9 (1.1)	14.2 (1.0)***

Data are expressed as mean (SEM). Statistical analysis was performed with the unpaired, two-tailed Student's *t* test for parametric and the Fisher's exact test for non-parametric data (Macintosh IIsi, StatView II). $P < 0.05$ was considered significant.

There were no differences between the groups in age mean 29.4 (range 25–44), 30.1 (23–42) and 29.2 (20–44) yr), weight (81 (SD 14), 75 (16) and 78 (17) kg) or duration of pregnancy (38.0 (1.5), 38.2 (0.5) and 37.8 (2.6) week). All procedures were uneventful and the mean upper sensory level, determined with an ether swab, reached T2–3 in all groups (table 1). Extradural supplementation was not necessary before delivery in any patient. Severe hypotension (< 90 mm Hg) was noted in one of 10 patients in the lactated Ringer's–HES group compared with at least one of three patients in the lactated Ringer's–gelatin and HES groups ($P < 0.05$). Ephedrine was required less frequently $P < 0.05$) in the lactated Ringer's–HES group (11 patients *vs* 22 patients and 20 patients in the lactated Ringer's-gelatin and HES groups, respectively). As a consequence, the mean dose requirement of ephedrine was also lower in the former group. The mean lowest recorded systolic arterial pressure was higher in lactated Ringer's–HES treated patients but this was significant only compared with the group receiving HES alone ($P < 0.05$) in which hypotension occurred more abruptly.

PCV values in the groups receiving 2000 ml of preload revealed a decrease of 20.3 % and 21.9 %, respectively, whereas with 6 % HES alone it was 14.2 % ($P < 0.001$ compared with the lactated Ringer's–HES group). In none of the parturients was there evidence of respiratory or cardiac problems suggesting fluid overload.

All neonates had Apgar scores greater than 8 at 1 and 5 min and weighed more than 2800 g (mean weight 3170 (range 2820–3360) g, 3180 (2850–3340) g and 3210 (2800–3410) g).

Comment

This study demonstrated that volume preloading is worthwhile if the correct regiment is selected. Our finding that approximately 10 ml kg^{-1} of a colloid or 1000 ml of lactated Ringer's solution with modified gelatin was inadequate to increase the incidence of hypotension may cast doubt on the benefit of hydration compared with no volume treatment. As demonstrated recently, the use of 1000 ml of crystalloids alone did not appear to be better than preloading with only 200 ml [2]. The incidence of hypotension (< 90 mm Hg in one of three patients) was comparable with our results in the groups receiving gelatin with crystalloids or HES alone, although in the study of Jackson, Reid and Thorburn, extremely high doses (up to 50 mg) of ephedrine were required. In the present study in which therapy was started earlier, ephedrine requirements were significantly lower.

In addition to the lack of apparent haemodynamic benefit, volume preloading may have several other disadvantages. The risk of pulmonary oedema, as a result of accumulation of extravascular lung water, may be reduced by the use of colloids as these maintain the oncotic pressure of plasma. Efforts to increase placental blood flow may be counteracted partly by haemodilution. Marked decreases in PCV values decrease the oxygen-carrying capacity of maternal blood. If additional hypotension still occurs despite high preloading volumes, as with the crystalloid–gelatin combination, fetal oxygenation may be seriously compromised.

However, compared with crystalloids, the properties of the available colloids may differ considerably. Hydroxyethylstarch may offer several advantages such as venous thrombosis prophylaxis and an allergic potential which is seven times lower (1/2100) than that of the gelatins [3]. Even in concentrations of 10 % it seems to be safe for the neonate as placental transfer in a sheep preparation has been found to be almost negligible [4]. The 6 % concentration may be preferable in obstetric practice as, compared with the 10 % concentration, its volume retaining effect in excess of 100 % lasts only 30 min which is ideal to cover the interval between administration and delivery. Although hydroxyethylstarch costs twice as much as gelatin, it is six times less expensive than human plasma proteins.

Although we were able to maintain the most optimal haemodynamic stability with the crystalloid–HES combination, our findings were not different from the results of Jackson, Reid and Thorburn [2]. We confirmed that high volumes, even containing gelatins, may not prevent cardiovascular instability, but we suggest that more attention should be paid to the choice of the regimen, colloid, or both. Recently, another study confirmed the superiority of a crystalloid–HES combination compared with crystalloids alone [5]. After intrathecal injection of 0.75% hyperbaric bupivacaine 12 mg, the incidence of hypotension was 45% in those receiving the combination of 500 ml 6% HES and lactated Ringer's solution 1000 ml which was significantly lower than the 85% incidence in the group receiving 2000 ml of crystalloid alone.

We agree with the advice of Rocke and Rout [6] that hydration should not be abandoned routinely without additional studies. We would be interested to know the haemodynamic safety of the high preload used in the present study and the effect of colloids alone combined with the preventive use of vasopressor increments.

Hypotension during subarachnoid anaesthesia: haemodynamic effects of colloid and metaraminol

L. A. H. CRITCHLEY AND F. CONWAY

Summary

We have studied 45 patients, aged 60–95 yr, receiving subarachnoid block for neck of femur fractures. Patient received either colloid (polygeline, Haemaccel) 8 ml kg^{-1} ($n = 15$), metaraminol 5 µg kg^{-1} and 1.7 µg kg^{-1} min^{-1} ($n = 15$) or a combination of both treatments to maintain systolic arterial pressure (SAP) between 75 and 100% of baseline. If necessary, additional colloid 2×4 ml kg^{-1} or metaraminol 3×2.5 µg kg^{-1} was given. Arterial pressure was measured by automated oscillotonometry, central venous pressure (CVP) by a manometer and cardiac index (CI), stoke index (SI) and heart rate (HR) by transthoracic electrical bioimpedance. Systemic vascular resistance index (SVRI) was derived. Colloid was less effective than metaraminol ($P < 0.05$). In the colloid group, SAP and SVRI decreased and CVP, CI and SI increased ($P < 0.001$). In the metaraminol group, initial decreases in SAP, SVRI and CVP were restored after 10–15 min and HR decreased after 12 min ($P < 0.001$). In the combined group, initial decreases in SAP and SVRI were restored after 4 and 16 min, and CVP, CI, SI and HR increased ($P < 0.001$). Metaraminol was more effective than colloid because it increased SVRI, whereas colloid increased CVP without significantly increasing CI. (*Br. J. Anaesth.* 1996; **76**: 734–736)

Key words

Hypotension is a common problem during subarachnoid block and elderly patients are particularly at risk. Different views exist on how this hypotension should be managed [1]. There are few data on the elderly, and only the effects of crystalloid preloading and the use of ephedrine have been investigated [2, 3]. Recently, we showed that i.v. fluids and ephedrine were not always effective in preventing hypotension during subarachnoid block in the elderly and we suggested that treatment with a predominantly alpha adrenergic receptor agonist would be more effective [4]. In the present study, we have compared the haemodynamic effects during subarachnoid block of colloid solution and the alpha agonist metaraminol.

Methods and results

After obtaining local Ethnics Committee approval and written informed consent, we studied 45 ASA II and III Chinese patients undergoing surgical fixation of fractured neck of femur. Oral diazepam 5–10 mg was given 1 h before surgery. Subarachnoid block was performed using 0.5% bupivacaine 2.5–3.0 ml (Marcain Spinal 0.5% Heavy, Astra). We measured systolic (SAP) and mean (MAP) arterial pressures using automated oscillotonometry, central venous pressure (CVP) using a manometer and cardiac index (CI), stroke index (SI) and heart rate (HR) by transthoracic electrical bioimpedance using the BoMed NCCOM3-R7S (BoMed Medical Manufacturing Ltd, Irvine, CA, USA). We derived systemic vascular resistance index (SVRI). Data were collected at 1-min intervals (5-min intervals for CVP) for 3–5 min before and 0–25 min during subarachnoid block. For a more detailed description of our methodology, see previous publications [4, 5].

Patients were allocated to one of three regimens to prevent hypotension using block randomization with sequentially numbered sealed forms. Immediately after subarachnoid block, group I received a rapid infusion of colloid 8 ml kg^{-1} (3.5% polygeline, Haemaccel, Behringwerke, Germany), group II received an initial bolus of metaraminol 5 µg kg^{-1} followed by an infusion of 1.7 µg kg^{-1} min^{-1} and group III received both colloid and metaraminol. Rescue treatment was given if SAP decreased to less than 75% of baseline on two consecutive occasions. Group I received a rapid infusion of colloid 4 ml kg^{-1} and, if necessary, repeated once to restore SAP. If hypotension persisted, metaraminol was given, as per group II. Groups II and III received up to three boluses of metaraminol 2.5 µg kg^{-1} to restore SAP. If hypotension persisted, colloid 8 ml kg^{-1} was given.

Continuous haemodynamic data were analysed at 1-min intervals. Percentage changes compared with baseline were also calculated at 1-min intervals and their means compared. Numerical differences were used for CVP. Student's *t* test, analysis of variance

*Present address: St Vincent's Hospital, Merrion Road, Dublin, Ireland.

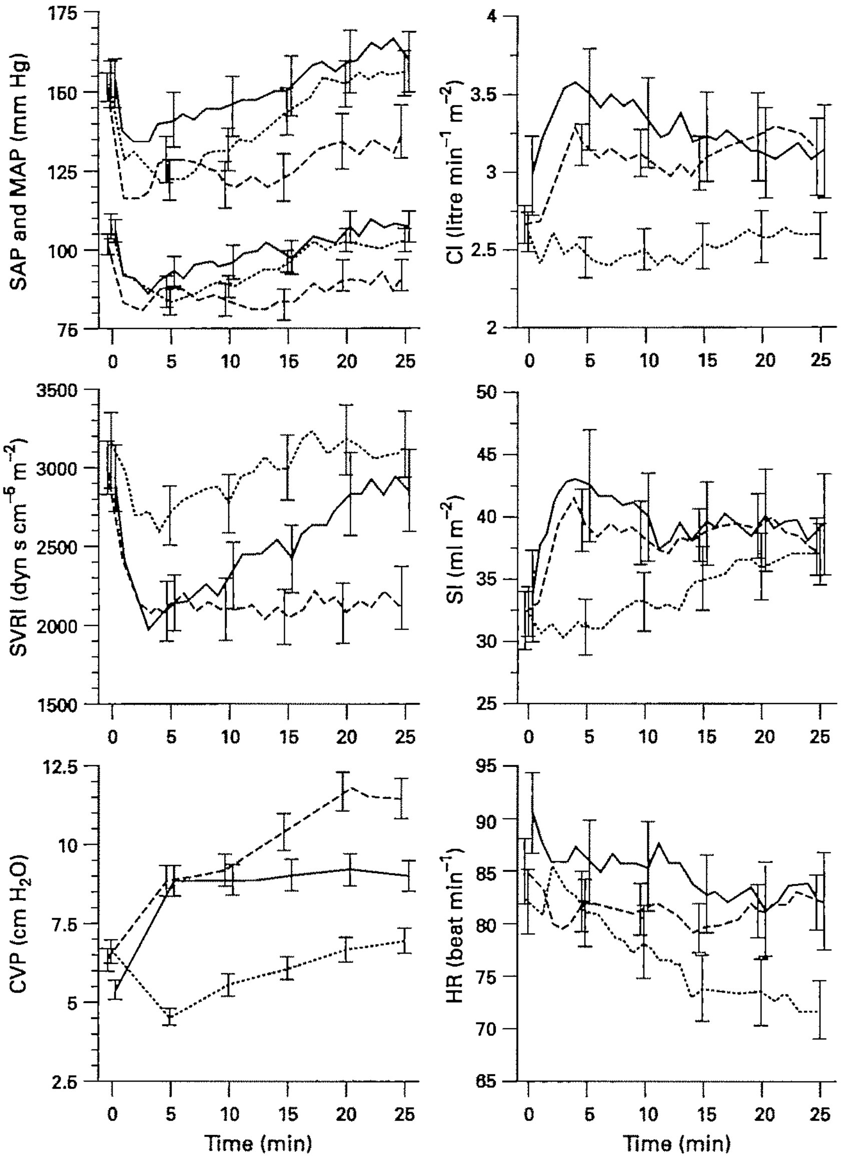

Figure 1 Mean (SEM) haemodynamic variables at baseline (0 min) and during the first 25 min of subarachnoid block for all patients in the three treatment groups: —— = colloid alone; ---- = metaraminol alone; and —— = metaraminol with colloid.

for factors and repeated measures and chi-square test were used for statistical analysis. $P < 0.05$ was considered significant and results are given as mean (SD or range). The power of the study was assessed using Altman's method [6]. Fifteen patients per group were required to detect changes of less than 10% between haemodynamic data.

We studied 11 male and 34 female patients, aged 78 (60–95) yr, weight 48 (7) kg and height 154 (8) cm. Maximum sensory level in pinprick was thoracic dermatome 6 (1–11). Patient characteristics, maximum sensory level and baseline haemodynamic data were similar in the three treatment groups. The colloid regimen failed to maintain an adequate SAP on eight occasions. The metaraminol regimen failed significantly less often ($P < 0.05$), once in group II and once in group III, and resulted in an excessive SAP in four patients in group II and six patients in group III.

Haemodynamic changes after subarachnoid block are shown in figure 1. In the colloid group, significant decreases in SAP, MAP and SVRI and increases in CVP, CI and SI occurred ($P < 0.001$). These changes were significant ($P < 0.05$) after 1 min for SAP, MAP and SVRI, after 5 min for CVP and after 2 min for CI and SI. There was no significant change in HR. In the metaraminol group, significant decreases in SAP, MAP, SVRI, CVP and HR occurred ($P < 0.001$). These changes were significant ($P < 0.05$) at 1–14 min for SAP, at 1–15 min for MAP, at 2–10 min for SVRI, at 5–10 min for CVP and at 12–25 min for HR. There were no significant changes in CI or SI. In the combined group there were significant decreases in SAP, MAP, SVRI and HR, and increases in CVP, CI and SI ($P < 0.001$). These changes were significant ($P < 0.05$) at 1–4 min for SAP, at 1–10 min for MAP, at 1–16 min for SVRI, after 5 min for CVP, after 2 min for CI and SI, and after 14 min for HR.

The magnitude of the haemodynamic effects of the three treatments during subarachnoid block are shown in table 1. Where treatment was effective,

Table 1 Percentage changes (Δ) or numerical differences (Diff.) (mean (SD)) compared with baseline values for haemodynamic variables, for the established effects of subarachnoid block when treatment was successful in the three treatment groups (15–25 min) and when treatment was unsuccessful in the colloid group (10–15 min). SAP = Systolic arterial pressure, MAP = mean arterial pressure, SVRI = systemic vascular resistance index, CVP = central venous pressure, CI = cardiac index, SI = stroke index and HR = heart rate. $^*P < 0.05$, $^{**}P < 0.01$ compared with baseline

			Colloid	
	Metaraminol ($n = 14$)	Combined ($n = 14$)	(Successful) ($n = 7$)	(Unsuccessful) ($n = 8$)

percentage changes were averaged between 15 and 25 min, and where additional colloid failed between 10 and 15 min.

Comment

Current clinical practice is to use crystalloid, up to 2 litre, before and during subarachnoid block to prevent hypotension [1]. In the present study, we used colloid solution during the onset phase of subarachnoid block. This practice prevents excessive increases in CVP (table 1) and reduces the fluid volume required [4]. However, we found that even large volumes of colloid, up to 16 ml kg^{-1}, failed to correct hypotension in more than 50% of our patients. Coe and Revanas [2] reported similar findings in patients with a high subarachnoid block (above T7) after preloading with crystalloid 16 ml kg^{-1}. In fact, administration of colloid appeared to decrease SVRI and yet cardiac output did not increase significantly despite increases in CVP, suggesting that elderly patients have a reduced ability to respond to i.v. fluids (table 1, fig. 1).

In the present study, metaraminol was effective at maintaining SAP during subarachnoid block in 93% of patients, the principal action of metaraminol being to maintain SVRI (table 1). However, metaraminol caused excessive treatment in some patients (33%). In these patients subarachnoid block may have caused only a small decrease in SAP and the use of prophylactic treatment may have been unnecessary. CVP during high subarachnoid block decreases by 2.5 (1.5) cm H_2O [5]. Metaraminol prevented this decrease (table 1), suggesting that metaraminol also acts by venoconstricting capacitance vessels. However, CVP did not increase sufficiently to increase cardiac output.

Ephedrine is the most frequently studied vasopressor during subarachnoid block. Comparing the present data with data from our previous study [4], we found ephedrine to be less effective than metaraminol at maintaining SVRI and that part of its action was to increase cardiac output and HR. Also, the efficacy of ephedrine depended on maintaining the patient well hydrated with i.v. fluids. In comparison, metaraminol was much less dependent on i.v. fluids.

Administration of i.v. fluids during subarachnoid block is important, because it maintains preload and cardiac output. However, the use of large volumes of fluid to increase preload sufficiently to raise cardiac output and SAP is not always successful in the elderly patient. Therefore, this practice should not be encouraged because of the risk of fluid overload. Hypotension may be treated more effectively by using a vasopressor and we found that infusion of metaraminol was highly effective because it acted by increasing systemic vascular resistance.

Interference of volatile anaesthetics with infrared analysis of carbon dioxide and nitrous oxide tested in the Dräger Cicero EM using sevoflurane

A. R. WILKES AND W. W. MAPLESON

Summary

In theory, setting an infrared multi-gas analyser to measure a volatile anaesthetic different from that in the sampled gas mixture may cause interference with carbon dioxide and nitrous oxide readings. The theory was investigated during evaluation of the Dräger Cicero EM anaesthetic workstation for the Medical Devices Agency. Interference occurred as predicted, and was most pronounced when the vapour analyser of the Cicero EM was deliberately and erroneously set to measure isoflurane, but with sevoflurane present in the gas mixture. With 6% sevoflurane in the gas mixture, the carbon dioxide reading decreased from 5% to 3.6%, and the nitrous oxide reading increased from 0% to 8% although, as the apparent isoflurane reading was 9%, the Cicero EM would alert the operator to the problem. However, operators are encouraged to ensure that, when using gas analysers such as that incorporated into the Cicero EM, the analyser is set to measure the correct volatile anaesthetic (the Cicero EM does this automatically when a Vapor vaporizer is attached) and the breathing system does not contain any other volatile anaesthetic agents. (*Br. J. Anaesth.* 1996; **76**: 737–739)

Measurement techniques, spectrophotometry. Anaesthetics volatile. Equipment, gas analysers.

Infrared absorption is a common method of gas analysis for measuring the concentrations of carbon dioxide, nitrous oxide and volatile anaesthetic agents in gas mixtures during anaesthesia. This type of analyser uses different wavelengths of infrared light to determine the concentrations of carbon dioxide, nitrous oxide and volatile anaesthetic; the same wavelength is used for all current volatile anaesthetics, but different sensitivities are set for each agent. Typically, the highest sensitivity is set for halothane and the lowest for sevoflurane. This method of analysis implies that the presence of a volatile anaesthetic different from that set to be measured causes an error in the volatile anaesthetic reading. For example, 1% isoflurane causes an apparent halothane reading of approximately 6% when the analyser is set to measure halothane [1].

Volatile anaesthetics also absorb infrared radiation at the wavelengths used for measurement of carbon dioxide and nitrous oxide. This is corrected by subtracting amounts from the carbon dioxide and nitrous oxide signals appropriate to the volatile anaesthetic being measured and its measured concentration. Therefore, provided the analyser is set to measure the correct anaesthetic, or the analyser detects the particular volatile anaesthetic automatically, the analyser can compensate for this effect. However, if the analyser is set to measure a volatile anaesthetic different from that present in the gas mixture, the wrong corrections are made and the carbon dioxide and nitrous oxide readings are in error.

An opportunity to test this theory occurred during evaluation of the Dräger Cicero EM anaesthetic workstation for the Medical Devices Agency. This anaesthetic workstation incorporates the ANDROS 4610 gas analyser, which is also used in the North American Dräger Narkomed 4 and Vitalert 3000 monitor, and the Drägerwerk PM 8050 monitor. Information provided by the manufacturer stated that the analyser software compensates for the cross-sensitivity of carbon dioxide, nitrous oxide and volatile anaesthetic, so that the displayed concentrations of these gases and vapours are accurate. However, it was found that if the ANDROS 4610 was set deliberately to measure a volatile anaesthetic different from that in the gas mixture being sampled, interference with the carbon dioxide and nitrous oxide readings occurred as predicted. The interference was most pronounced with sevoflurane present in the gas mixture and with the analyser set to measure isoflurane. The extent of the interference was investigated.

Methods and results

Carrier gas (4.95% carbon dioxide/balance nitrogen) (BOC Special Gases) was set at a flow of 2 litre min^{-1} using a RT-200 calibration analyser (Timeter Corp) and was passed through a vaporizer (Sevotec 3, Ohmeda) to add various concentrations of sevoflurane to the gas mixture. A turbine vane transducer cartridge from a 5410 volume monitor (Ohmeda), placed in the gas pathway, was used to ensure that the carrier gas and sevoflurane were mixed thoroughly. The resulting gas mixture was sampled from

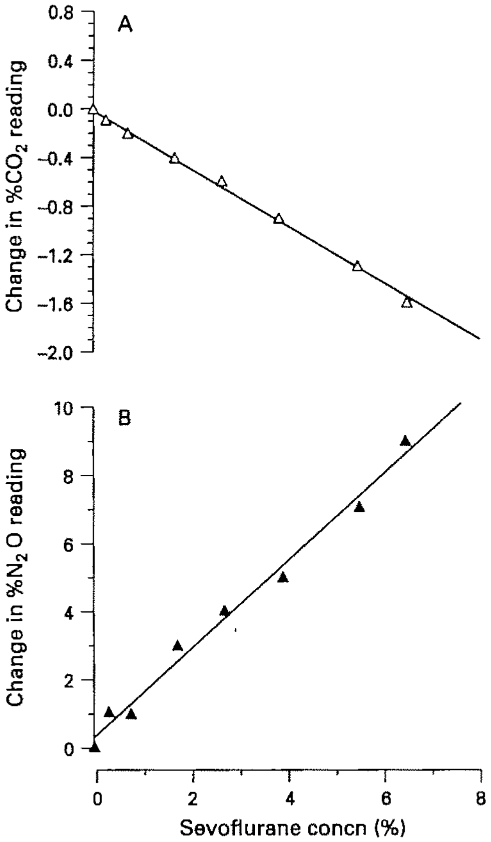

Figure 1 Change in carbon dioxide (CO_2) (A) and nitrous oxide (N_2O) (B) readings, with fitted regression lines, as the Cicero EM is changed from being set to measure sevoflurane to being set to measure isoflurane, against increasing sevoflurane concentration. The changes in the CO_2 and N_2O readings are −0.24% CO_2 and +1.27% N_2O, respectively, for each 1% increase in sevoflurane concentration.

a common sampling point, both by the ANDROS analyser on a Cicero EM anaesthetic workstation (Dräger, Germany) and by an interference refractometer on loan from the National Physical Laboratory [2]. The gas mixture sampled was therefore independent of the breathing system of the Cicero EM. At each vaporizer setting, the analyser was set to measure sevoflurane and the carbon dioxide, nitrous oxide and volatile anaesthetic readings were noted; the analyser was then set to measure isoflurane and the readings repeated. The readings were also logged automatically onto a computer (Apple Macintosh LC475 running Kermit communication software) via the RS232 serial output on the Cicero EM. Changes in the carbon dioxide and nitrous oxide readings were taken to be the difference between the pairs of readings obtained at each vaporizer setting. The actual concentration of sevoflurane in the gas mixture was determined from the refractometer using refractive powers of 1428.6 for sevoflurane, 413.56 for carbon dioxide (at 22 °C and 101.3 kPa [3]) and 282.12 for nitrogen (at 15 °C and 101.3 kPa [4]), assuming that the relative concentrations of carbon dioxide and nitrogen remained the same, and correcting for temperature and pressure [3]. The concentration of carbon dioxide in the carrier gas was also checked with the refractometer.

The carbon dioxide and nitrous oxide readings changed linearly with sevoflurane concentration (fig. 1). The slope of the change in carbon dioxide reading with increasing sevoflurane concentration was −0.24, and that for nitrous oxide, +1.27.

Comment

The International Standard for capnometers (ISO 9918:1993) specifies gas mixtures to be used to determine the interference effect of gases and vapours on the carbon dioxide reading. One such gas mixture specified is 6% sevoflurane in 5% carbon dioxide, balance nitrogen. If the ANDROS analyser in the Cicero EM is set correctly to measure sevoflurane in the gas mixture, then carbon dioxide readings are displayed which are within the tolerance specified in ISO 9918:1993. However, if the analyser is set to measure isoflurane, the carbon dioxide reading decreases with this gas mixture from 5% to 3.6%. Conversely, if isoflurane is present in the gas mixture, and the analyser is set to measure sevoflurane, the carbon dioxide reading increases as the isoflurane concentration increases. The draft International Standard for anaesthetic gas monitors (ISO/DIS 11196) specifies gas mixtures to be used to determine the interference effect on the nitrous oxide reading. Again, if the analyser is set correctly to measure sevoflurane, then the nitrous oxide reading is accurate. However, if the analyser is set to measure isoflurane, and 5% sevoflurane is in the gas mixture (as specified in ISO/DIS 11196), the nitrous oxide reading increases from 0 to 6%.

The Cicero EM detects which vaporizer has been fitted using a coding on the rear of Dräger Vapor 19.n vaporizers and automatically selects the appropriate sensitivity on the gas analyser. Therefore, in normal clinical practice, it would require a deliberate action by the anaesthetist to set the analyser to measure a volatile anaesthetic different from that of the vaporizer on the Cicero EM workstation. Even then, an advisory message is displayed and, if the vaporizer is changed, the setting of the analyser is automatically changed appropriately. Therefore, in the Cicero EM, inappropriate setting of the gas analyser is extremely unlikely. However, when that analyser (or any other analyser working on the same principle) is used in isolation (as was effectively the case in these experiments), the correct setting of the anaesthetic to be measured is dependent on the operator.

In addition, the volatile anaesthetic in use is absorbed into the walls of the breathing system [5, 6]. During subsequent use with a different anaesthetic, the anaesthetic used previously desorbs from the breathing system and is present in the gas sampled by the analyser, causing interference. Using a low-flow system exacerbates this effect.

Whatever the circumstances—whether the analyser is set to measure the wrong volatile anaesthetic or the sample from the breathing system contains an additional, "foreign", agent—the displayed concentration of the volatile is the concentration used to correct the carbon dioxide and nitrous oxide readings. However, any error in the reading for the volatile anaesthetic is likely to be more important clinically than the resulting error in carbon dioxide or nitrous oxide. Nevertheless, it is important to be aware that the carbon dioxide and nitrous oxide readings are also in error.

The Dräger Cicero EM incorporates a sophisticated and generally accurate gas analyser. However, when using this, or a similar gas analyser, operators should check that the analyser has been set to measure the correct anaesthetic, and should be vigilant that the breathing system does not contain a mixture of volatile anaesthetics. Failure to do so could cause interference with the carbon dioxide and nitrous oxide readings and also give a false reading for the volatile anaesthetic.

CASE REPORT

Use of recombinant human erythropoietin to facilitate liver transplantation in a Jehovah's Witness

N. J. SNOOK, H. A. O'BEIRNE, S. ENRIGHT, Y. YOUNG AND M. C. BELLAMY

Summary

A 46-yr-old woman with rapidly progressing primary biliary cirrhosis presented for liver transplantation. The use of preoperative recombinant human erythropoietin enabled this to be achieved without prohibited blood products. Perioperative management of this patient and general principles of management of Jehovah's Witnesses undergoing major surgery are discussed. (*Br. J. Anaesth.* 1996; **76**: 740–743)

Key words
Liver, transplantation. Blood, erythropoietin. Complications, Jehovah's Witness.

Patients who are Jehovah's Witnesses are unable, for religious reasons, to accept blood (including predonated autologous blood) and several blood products. Major surgery in these patients is therefore challenging both to the surgeon and anaesthetist. Liver transplantation represents the acme of major surgery with considerable potential for blood loss. It involves division and re-anastomosis of major vessels, including the vena cava, is performed in patients with underlying liver disease and involves removal of the liver (anhepatic period) with a consequent obligatory coagulopathy and fibrinolytic tendency.

Case report

a 46-yr-old female Jehovah's Witness presented to the regional hepatology unit with a 4-yr history of lethargy and pruritis, and a 1-yr history of jaundice. She was tea-total and otherwise healthy with no past medical history of note. On examination she was icteric (serum bilirubin 51 μmol litre^{-1}) and well nourished. An increased anti-mitochondrial antibody titre was detected. Abdominal computed tomography and bone scan were normal. Magnetic resonance imaging was consistent with cirrhosis. A diagnosis of primary biliary cirrhosis was made. In view of the patient's religious beliefs no liver biopsy was performed because of the risk of bleeding.

At this time, liver synthetic function was relatively good, with a prothrombin time (PT) of 12 s and a serum albumin concentration of 30 g litre^{-1}. She therefore presented a dilemma. Her state of health at presentation placed her in a low-risk group for liver transplantation. With this clinical picture she could be expected to enjoy 2 yr of reasonable quality life before end-stage liver failure developed and therefore she did not need urgent transplantation. Waiting for end-stage disease, however, would imply deteriorating clotting function and general metabolic reserve, hence liver transplantation would be more hazardous. During counselling, expected disease progression, prognosis and treatment options were explained. After discussion with hepatologists, surgeons, anaesthetists and the Jehovah's Witness Hospital Liaison Committee, the patient decided to accept liver transplantation.

A blood products regimen acceptable to both the patient and the Jehovah's Witness Hospital Liaison Committee was established. This precluded transfused bank blood (either homologous or autologously pre-donated) and fresh frozen plasma. Platelets, factor concentrates, human albumin and modified fluid gelatin (Gelofusine) were allowed under the regimen. Continuous circuit cell salvage and reinfusion whereby scavenged blood was maintained in continuity with the patient's circulation was also permitted.

At the time of consideration for transplantation, haemoglobin concentration was 11.1 g dl^{-1}. Vitamin B_{12} and folate concentration were within the reference range. Human recombinant erythropoietin therapy (r-HuEPO) was commenced at a dose of 2000 iu s.c. for 5 days in every 7. Ferrous sulphate supplementation was given daily.

During r-HuEPO therapy she was reviewed initially twice weekly, then weekly to monitor treatment. Apart from mild headaches experienced in the first week of treatment, there were no other side effects. Hypertension was not observed.

Figure 1 shows the increase in haemoglobin concentration after commencement of r-HuEPO. Erythropoietin dose was reduced in 1000 iu day^{-1} when haemoglobin concentration reached 14 g dl^{-1} after 5 weeks of treatment. The patient was then scheduled for liver transplantation.

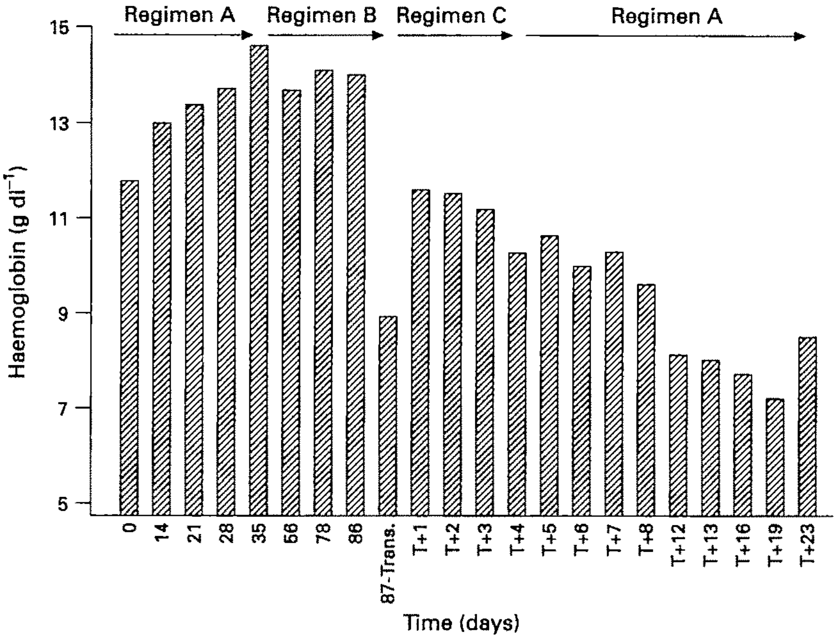

Figure 1 Increase in haemoglobin concentration in the liver transplant Jehovah's Witness after commencement of recombinant human erythropoietin treatment.

PEROPERATIVE MANAGEMENT

Twelve weeks after commencing erythropoietin, a suitable liver became available. The patient was admitted to hospital and prepared for theatre. Non-invasive monitoring was commenced and anaesthesia induced with midazolam 7.5 mg, alfentanil 7.5 mg and atracurium 50 mg. After tracheal intubation, the lungs were ventilated with desflurane in oxygen-enriched air. Anaesthesia was supplemented with alfentanil 3 mg h^{-1} and neuromuscular block was produced with atracurium 0.5 mg kg^{-1} h^{-1} [1]. Additional monitoring included a triple-lumen central venous catheter, mixed venous oximetric right-ejection fraction pulmonary artery flotation catheter, and a radial arterial cannula. An 18-French gauge percutaneous cardiac bypass cannula was inserted into the internal jugular vein and connected to a rapid infusion system (RIS) (Hemonetics, Braintree, MA, USA) [2]. This is standard practice for liver transplantation and provides access for venovenous bypass and rapid infusion of fluids (up to 1500 ml min^{-1}) in the event of acute loss. In this case only salvaged blood (infused in continuity with the patients circulation), crystalloid or colloid was used. An 18-French gauge bypass cannula was inserted surgically into the right femoral vein to allow venovenous bypass [3]. Dopamine 3 μg kg^{-1} min^{-1} and 4 % glucose in 0.18 % saline (70 ml h^{-1}) infusions were commenced and continued into the post-operative period according to our regimen [4].

An inverse-T abdominal incision was made. During the dissection phase (I), meticulous surgical haemostasis was achieved using argon beam coagulation. All bleeding was scavenged to a cell saver [5] and immediately washed and reinfused by RIS. This enabled salvaged cells to remain in continuity with the circulation. The liver showed early cirrhosis. Primary biliary cirrhosis was later confirmed on histology.

Coagulation was monitored using PT, activated partial thromboplastin time, thrombin time, fibrinogen concentration, platelet count and thrombelastography [6, 7]. At the beginning of the anhepatic phase (II) a bolus dose of tranexamic acid 1000 mg was given and an infusion commenced to prevent fibrinolysis. This dose has been found to reduce blood loss by 50 % [8, 9].

Haemoglobin concentration decreased from 10.7 g dl^{-1} in phase I to 8.9 g dl^{-1} in phase III. Much of this reduction resulted from aggressive haemodilution with colloid during phase I. Cryoprecipitate and platelets (8 u.) were administered after reperfusion. A total of 800 ml of salvaged blood was reinfused. Remaining fluid replacement consisted of modified fluid gelatin 3329 ml.

Surgery was completed uneventfully. After tracheal extubation in the operating theatre, the patient was transferred to the intensive care unit for overnight observation. Postoperative haemoglobin concentration was 10.8 g dl^{-1}, necessitating prophylactic venesection before discharge to the liver unit [10].

On the second day after operation, the patient developed an increased PT (99 s), oliguria and metabolic acidosis. Hepatic angiography and Doppler studies excluded a diagnosis of hepatic artery thrombosis. A provisional diagnosis of primary non-function was made [11]. Management was conservative, with venovenous haemodiafiltration (CVVHD) to control acidosis. Spontaneous improvement of PT forestalled listing for re-transplantation. Over the next 5 days, urine output improved and CVVHD was discontinued. During this time haemoglobin concentration remained stable at 8.4 g dl^{-1}. After another 10 days, erythropoietin was reduced to 1000 iu on alternate days and she was discharged home, exactly 1 month after transplantation.

At the 6-month follow-up she remained well, with a haemoglobin concentration of 11.5 g dl^{-1}. Her liver function tests had improved compared with results at hospital discharge (shown in parentheses): bilirubin 10 (44) µg ml, ALT 63 (96) iu ml^{-1} ALP 446 (629) iu ml^{-1} albumin 43 (37) g ml^{-1}.

Discussion

We have described a case of liver transplantation in a Jehovah's Witness when preoperative recombinant human erythropoietin was used to avoid perioperative blood transfusion. There is one previous description in the literature of liver transplantation in Jehovah's Witnesses [12]. This article was interesting both for its financial conclusions and the acceptance of plateletpheresis. This demonstrates the variability between different groups of Jehovah's Witnesses in their beliefs, and the importance of consulting Liaison Committees.

Jehovah's Witnesses present a special clinical and ethical problem. They believe that blood transfusion is forbidden and use scriptural passages in support of this view: "only flesh with its soul—its blood you must not eat" (Genesis 9: 3–4), "you must pour its blood out and cover it with dust" (Leviticus 17: 13–14), "abstain from fornication and from what is strangled and from blood" (Acts 15: 19–21) [13]. Jehovah's Witnesses will not accept red blood cells, whole blood, plasma, white cells and usually platelets. This includes pre-donation and transfusion with autologous blood, believing any blood removed from the body should be destroyed. Uninterrupted intraoperative cell salvage systems are accepted by some individuals, as are immunoglobulins, albumin and clotting factor concentrates. Consultation with the local advisory body is therefore essential to establish individual beliefs and wishes. Witnesses will accept solid organ donation.

Major surgery on Jehovah's Witnesses requires careful planning and of all procedures liver transplantation is the most hazardous [12]. Bontempo, Lewis and Van Thiel quote median red blood cell transfusion requirements of 10 u. in an unselected liver transplant population [14] (although in some cases it greatly exceeded this value). Improvements in surgical haemostasis using argon beam coagulators, cell salvage and improved understanding of coagulopathy and fibrinolysis [9] have reduced demand for red cells, but transfusion-free liver transplantation still presents a major challenge.

Timing of the procedure was crucial. In our centre, patients presenting with primary biliary cirrhosis are usually considered for transplantation only when serum bilirubin concentration exceeds 100 µmol litre^{-1} and hepatic synthetic function is impaired. Associated coagulopathy however could have increased the perioperative risk. A decision to offer transplantation relatively early in the clinical course was therefore made.

In anticipation of major blood loss, we decided to increase our patient's haemoglobin concentration to the highest preoperative value safely achievable. Erythropoietin is a circulating glycosylated polypeptide. Recombinant human erythropoietin (r-HuEPO; manufactured using Chinese hamster ovarian cell lines) acts on bone marrow selectively to stimulate erythropoiesis. This leads to an increased packed cell volume (PCV) and reticulocyte count. Side effects reported include allergic reactions, hypertension and convulsions. Iron deficiency is prevented with supplementation [15].

Erythropoietin has been used to facilitate autologous blood transfusion before elective surgery [16]. Its use in Jehovah's Witnesses has been reported widely. Koestner and co-workers [17] first used it in 1990 to treat severe anaemia in a major trauma victim, increasing PCV from 15% to 30% after 18 days. Since then it has been used to treat a child with resistant anaemia [18] and before operation in patients requiring cardiac surgery [19].

Our patient's haemoglobin concentration increased from 11.8 to 14.1 g dl^{-1} over 11 weeks. The intraoperative reduction by 4 g dl^{-1} to 10.7 g dl^{-1} was more manageable than a predicted reduction to 6 g dl^{-1} had no measures been taken before operation. Treatment with r-HuEPO was without adverse effects.

During operation we aimed to minimize blood loss and maximize cell salvage by limiting the use of laparotomy swabs within the operative field. Aggressive early haemodilution reduced the cell content of shed blood. Optimizing coagulation was imperative and based predominantly on thrombelastography. Although other centres have used plateletpheresis [12] more on an economic basis than clinical need, our patient had decided to accept platelets which she received on graft reperfusion. During the anhepatic and reperfusion stages of transplantation, there is an imbalance between the activators and inhibitors of fibrinolysis leading to activation of fibrin and an increase in fibrinolysis. This imbalance can be redressed pharmacologically with tranexamic acid which was administered prophylactically during the anhepatic phase at this has been shown to decrease overall blood loss by 50% [8, 9].

Blood conservation continued into the postoperative period. Chernow [20] demonstrated that iatrogenic anaemia caused by overzealous blood sampling is reduced by microchemistry (restricting samples to a maximum of 4 ml per day) and limiting line dead-space, allowing all haemotological and biochemical analyses.

Primary non-function of the liver occurs in up to 10% of cases. This is usually associated with preservation injury [21]. It is relatively uncommon with short preservation times in well-perfused grafts, so it is surprising that primary non-function occurred in this case. Fortunately, it was self-limiting and did not necessitate regrafting. This could have been associated with poor outcome.

EQUIPMENT

Validation of the Edslab dual lumen oximetry catheter for continuous monitoring of jugular bulb oxygen saturation after severe head injury

M. J. SOUTER AND P. J. D. ANDREWS

Summary

Continuous jugular bulb venous oximetry has been validated previously for periods of up to 12 h after calibration. We assessed a new Edslab venous oximetry catheter in 15 patients with brain injury in the intensive care unit. After insertion into the jugular bulb, the catheter was calibrated using a laboratory co-oximeter. Subsequent comparisons were made at varying intervals (range 20 min to 100 h); 78 paired samples were obtained during periods of stable recordings. Estimation of haemoglobin saturation by the methods correlated well ($r^2 = 0.97$, $P < 0.0001$). Mean difference(d) was small (0.28% (SD 2.35%)) and limits of agreement ($d \pm (\text{SD} \times 1.96)$) were acceptable (−4.88% to 4.32%). There was no appreciable drift and there was negligible bias. This catheter did not suffer from problems of light intensity described with other systems, and it provided acceptable accuracy for clinical use for periods of up to and exceeding 24 h after calibration. (*Br. J. Anaesth.* 1996; **76**: 744–746)

Key words

Brain, injury. Brain, ischaemia. Measurement techniques, oximetry. Monitoring, oxygen saturation. Oxygen saturation. Equipment, catheters oximetry.

Continuous jugular bulb venous oximetry has developed into a valuable monitoring tool in the care of patients after head trauma. A cannulation technique and assessment of equipment accuracy have been described [1]. A limiting factor was that the apparatus was valid for periods of up to 12 h after *in vivo* calibration. This apparatus used a 40-cm flexible reflectance spectrophotometric catheter which had been designed for use within the umbilical artery in neonatal intensive care. The Edslab 4-French gauge catheter (Baxter Healthcare Corporation, Irvine, CA, USA), designed for venous oximetry, has been introduced recently.

This catheter offers several design advantages in that it has improved distance measurement markings and uses a firmer material which reduces flexing and kinking, but permits insertion without perforation of vessel walls. It is coated with an antimicrobial heparin coating and is also reportedly less subject to drift than catheters described previously.

We performed a prospective study in patients with severe head injury in the intensive care unit comparing *in vivo* measurements with samples aspirated from the jugular bulb measured *in vitro* with a Corning 270 laboratory co-oximeter (Ciba-Corning Diagnostics Ltd, Halstead, Essex, UK).

Methods

We evaluated the catheter in 15 patients with brain injury. Ethics Committee approval was obtained in advance for insertion and validation of jugular bulb catheters, without informed consent, in this group of patients.

Patients were referred to the Regional Neurosurgical Unit at the Western General Hospital, Edinburgh, from Edinburgh and Southeast Scotland. Eleven patients had suffered traumatic head injury and four had suffered a subarachnoid haemorrhage of World Federation of Neurological Surgeons grade 4 or 5. All subjects scored less than 8 on the Glasgow coma score on their last neurological examination, before muscle paralysis and artificial ventilation of their lungs for CT scan, any requisite surgery and insertion of an intraparenchymal intracranial pressure monitor. They were then transferred to the intensive therapy unit where they were sedated, paralysed and their lungs ventilated to mild hypocapnia (Pa_{CO_2} 3.5–4 kPa).

All treatment and care followed standard procedures agreed within our unit. Catheters were inserted using the Seldinger technique in a manner similar to cannulation techniques described previously. A compression test was performed to identify the dominant internal jugular vein and then the vein was entered percutaneously, lateral to the carotid artery at the level of the cricoid cartilage, directing the needle towards the external auditory meatus [1].

An important difference was that, rather than using a Vygon 14-gauge Leadercath cannula as an introducer (which is not haemostatic and must be withdrawn subsequently), the catheter was inserted using an 18-gauge Cook needle and a Daig 7-gauge Fast-Cath introducer, which has a Buorst–Tuohy

M. J. SOUTER, MB, CHB, FRCA (Department of Clinical Neurosciences); P. J. D. ANDREWS, MD, FRCA (Department of Anaesthesia); Western General Hospital, Crewe Road South, Edinburgh EH4 2XU. Accepted for publication: December 21, 1995.

haemostatic valve. The fibreoptic catheter was covered by a Baxter catheter contamination shield. The introducer is sutured to skin, remaining within the vein and, with the sheath, allows manipulation of the catheter after insertion to maintain accuracy, in a manner similar to that of pulmonary catheter insertion. This arrangement has not been reported previously for insertion into the internal jugular vein.

Catheters were inserted 15–20 cm, depending on patient size. Satisfactory catheter tip position was checked radiologically, ensuring that the tip was above the lower border of the first cervical vertebrae and was not kinking. This reduces extracranial contamination from the facial vein and reflectance errors. The catheter was connected to a Baxter Edwards Explorer System (Baxter Healthcare Corporation, Irvine, CA, USA) which contains an optical module and signal processor. The reading obtained was then calibrated against jugular venous samples analysed by a Corning 270 co-oximeter.

Subsequent comparisons were made at various intervals (mode 195 min; range 20 min to 100 h). If differences between catheter and co-oximeter values exceeded 5 %, the catheter was recalibrated. Samples were obtained slowly during periods of stable recordings (< 3 % oscillation).

Co-oximeter and catheter measurements were compared using linear regression and the method comparison technique recommended by Altman and Bland [2].

Results

Paired recordings ($n = 78$) were compared between 15 catheters and the co-oximeter using the difference in jugular saturation, the average difference and the SD of this difference to assess agreement between methods of measurement. These were also compared against time since the previous calibration, illustrating drift (fig. 1).

Forty-four samples were obtained at intervals of up to 24 h and 34 samples at intervals of 24–100 h. There was no appreciable drift, with accuracy being maintained, in some cases, to 3 or 4 days without recalibration.

There were only two points at which catheters required recalibration because they exceeded the 5 % agreement limits (errors of 7 % and 6 %, respectively). Estimation of haemoglobin saturation by the two methods correlated well ($r^2 = 0.97$, $P < 0.0001$) (fig. 2). Mean difference was small (−0.28 % (SD 2.35 %)) and limits of agreement (mean − (SD × 1.96)) were acceptable clinically (−4.88 % to 4.32 %).

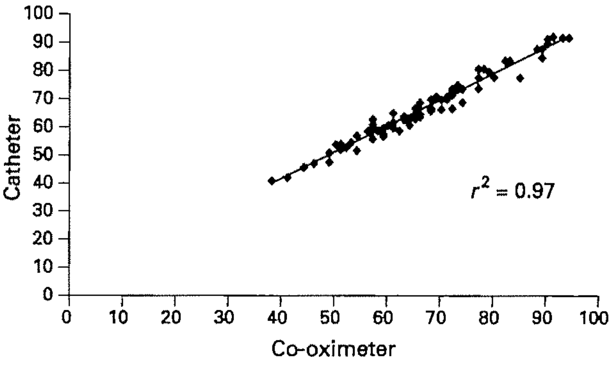

Figure 2 Co-oximeter *vs* catheter haemoglobin saturation readings.

Individual catheter mean differences were all within the limits of agreement (fig. 3). There was negligible bias on a method comparison plot (fig. 4), with 95 % confidence intervals of bias ($d \pm (t \times \text{SEM})$) of 0.25 % to −0.81 %.

Mean change in haemoglobin concentration over the period of monitoring was 0.68 (range 0–4.8) g dl^{-1}. There was no relationship between changes in haemoglobin concentration and catheter/co-oximeter measurement differences.

Discussion

Continuous jugular venous oximetry has been criticized previously because of the high degree of drift and requirement for frequent recalibration [3]. We have noted significant errors even with 12-hourly calibration. This problem was aggravated by inability to rectify position after misplacement or slippage. The advantage of the previous Oximetrix 3 system was that it was a triple wavelength system providing two light intensity ratios with a theoretically superior accuracy. A large number of the readings are discarded however because of light intensity alarms and drift errors, which is not surprising, given the limited venous flow present.

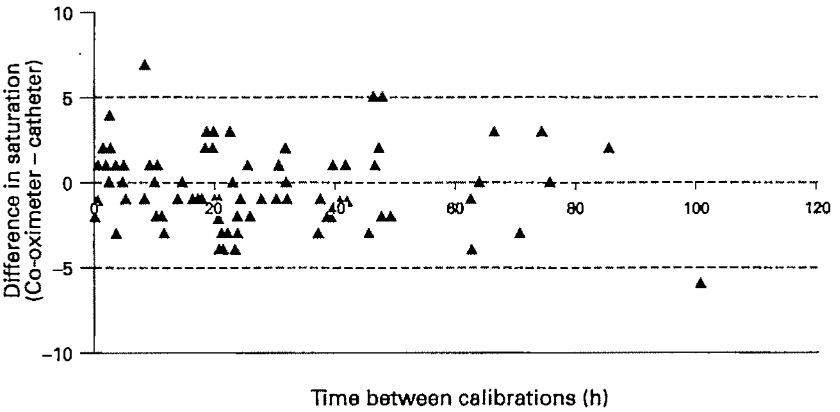

Figure 1 Difference in haemoglobin saturation between the co-oximeter and catheter with time.

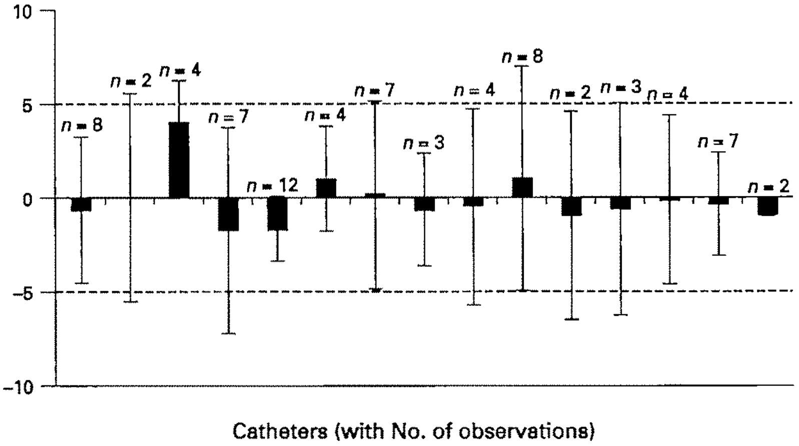

Figure 3 Mean difference (2 SD) in saturation between the co-oximeter and individual catheters.

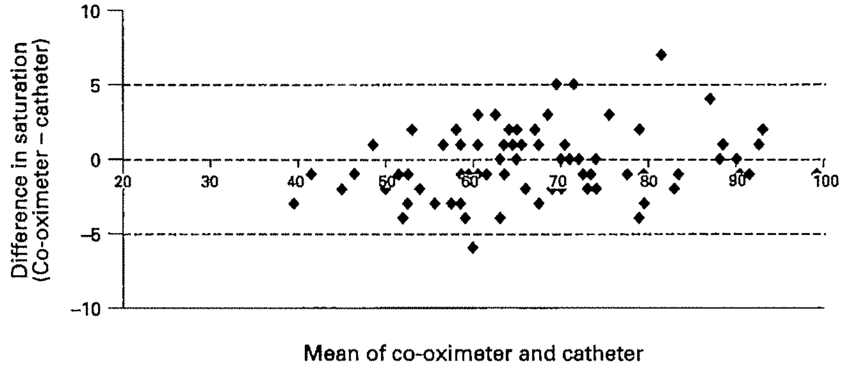

Figure 4 Method comparison plot of difference in haemoglobin saturation between the co-oximeter and catheter.

The Edslab catheter is a dual wavelength system which relies on haemoglobin concentration or packed cell volume being entered during calibration. These values are unlikely to change dramatically from day to day in this patient population and the system appears to be tolerant of minor fluctuations with the benefit of a greatly reduced degree of drift and relative independence of light intensity in a poor flow environment.

The Edslab catheter provides acceptable degrees of accuracy for clinical use for periods up to and exceeding 24 h after *in vivo* calibration. We are unable to give a threshold of time over which readings are invalid or suspect. Theoretically, significant changes in packed cell volume may introduce error into the system and should probably necessitate recalibration; this process requires the current laboratory measured haemoglobin concentration or packed cell volume. The mean change in haemoglobin concentration per patient was small (0.68 g dl^{-1}). However, we have observed changes of up to 4 gl dl^{-1} in haemoglobin concentration between measurements without loss in accuracy. It is also true that this patient population, when resuscitated, usually maintain a stable packed cell volume.

Nevertheless, we would suggest that daily recalibration is an easy compromise and within the bounds of maintained accuracy. For two catheters there were only two comparisons made after the initial calibration. However, in both cases the time interval was greater than 24 h and on that basis the comparisons made indicated a satisfactory performance over time.

The identification of a suitable introducer allows manipulation of catheter position and maintenance of accurate readings. In conjunction they represent a significant improvement in the quality of clinical monitoring.

CORRESPONDENCE

Ventilatory response to carbon dioxide

Sir,—Saito and colleagues examined the influences of administration of morphine and lignocaine in the extradural space on the ventilatory response to carbon dioxide in female patients [1]. One of their observations was that ventilatory carbon dioxide sensitivity decreased significantly after morphine.

Saito and co-workers used a modification of Read's rebreathing method to obtain the ventilatory response to carbon dioxide [2]. Read introduced his method in 1967 which consists of rebreathing from a small rebreathing bag (4–6 litre) filled with 7% carbon dioxide in oxygen. The modification by Saito and colleagues was the use of a 10-litre rebreathing bag. Features that are observed when rebreathing is carried out in this way are [3–5]: end-tidal $P\text{CO}_2$ ($P\text{E}'_{\text{CO}_2}$) increases in a step-wise manner and rebreathing is initiated at a $P\text{CO}_2$ value close to that of mixed venous blood; rapid equilibrium is established between the $P\text{CO}_2$ of end-tidal, mixed venous and arterial blood, the gas in the rebreathing bag, and presumably also brain tissue $P\text{CO}_2$, all increase with the same rate of increase; ventilation ($\dot{V}\text{E}$) increases linearly in time and the $\dot{V}\text{E}$–$P\text{E}'_{\text{CO}_2}$ relation is linear; the rate of increase in $P\text{E}'_{\text{CO}_2}$ is independent of the ventilatory response; Read observed in an initial study in three subjects that the slopes of the $\dot{V}\text{E}$–$P\text{E}'_{\text{CO}_2}$ responses obtained from rebreathing and a steady-state method were not different.

Read's method allows acquisition of carbon dioxide sensitivity with minimal discomfort to the subject within a short period of time. Despite its popularity, there are several misconceptions regarding Read's rebreathing technique, especially when considering the effects of drugs on ventilatory control. Several recent studies have shown that carbon dioxide sensitivity from rebreathing exceeds steady-state carbon dioxide sensitivity by a factor of 2 [6–8]. The larger carbon dioxide sensitivity obtained from Read's method is explained by the increase in brain blood flow on increasing arterial $P\text{CO}_2$, resulting in a decreased cerebral venous to arterial gradient at steady-state (see [6]). Abolishing the mixed venous–arterial $P\text{CO}_2$ gradient to zero is insufficient to reduce brain tissue–arterial $P\text{CO}_2$ sufficiently close to zero. The mixed venous to arterial $P\text{CO}_2$ gradient is approximately 0.8 kPa in humans, while the jugular venous to arterial $P\text{CO}_2$ gradient is 1.5–2.0 kPa [9]. In contrast with the steady-state method, the measured carbon dioxide sensitivity from Read's rebreathing method depends on the magnitude of the initial step increase in $P\text{E}'_{\text{CO}_2}$ at the start of rebreathing and, to a lesser extent, on the subsequent rate of increase in $P\text{E}'_{\text{CO}_2}$ in time [9]. The larger the initial step increase in $P\text{E}'_{\text{CO}_2}$, the larger the measured carbon dioxide sensitivity. This is important when considering the effects of drugs that affect ventilatory control such as morphine. Ventilatory depression and the subsequent increase in $P\text{E}'_{\text{CO}_2}$ changes (i.e. decreases) the magnitude of the initial step increase in $P\text{E}'_{\text{CO}_2}$ at the start of rebreathing and consequently decreases the slope of the $\dot{V}\text{E}$–$P\text{E}'_{\text{CO}_2}$ response curve. This decrease may then reflect the change in initial conditions and not a drug effect on chemoreceptors, respiratory integration centres or the link between brainstem and respiratory movements.

However, an effect at these sites cannot be excluded. Read's rebreathing method yields results that are difficult and sometimes impossible to interpret. Bourke and Warley [8] showed this elegantly in a study comparing the steady-state method and Read's rebreathing method during i.v. administration of morphine. Morphine caused a decrease in the rebreathing carbon dioxide response slope, while the steady-state carbon dioxide response slope was shifted to higher $P\text{E}'_{\text{CO}_2}$ levels without any change in slope. They concluded that this parallel shift is specific to drugs acting on opioid receptors. Changes in overall and brain metabolism, steady-state brain blood flow and brain blood flow reactivity to carbon dioxide affect the rebreathing carbon dioxide response slope differently from the steady-state carbon dioxide response slope [9]. For example, drugs that reduce brain metabolism and steady-state brain blood flow cause a reduction in the rebreathing carbon dioxide response compared with the steady-state carbon dioxide response slope [9].

It is possible that the decrease in the $\dot{V}\text{E}$–$P\text{E}'_{\text{CO}_2}$ response slope after extradural morphine in the study of Saito and co-workers [1] is related to the above mentioned items.

In summary, we plead for the use of the steady-state method instead of Read's rebreathing method to study the effects of drugs on ventilatory control.

Sir,—We recognize the expertise of Drs Dahan and Berkenbosch in the field of ventilatory control and thank them for their valuable comments. We agree that Read's rebreathing technique (RB) is associated with results that are affected by various factors other than the central chemoreceptors and that the steady-state (SS) technique is suited to examine the effects of drugs on ventilatory control. However, the SS method did not fit in with our study design. The aim of our study was to investigate if extradural administration of lignocaine increased the risk of ventilatory depression induced by extradural morphine, which had been well established [1]. In contrast with morphine, transient effects of extradural lignocaine require a more strict study design regarding its baseline and use of a method that can be performed easily. While a measurement with RB can be completed within 6 min, SS takes more than 20 min to perform. Indeed, most previous studies examining the effect of extradural lignocaine have measured the ventilatory response 20–30 min after administration of local anaesthetic using RB [2]. One might argue that we could have used SS if a continuous infusion had been taken. However, on ethical grounds we could not take a longer time before surgery.

In interpreting our results, we should consider that the parallel shift of the carbon dioxide response curve without the decrease in slope in the SS method is specific to drugs acting on opioid receptors [3]. However, we believe that we can compare the ventilatory effects of extradural morphine and the combination of morphine and lignocaine, and conclude that extradural co-administration of lignocaine does not increase the risk of respiratory depression associated with morphine because the two groups include the same modulatory factors, as pointed out by Drs Dahan and Berkenbosch.

It is undeniable that we should choose the best technique available to obtain reliable results that are not contaminated by other undesirable factors in a scientific study. However, it is as important to use a technique that is practicable in a study using real patients.

Improving preoxygenation

Sir,—McGowan and Skinner are to be congratulated on their attempts to reproduce in their study some of the factors which confound our efforts at optimal preoxygenation in clinical practice [1]. It is reasonable to suppose that a leak around the face mask leads to less efficient denitrogenation of the lungs, but it is pleasing to see it demonstrated. However, reading this article prompted several questions.

First, how did the authors determine the order of the six "preoxygenations" performed by each volunteer? Were they randomized and, if not, would this tend to introduce an element of bias in that the subject's breathing pattern might alter during the course of the sequence? Did the subjects receive any specific training or instruction on what to do when breathing from the face mask? In my experience, when a patient is requested to "breathe normally" this may result in something quite abnormal, and the instruction to "take slow, deep breaths" may be more helpful. In a study such as this it might have been preferable to standardize on a particular minute volume, or at least have some estimate of peak inspiratory flow.

Second, do the authors think that sampling the gas stream further from the mouth might have improved their study? It is possible to introduce the tip of the sampling line into the nasopharynx, similar to Ooi, Joshi and Soni [2]. This would then have made it unnecessary to clamp the subjects' noses, more closely resembling clinical practice.

Third, while I can understand the choice of the Mapleson A system, why was a 4-litre reservoir bag used? Were any comparisons made between this and the standard 2-litre bag before selecting the latter? This is not usual clinical practice but, if it produces better results, perhaps it should be.

Fourth, what, if anything, was different about the subjects who did not reach an end-tidal oxygen concentration of greater than 0.9?

It is clearly important to use any manoeuvre which improves the efficiency of preoxygenation; substituting their standard face mask for another design (for instance the Everseal) might have produced better results by fitting certain faces more closely, and the authors may like to examine this. Berthoud, Read and Norman (using a fresh gas flow of 8 litre min^{-1}) showed that the Bain system was less efficient [3] and although more modern machines can deliver much higher flows, I have seen many trainees believing they are preoxygenating the lungs of patients with 6–8 litre min^{-1} of oxygen via the Bain system. The face mask seal is clearly important, but other factors need to be addressed if we are to improve the application of this vital technique.

3. Berthoud M, Read DH, Norman J. Preoxygenation—how long? *Anaesthesia* 1983; **38**: 96–102.

Sir,—It is clearly correct to say "it is reasonable to suppose" that a leak impairs preoxygenation. Our aim was to quantify the leak, not to embark on a wide ranging investigation of preoxygenation. In the light of this, the variations from normal practice are less important and were introduced after a pilot study to improve reproducibility.

Either oral breathing and sampling or nasal breathing and sampling were needed for reproducibility and we opted for the former. Ooi, Joshi and Soni [1] suggest that the latter would work equally well. A nasal sampling tube would probably have been less acceptable to subjects.

The six episodes of preoxygenation performed with each volunteer were carried out in the same increasing order of inspired oxygen concentration; following this, two experiments were performed with sub-optimal face mask seals and 100% oxygen. It is unlikely that this sequence introduced any bias as at least 15 min breathing room air were allowed for the individual to return to the pre-experimental state. Subjects were asked to place the face mask against their faces to produce a good seal, they were not required to hold it thereafter. Each subject was told to "breathe normally" and it was suggested that they close their eyes in order to make themselves feel more relaxed. The suggestion of standardizing minute volume would certainly lead to abnormal breathing; each subject has an individual natural minute volume. Peak inspiratory flow measurements may give an indication of abnormal breathing patterns but they would need validation against controls which would similarly be influenced by the abnormal environmental factors surrounding experiments such as this. Similar ventilatory frequencies were observed for each subject during each of the six preoxygenations.

Thus, although our study did not wholly reflect current UK clinical practice, we believe that we have quantified the magnitude of leaks with a sub-optimal mask fit and shown that they are appreciable.

The other questions, such as use of the "Everseal" masks or larger reservoir bags, clearly merit investigation in the future, but are not central to our work.

Serotonin in pre-eclampsia

Sir,—We read with interest the review article by Mushambi, Halligan and Williamson on recent developments in the pathophysiology and management of pre-eclampsia [1]. However, there was no mention of the possible role of serotonin which we believe may be important.

We suggest that serotonin, released from platelet aggregates, stimulates 5-HT_2 receptors causing generalized vasospasm and subsequent endothelial damage. Platelets could be attracted by embolic trophoblastic fragments which have been found in increased amounts in the venous circulation of women with pregnancy-induced hypertension compared with non-hypertensive controls [2, 3]. This role of serotonin is supported by Filshie and colleagues [4] who demonstrated increased concentrations of the serotonin metabolite 5-hydroxyindole acetate (5-HIAA) in the urine of pre-eclamptic patients. In addition, ketanserin, a 5-HT_2 receptor blocker, has been used successfully in the treatment of pre-eclampsia [5, 6]. Clearly, the role of 5-HT_2 receptor blockers in the management of pre-eclampsia and eclampsia requires further study.

Cost of volatile agents

Sir,—In 1992, Dion published a formula by which the cost of volatile agent use could be calculated [1]. I have recently had cause to use this for newer agents and UK prices. Colleagues may find it of use when dealing with their pharmacies, etc. The cost is calculated by:

$$\frac{PFTMC}{d2412}$$

where P = agent concentration (%), F = fresh gas flow (litre min^{-1}), T = time (min), M = molecular weight, C = price of the agent (£ ml^{-1}) and d = density of liquid agent (g ml^{-1}).

Using values taken from Dion, the British National Formulary [2] and the manufacturers, I have calculated that at a fresh gas flow of 1 litre min^{-1} for 1 h, the costs, in pounds sterling, at different concentrations are those shown in table 1.

Table 1 Costs of different volatile agents

	Concentration	
	1 %	1 MAC (adult in 100 % O_2)
Halothane	£0.172	£0.148
Enflurane	£0.428	£0.812
Isoflurane	£1.193	£1.431
Sevoflurane	£1.445	£3.189
Desflurane	£0.551	£3.306

Alternatively "gas induction" using 8 % sevoflurane at a fresh gas flow of 6 litre min^{-1} for 1 min costs £1.16p.

Effect of transdermal hyoscine on nausea and vomiting

Sir,—I read with interest the recent article by Honkavaara on the effect of transdermal hyoscine on nausea and vomiting during and after middle ear surgery under local anaesthesia [1].

It was interesting, although not surprising, that the incidence of intra- and postoperative nausea and vomiting was lower in the treatment group (receiving prophylactic transdermal hyoscine) than in the placebo group, who received no prophylactic antiemetic treatment, as the antiemetic properties of hyoscine are already well known and documented [2, 3].

Honkavaara makes the assumption that the reduction in nausea and vomiting in the hyoscine group, in relation to motion sickness, may result from specific inhibition of the postsynaptic potential in the neurones of the vestibular nuclei. This may well be so, but one fact appears to have been overlooked in the design of the study. The two groups received preoperative oxycodone and intraoperative fentanyl, both of which have emetic side effects. The placebo group therefore received potentially emetic drugs without prophylactic antiemetic treatment. This would influence the incidence of nausea and vomiting in its own right, and the assumption that the reduction in nausea and vomiting in the hyoscine group was caused by reduced stimulation of the vestibular apparatus cannot be validated. One can only speculate on how the results would have been affected if another group had been included, receiving prophylactic antiemetic therapy known not to be as effective as hyoscine in motion sickness, such as metoclopramide.

R. N. Foster
Department of Anaesthesia
Hope Hospital

3. Bailey PL, Streisand JB, Pace NL, Bubbers SJ, East KA. Transdermal scopolamine reduces nausea and vomiting after outpatient laparoscopy. *Anesthesiology* 1990; **72**: 977–980.

Sir,—I agree with Dr Foster that one of the causes of multifactorial postoperative nausea and vomiting (PONV) after middle ear surgery might be the emetic effect of the opioids used. However, I would hesitate to ascribe significance to opioids in this type of surgery causing physical stimuli to the inner ear. The amount of opioids used (oxycodone or fentanyl) did not predict PONV in middle ear surgery, as assayed by logistic regression analysis [1, 2].

In patients undergoing middle ear surgery, the noise from the drilling and suctioning exceeds 107 dB(A) in the mastoid cavity and furthermore, low frequency vibrations caused by the slowly rotating cutting burr can lead to a Tullio-phenomenon-like state [2]. In the Tullio phenomenon, sound pressure induces electrical potentials equivalent to cochlear microphonics from different receptors of the vestibular labyrinth leading to vestibular stimulation [3]. Patients with chronic otitis media or cholesteatoma are more susceptible to the Tullio phenomenon than healthy controls [3].

Dr Foster suggests that another group receiving metoclopramide should be included in the design of the study. This seems to be unjustified on the following grounds. Even though several studies support the efficacy of metoclopramide in PONV, there is at least an equal number of reports which do not confirm this result. Rowbotham concluded in his review [4] that i.v. administration of metoclopramide at induction appeared to be ineffective against PONV.

Thus the results presented in this letter and in earlier reports [1, 2] suggest that physical stimuli resulting in vestibular dysfunction are the main cause of the emetic episodes associated with ear surgery. The contributing effect of opioids on PONV, possibly sensitizing the vestibular system, is unclear, but it should be of equal intensity in both the placebo and hyoscine groups because of the same amount of opioid received by both groups.

Gastric tonometry

Sir,—In a recent letter [1], Dr Fiddian-Green stated that an article written by us [2] was deficient and misleading. In support of his allegations Dr Fiddian Green cited three letters [3–5]. None of these letters was written by him at the time, and none found our article either "deficient" or "misleading". Our article clearly states that the purpose was to "...investigate the association between pH_i and other measures of metabolic acidosis..." by examining correlations between measurements. The numbers of patients involved were too small to make statements concerning any predictive effect, and no such claims were made. All three letters erroneously implied that this was the purpose of our study. Also, the letters suggested that there might be some patients in whom measurement of "intramucosal" pH might provide additional information. We made the same point, stating that we are unable to "...exclude the possibility that there are some patients with selective splanchnic ischaemia not reflected by systemic acidosis...". This hardly represents deficiency or an attempt to mislead.

Dr Fiddian-Green [1] went on to describe two studies [6, 7] which showed results contradictory to ours. He stated that these studies were more definitive, but did not mention others which disagreed with aspects of their results. Maynard and colleagues [6] showed that intramucosal pH was a better predictor of outcome than base deficit. However, continued data collection from the same institution, recording the same variables, has not confirmed the original findings. A retrospective analysis of a clinical database of 214 patients admitted to intensive care [8] showed that by 12 h after admission, base deficit was significantly different between survivors and non-survivors. This difference was found only for intramucosal pH at 24 h. Furthermore, analysis of ROC curves showed that discrimination by intramucosal pH was no greater at any time than measurement of base deficit. The authors concluded that "the routine measurement of [intramucosal] pH_{im} in clinical practice does not contribute additional information about likely outcome over and above that available from the simultaneous measurement of base excess and arterial pH".

In the careful study of Gutierrez and colleagues [7], three data points were collected for 21 patients, while investigating the effect of dobutamine on intramucosal pH. They did not specifically study the correlation between the variables, but the data showed that an increase in the mean value of intramucosal pH after infusion of dobutamine was not accompanied by an increase in the mean value for base deficit. Interestingly, a more recent study [9] on the effects of dobutamine on intramucosal pH has shown contrasting results, although the results of blood-gas analysis were not given. In this study dobutamine reduced intramucosal pH, particularly in patients who already had low intramucosal pH and low cardiac output. While the two carefully conducted studies quoted by Dr Fiddian-Green [6, 7] clearly suggested results different from our own, it is unclear as to which of these studies is the more "definitive".

Measurement of competence

Sir,—Ellis's editorial [1], using the stimulus of Kestin's application of cusum analysis in the assessment of training [2], had me nodding in agreement until the concluding paragraph: "A quantitative approach to *education* is overdue. In the past there has been too much reliance on examinations as the only guide to the acquisition of *knowledge*." (My italics.) Training is not education; skills are not knowledge [3]. McManus listed the differentiating characteristics. For a course intended to educate, competency is not easy to assess, nor is the content of the course readily definable in any core curriculum. Training can be taught by restrictive methods, without insight, and the content of the course is readily put into compartments and tested in parts.

Before we go further down the road of syllabuses and structured training, we should stop to ask if we are training or educating.

BOOK REVIEWS

600 MCQs in Anaesthesia: Clinical Practice, 2nd Edn. N. W. GOODMAN AND C. JOHNSON. Published by Churchill Livingstone, London. Pp. 285; indexed. Price £12.50.

This is the second edition of an MCQ book first published in 1987 and is designed for those preparing for the final part of the FRCA. It covers the subjects of anaesthesia, medicine and surgery. Although many of the subjects overlap with the primary FRCA (that replaces the old part 1), the material is not appropriate for those preparing for that examination.

There is a useful section at the beginning of the book on technique, giving helpful advice on strategies for answering MCQs and on self-testing. The book consists of 20 mock papers with 30 stem questions of five parts each. The length of these "papers" is designed so that they can be completed in 45 min, which is an appropriate period to find for private study. The answers are well separated from the questions and include some explanation.

This book is a considerable improvement on the first edition that contained a number of questions that had become outdated. The new edition also contains fuller explanations to the answers, those in the earlier edition being rather limited. Although the book is designed for mock MCQ practice, there is an index of subjects that also allows for its use as a revision aid and to identify areas requiring further study.

This is a useful book for those preparing for the final FRCA (old part 3), both for practising MCQ technique and as a study aid. I would recommend it to them.

J. Raphael

Regional Anesthesia: An Atlas of Anatomy and Techniques. M. B. HAHN, P. M. MCQUILLAN AND G. J. SHEPLOCK (editors). Published by Mosby, St Louis, USA. Pp. 311; indexed; illustrated. Price £99.50.

The past decade has seen a veritable explosion in the number of books available to inform the practitioner of regional anaesthesia and any new product must offer something additional to the existing volumes. This book has achieved this because it is based on the work of the third editor, George Sheplock, who has combined traditional anatomical dissection with modern imaging techniques and computer-based display methods to build three-dimensional pictures. The application of these to regional anaesthesia is entirely appropriate because it is important that the practitioner thinks beyond the two-dimensional surface through which the needle is inserted and considers the structures that are encountered as the needle tip is advanced. This concept should apply as much to those structures that should *not* be encountered, as to those that should!

Two types of illustrations are used commonly. The first is a pair of pictures, one a traditional anatomical section and the other an exactly corresponding computer-enhanced and labelled image of the same section. The second illustrative method is to superimpose an anatomical dissection on a clinical photograph to the same scale to create an anatomical "window". The former method works well, but I am less impressed with the latter, perhaps because the size of the "window" tends to be rather small. However, a beginner might find them more useful. There are many other, more traditional type illustrations and many (clinical photographs and line diagrams) are of such a high standard that I wonder if concentrating on these more traditional methods would have been more successful. The gold standard in this area of publishing is Eriksson's *Handbook,* a work which is now nearly 30 years old, but for all its modern illustrative methods this book still fails to reach that standard of clarity of illustration.

In a work presented as an atlas, text is clearly of secondary importance, but in regional anaesthesia the "do's and don'ts", and answers to questions such as "how, why and when" are just as important as "where". Each chapter describing an individual block technique has a short section of text, all by acknowledged experts in the field of regional anaesthesia, but there is rarely sufficient information to provide all the necessary instruction and knowledge. There are two short introductory chapters, one on pharmacology and the other on general guidelines for practice. These add to the value of the volume, but are not comprehensive and the book would have been better produced as an atlas of anatomy for regional block rather than as an instructional manual. If it is approached as a source of helpful anatomical illustrations it works well. The quality of illustration and book production is high, but is reflected in the price. Many teachers of regional anaesthesia may find it useful to have a copy, but I doubt if it merits a place in the departmental library, particularly as some of the illustrations depicting needle insertion (e.g. stellate ganglion block) do not convey the correct approach and none depict appropriate aseptic technique. I appreciate the difficulties, but it is possible to produce informative pictures with drapes, etc., in place.

J. A. W. Wildsmith

Essentials of Anaesthetic Equipment. B. AL-SHAIKH AND S. STACEY. Published by Churchill Livingstone, Edinburgh. Pp. 147; illustrated. Price £20.00.

This is a beautifully designed and produced book of size 7½ × 9½ inches in triple column format. The text is lavishly illustrated with diagrams and colour photographs of high quality. Although many colour illustrations are small, they are perfectly clear, with the odd exception (e.g. fig. 10.18). The cost of the colour printing has been met by several medical companies, otherwise the price of production would have been prohibitive.

The text is easy to read and consists of short numbered paragraphs of short sentences. Topics covered include: medical gas supplies; the anaesthetic machine; scavenging of gases and vapours; breathing system; tracheal and tracheostomy tubes and airways; masks; laryngoscopes and tracheal intubation equipment; lung ventilators; humidification; monitoring; pain management and regional anaesthesia; and equipment used in intensive care. There are two appendices, both authorized by the Association of Anaesthetists of Great Britain and Ireland (AAGBI). The first is the elements of *Checklist for Anaesthetic Machines* published in 1990, and the second is their *Recommendations for Standards of Monitoring during Anaesthesia and Recovery* published in 1988. Presumably the revised 1994 version of the latter came too late for inclusion in this book. Nevertheless, only the very basic main points of the summary of "monitoring" are included in the appendix and not to have provided a more comprehensive account gives a poor impression of the input of the AAGBI into such an authoritative area of clinical practice.

A knowledge of anaesthetic equipment has always been the mainstay of the specialty. Obviously, the authors had to be selective in choosing what topics to include. However, it is amazing that so much has been included in a book of only 147 pages. Sadly, there is not one reference in the whole of the book so the reader is deprived of the chance to extend his reading or to appreciate the enormous work done by the inventors of anaesthetic equipment. The book is refreshingly up to date and should be a runaway best seller. It is thoroughly recommended not only to trainee anaesthetists but to others in the anaesthetic team. It is marvellous value for money.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 76, No. 6 JUNE 1996

EDITORIAL I

Impact factors in anaesthesia journals

For many years, there have been attempts to assess journals in terms of the quality or importance of the information they contain. Perhaps the best known is the Science Citation Index (SCI) developed in the 1960s in the United States by a commercial organization, the Institute for Scientific Information (ISI). This organization produces what is the most widely known measure and generally believed to be an index of a journal's scientific quality, namely the SCI impact factor. As noted in a previous editorial in this journal [1], impact factors have assumed increasing importance in Western Europe where in many countries they have been used as part of internal promotion procedures for academic staff, and in the UK they have been used to some extent recently in the research assessment exercise [1].

The impact factor is a measure of the frequency with which an average article in a journal has been cited in a particular year. For the SCI, it is calculated by dividing the number of all current citations of items published in Journal X in the previous 2 yr, by the number of articles published in Journal X during those 2 years. Another commonly used index is the cited half-life which describes the number of journal publication years going back from the current year which account for 50% of the total citations received by the cited journal in the current year.

Table 1 lists the impact factors and citation half-lives for the 12 anaesthesia journals with the highest ratings for the year 1994 and this refers to articles appearing in 1992–93. The impact factors for the year 1995 will not be available until the autumn of year 1996.

Despite the superficial attraction of the impact factor as an objective evaluation of the quality of the journal, there are considerable problems with this concept and these factors must be used cautiously; in particular, comparisons between different journals should be made with great care. In a brief evaluation of recent literature on impact factors, the majority of articles were hostile to the usefulness of impact factors as an index of the quality of a journal [2–6], with the exception of a recent letter in *Lancet* [7].

The problems inherent in the interpretation of impact factors have been reviewed extensively by Séglen from Oslo [4–6]. He described four major areas of concern which impeded the use of impact factors for evaluation of quality; namely citation bias, incomplete journal coverage, author variability and field effects.

It will be obvious to even the most inexperienced reader of scientific journals that there is considerable bias in the choice of articles for citation. Apart from the clear tendency of North American authors to cite the North American literature and for Europeans to demonstrate similar chauvinism, other factors include self-advertising (self-citation), flattery, within-institution parochialism, lack of knowledge of the literature and attempts to ingratiate the authors with the referees for a journal. Perhaps the largest citation bias is the failure of English speaking authors to cite articles in non-English scientific literature.

The SCI covers only a small proportion of the total scientific literature available. For the most part, this does not usually exclude the majority of anaesthetic literature but there is no attempt to assess the accuracy of data incorporated on the database of SCI.

The choice of a short period of time from which citations are made to a particular journal also introduces a confounding factor. Clearly, it would be more appropriate if some index were obtained of the lifetime citation of specific articles.

Séglen [5] has drawn attention to the fact that the greatest impediment to the use of impact factors in the evaluation of scientific work is the difference that clearly exists between different scientific fields. It will be clear from examining the list of impact factors for different journals that some disciplines seem to have higher impact factors than others. In rapidly developing fields such as immunology and molecular biology, journal impact factors tend to be much higher than in more established fields where the rate of change is not dramatic, for example in some of the clinical disciplines such as ophthalmology.

Table 1 Impact factors for 1994 available in late 1995; these relate to articles published in 1992–93

Journal	Impact factor	Citation half-life
1. *Anesthesiology*	4.711	6.2
2. *British Journal of Anaesthesia*	2.298	6.4
3. *Anesthesia and Analgesia*	2.166	5.8
4. *Anaesthesia*	1.813	5.6
5. *Canadian Journal of Anaesthesia*	1.433	5.3
6. *Journal of Neurosurgical Anaesthesia*	1.433	2.6
7. *Anaesthesia and Intensive Care*	0.996	4.8
8. *Acta Anaesthesiologica Scandinavica*	0.939	6.8
9. *Regional Anesthesia*	0.873	4.4
10. *European Journal of Anaesthesiology*	0.567	3.9
11. *Anaesthetist*	0.557	6.0
12. *Annals of French Anaesthesia*	0.194	5.1

In general terms, it is also obvious that basic science journals tend to have higher impact factors than clinical journals. The reason is clearly that clinical investigations may be dependent on basic science investigations for developing hypotheses or invoking mechanisms of clinical effects while the converse is less common. Consequently, there is a 3–5 fold difference in citations between clinical medicine and basic science medicine.

The geographical size of a scientific community also has a marked impact because of the tendency for citation of articles from friends or colleagues encountered frequently at scientific meetings. Thus in general terms, journals published in North America and catering largely for the North American market have higher impact factors than those published in Europe.

In a recent study, Séglen investigated the relationship between the extent to which a specific article was cited and journal impact factors by assessing complete publication lists provided by 16 senior scientists from a single institution in Norway [4]. He found a very skewed distribution in journal impact values and also in the distribution of article citedness leading to a poor general correlation between journal impact factor and article citedness. The major conclusion which he drew from this study was that the extent to which a particular article was cited in the literature was not influenced appreciably by the status of the journal in which it was published. Despite this, there seems to be a general assumption that authors send their work to journals with the highest impact factors. While it is true that highly cited articles tend to appear in high impact factor journals, Séglen concluded that it was not because the articles were published in a high impact factor journal that they were cited but that the converse existed, namely that some journals had high impact because they published high impact articles.

It has also been suggested recently that impact factors favour short-term studies [3]. Hansson plotted impact factors (IF) against pattern factor (PF), calculated as the number of citations of articles in a 2-yr period divided by the number of articles in the journal during the same 2-yr period; a high correlation was found between IF and PF [3]. He concluded that IF was predicted by the habit of citing articles published within 2 yr thus favouring areas that generate short-term studies. This conclusion was disputed by Brody on the grounds that two clinical journals with the highest impact factors had published many long-term studies [7]. Interestingly, in a survey of scientists at NIH who were asked to list the most prestigious journals in rank order, there was no correlation between these rankings and journal impact factors [2].

Despite the problems inherent in impact factors, the desire to quantify the "quality" of both articles and journals is unlikely to wane. However, for reasons many of which are outlined above, great caution should be exercised in the interpretation of these data. They may be useful to follow the fortunes of an individual journal but comparison between journals of difficult geographical origin or specialty is fraught with problems.

EDITORIAL II

Airway management in cleft lip and palate surgery

Cleft lip and palate are the most common of the craniofacial anomalies, with an incidence of approximately 1 in 800 live births. Twenty-five percent of cases of cleft lip are bilateral, and 85 % of these are associated with cleft palate. In recent years there has been a move towards earlier surgical repair of both cleft lip and palate, with cleft lip repair being performed in the neonatal period in some centres.

The presence of other associated congenital anomalies, including cardiac and renal anomalies, should always be borne in mind, particularly in children with isolated cleft palate. Over 150 syndromes have been described in association with cleft lip/palate, but fortunately all are rare. Some, however, have considerable anaesthetic implications, and many involve potential airway problems. The most well-known of these are the Pierre Robin, Treacher Collins and Goldenhar syndromes. Other, such as the Klippel-Feil syndrome, may include abnormalities of the cervical spine.

Airway problems in children with cleft lip and palate were recognized by Magill more than 70 yr ago [1], and since then many methods of managing the child with the difficult airway have been described. Some, such as the use of firm pressure over the larynx to aid laryngoscopy with a bougie as a guide to tracheal intubation, are relatively simple to perform by any competent anaesthetist and are successful in most cases. Digitally assisted tracheal intubation is used rarely, but also requires no special equipment [2]. Other more sophisticated methods, such as those involving fibreoptic techniques, require special equipment, training and experience [3, 4]. The laryngeal mask has been recommended as a guide to fibreoptic intubation in children [5] and has been used successfully in Pierre Robin [6–8] Treacher Collin [9] and Goldenhar syndromes [10]. It has been used for cleft palate repair in a baby with Pierre Robin syndrome when intubation proved impossible [11]. Specially designed light wands and laryngoscopes are available for difficult intubation in children [12–14], but these are either expensive or not readily available in most anaesthetic departments. Retrograde techniques have been described in infancy [15], but their success rate is much lower than in older children or adults. Even when a guide wire or bougie is manipulated successfully into the trachea, it may prove impossible to pass a tracheal tube over it. Threading the guidewire through the Murphy eye of the tracheal tube instead of the end hole allows an extra length of tube to pass into the trachea before withdrawal of the guidewire and this technique was used successfully in a 5-month-old infant with Goldenhar syndrome [16].

Assessment of the degree of difficulty of intubation before operation is not always possible in these children, as methods of assessment used in adults which require patient co-operation are not easy to apply in young infants. Radiological assessment of the paediatric airway has been described based on measurement of the maxillo-pharyngeal angle on lateral x-ray. This angle is normally greater than 100°, and angles less than 90° suggest that it will be impossible to see the larynx at laryngoscopy [17]. Awake fibreoptic intubation via a laryngeal mask has been described in an infant [10], but most anaesthetists perform laryngoscopic assessment of the airway during general anaesthesia. Anaesthesia is commonly induced with halothane, although sevoflurane may become the agent of choice in the future. Application of increased airway pressure with a well fitting face mask minimizes the risk of airway obstruction during induction. Neuromuscular blockers are contraindicated before intubation whenever the ability to inflate the lungs is in doubt. The applicability of adult gradings of the laryngoscopic view to children has not been evaluated widely, and the child with a difficult airway at induction will not necessarily have an airway that is difficult to intubate. Fibreoptic evaluation of the paediatric airway through an endoscopic face mask has been advocated recently [18], but is unnecessary in most cases.

In this issue, Gunawardana [19] reports the findings of a 10-yr prospective study of 800 consecutive patients presenting for cleft lip or palate surgery in whom an attempt was made to correlate the Cormack and Lehane gradings found at laryngoscopy [20] with the degree of difficulty experienced at intubation. All children were ASA I, and none was apparently suffering from any of the syndromes associated with cleft lip or palate. In 59 cases, however, the cleft lip was bilateral, and 52 children demonstrated retrognathia. Cormack and Lehane grading of III or IV, assessed after application of external laryngeal pressure, was associated with difficult intubation in 86 % of cases, and a lower grading in only 2 %. The degree of laryngoscopic difficulty decreased with increasing age, with no difficult laryngoscopies occurring in children aged 5 yr or more. This contrasts strikingly with conditions such as Goldenhar syndrome, where intubation often becomes more difficult with increasing age. Virtually all difficult laryngoscopies occurred in children with bilateral clefts or retrognathia. This finding is particularly encouraging, as both of these situations are readily assessed at the preoperative visit. The importance of carefully studying the child's profile at this time cannot therefore be emphasized too strongly. In infants with severe upper airway problems there is also usually a history of significant feeding difficulties.

Despite the laryngoscopic findings, failure to intubate occurred in only 1 % of patients in Gunawardana's series, all of whom were less than 6 months of age. There were no significant episodes of hypoxaemia. Heart rate decreased to less than 80 beat min^{-1} in nine children, but the clinical significance of this is impossible to assess without knowing their ages and resting heart rates. The author attributed these results largely to the use of a spontaneously breathing technique. However, intubation might have been successful in more infants had a straight-bladed laryngoscope been available or if neuromuscular blockers had been used to facilitate intubation when the ability to inflate the lungs manually had been confirmed. The use of neuromuscular blockers might also have reduced the incidence of airway bleeding. In a recent study, fewer children coughed during intubation using suxamethonium than alfentanil [21].

The presence of retrognathia or other congenital anomaly involving the upper airway may cause respiratory problems in the immediate postoperative period and extubation should be delayed until the child is awake. Provision of adequate postoperative analgesia is made more difficult because of the potential for respiratory depression which most analgesic drugs possess. Infraorbital nerve block offers an attractive alternative method of pain relief after cleft lip repair [22, 23].

CLINICAL INVESTIGATIONS

Difficult laryngoscopy in cleft lip and palate surgery

R. H. GUNAWARDANA

Summary

We studied prospectively 800 paediatric patients undergoing repair of cleft lip and palate to determine the predictors of difficult laryngoscopy. The incidence of difficult laryngoscopy (Cormack and Lehane grade III and IV) was 2.95% in patients with unilateral cleft lip, 45.76% in bilateral cleft lip and 34.61% in patients with retrognathia. Tracheal intubation was successful in 99% of patients in whom laryngoscopy was difficult. There was a significant association between age and laryngoscopic view ($P < 0.01$). (*Br. J. Anaesth.* 1996; **76**: 757–759)

Key words

Anaesthetic techniques, laryngoscopy. Larynx, laryngoscopy. Surgery, plastic. Anaesthesia, paediatric.

Successful management of cleft and palate requires early surgery. It is imperative that the trachea of these patients be intubated, not only to maintain the airway, but to prevent aspiration. However, intubation may be difficult in the paediatric patient because of normal variations in airway anatomy. The difficulty may be exaggerated by the congenital anatomical anomaly.

Difficulties with intubation continue to be a major cause of anaesthesia-related morbidity, mortality and litigation [1, 2]. Preoperative identification of patients in whom intubation may be difficult may save lives. The existing bedside tests as predictors of difficult intubation [3–5] are not practical in children. Also, they are not sensitive or specific enough for routine use [6, 7]. The aim of this study was to determine the predictors of difficult laryngoscopy in paediatric patients presenting for repair of cleft lip and palate.

Patients and methods

During a 10-yr period (1985–1994), we studied prospectively 800 consecutive ASA I patients, presenting for cleft lip (533) and cleft palate (267) surgery. Patients were aged 2 months to 8 yr (65% were less than 1 year of age) and 49% were males.

Anaesthesia was induced with halothane and nitrous oxide in oxygen. Neuromuscular blockers were not administered. A towel roll was placed under the shoulders and laryngoscopy was performed with a small curved blade (Macintosh) laryngoscope when there was adequate jaw relaxation. The larynx was seen with the aid of external laryngeal compression. The distal end of the Portex tracheal tube was curved appropriately using a flexible introducer to aid in intubation.

The appearance at direct laryngoscopy after application of laryngeal pressure was recorded by the anaesthetist using the classification of Cormack and Lehane [8]. The relationship between congenital anomaly and laryngoscopic view and the association between age and view on laryngoscopy were studied. Data were analysed using the chi-square test.

Outcome of tracheal intubation was classified as easy (successful with one or two attempts), difficult (two to four attempts) and failed, when intubation was not possible with four attempts.

The lowest arterial oxygen saturation (Sp_{O_2}) and heart rate recorded during laryngoscopy were compared with values before laryngoscopy.

Results

The cleft lip was unilateral in 474 patients (172 involved the right or left lip with or without involvement of the alveolus, and in 302 the clefts involved the lip, alveolus and palate). In the 59 patients with bilateral cleft lip, the cleft passed down both sides of the premaxilla into the palate. Of the 267 patients with isolated cleft palate, 52 had retrognathia.

Laryngoscopy was easy (grade I or II) in 741 (92.62%) and difficult (grade III or IV) in 59 (7.38%) patients (fig. 1). There was a highly significant association between anomaly and laryngoscopic view ($P < 0.01$). The incidence of difficult laryngoscopy in each anomaly is shown in figure 2. In the bilateral clefts of the lip and alveolus, the protruding premaxilla obstructed the laryngeal view.

Of the 59 patients with difficult laryngoscopy, 39 (66.10%) were less than 6 months of age, 12 (20.34%) were 6–12 months and 8 (13.56%) were 1–5 yr old (table 1). There was a significant association between age and laryngoscopic view ($P < 0.01$). Laryngoscopy was easier with increasing age. The incidence of difficult laryngoscopy was 11.14% in children less than 6 months of age, 7.05% in the age group 6–12 months and 4.12% in 1–5 yr olds

Table 2 Ease of tracheal intubation in relation to laryngoscopic view (number of patients)

Laryngoscopic view	Tracheal intubation			
	Easy	Difficult	Failed	Total
I	459	3	0	462
II	266	13	0	279
III	0	48	3	51
IV	0	3	5	8
Total (%)	725 (90.62)	67 (8.38)	8 (1)	800

Table 3 Adverse outcomes with laryngoscopy and intubation

Adverse outcome	No. of patients (%)
Airway bleeding	21 (3)
Pulmonary aspiration of blood	5 (0.6)
Arterial oxygen desaturation < 94%	6 (0.8)
Bradycardia (< 80 beat min^{-1})	9 (1)
Oesophageal intubation	7 (0.9)

(fig. 3). Laryngoscopy was not difficult in children more than 5 yr of age.

Figure 4 shows the distribution of ease of tracheal intubation. Table 2 shows the distribution of ease of tracheal intubation in relation to laryngoscopic view. Tracheal intubation was easy in the majority (90.62%) of patients. All had a grade I or II view. Intubation was difficult in 67 (8.38%), of whom 51 (76.12%) had a grade III or IV view and 16 (23.88%) a grade I or II view. Intubation failed in eight patients (1%); all had a grade III or IV laryngoscopic view and were less than 6 months of age. Four had bilateral cleft lip and alveolus with protruding premaxilla and the remaining four had cleft palate with retrognathia.

Table 3 shows the adverse outcomes associated with laryngoscopy. There was no loss of airway control or any postoperative airway problems. There was no significant decrease in Sp_{O_2} or change in heart rate during laryngoscopy or intubation.

Discussion

In these patients, the airway was patent and not compromised, and the larynx was inaccessible and difficult to view because of various anatomical anomalies. The incidence of difficult laryngoscopy was 7.38%. Comparison with other published reports is difficult because of differences in definition

[9–12]. The age groups and mitigating factors (use of neuromuscular blockers, type of laryngoscope blade) also differed between studies.

The use of optimal laryngeal pressure improves the laryngoscopic view and increases the intubation angle in high anterior larynx. The incidence of grade III view is reduced from 9 % to 5.4–1.3 % by routine use of external laryngeal pressure [13].

Difficult laryngoscopy was not synonymous with difficult intubation. The incidence of failed intubation was only 1 %. Poor outcome with failed or difficult tracheal intubation was avoided by maintenance of spontaneous ventilation and adequate ventilation with face mask and airway in between attempts. There was no instance of "cannot intubate and cannot ventilate by mask", the reported incidence of which is 0.001–0.02 % [9].

In summary, extensive clefts, retrognathia and age less than 6 months were found to be associated with difficult laryngoscopy. These factors must be considered in planning the anaesthetic technique. Where difficulty is anticipated, senior skilled personnel should be present.

Volumetric analysis of aeration in the lungs during general anaesthesia

A. REBER, G. ENGBERG, B. SPORRE, L. KVIELE, H.-U. ROTHEN, G. WEGENIUS, U. NYLUND AND G. HEDENSTIERNA

Summary

Spiral computed tomography (CT) allows volumetric analysis of formation of atelectasis and aeration of the lungs during anaesthesia. We studied 26 premedicated patients undergoing elective surgery allocated to group 1 (conscious, spontaneous breathing, investigating inspiration and expiration), group 2 (general anaesthesia with mechanical ventilation, investigating inspiration and expiration) or group 3 (general anaesthesia with mechanical ventilation, investigating changes over time). Using spiral CT, the lungs were studied either before or during general anaesthesia. CT scans were grouped into the following areas: overaeration, normal aeration, reduced aeration, poor aeration and atelectasis. The mechanism of atelectasis appeared to be both gravitational forces and a diaphragm-related force that acts regionally in caudal lung regions. Mean atelectasis formation and poorly aerated regions comprised approximately 4% of the total lung volume between the diaphragm and carina, giving a mean value of 16–20% of the normal aerated lung tissue being either collapsed or poorly aerated. The vertical ventilation distribution was more even during anaesthesia than in the awake state. (*Br. J. Anaesth.* 1996; **76**: 760–766).

Key words

Anaesthesia, general. Lung, atelectasis. Measurement techniques, tomography. Ventilation, mechanical.

It has been shown in previous studies that approximately 90% of all patients who are anaesthetized develop atelectasis in dependent lung regions, that is in the dorsal area of the lungs with the patient in the supine position [1]. Decreases in arterial oxygen tension and increases in the magnitude of shunt correlate with the size of the atelectasis [2, 3]. It can be concluded therefore that formation of atelectasis is a major cause of gas exchange impairment during general anaesthesia [4, 5]. The distribution of atelectasis can assist in elucidating the causative mechanisms. This has not been investigated previously except for the limited analysis performed by single or double exposures through the chest [6]. Volumetric analysis can be achieved using spiral computed tomography (CT) enabling continuous exposure of the lungs while the patient moves slowly through the gantry of the CT scanner [7]. Continuous volume acquisition followed by multiplanar reconstructions makes it possible to detect more details than with standard CT, especially in the lung, while at the same time determining more exactly the relationship of collapsed lung tissue to the surrounding structures.

In this study, we have investigated, by means of volumetric scanning, the changes which occur in the regional variation of aeration and regions of atelectasis formation in the lungs during general anaesthesia and mechanical ventilation. Furthermore, the contribution of diaphragm displacement to tidal ventilation was evaluated using measurements of functional residual capacity and chest–abdomen movement.

Patients and methods

The study was approved by the Ethics Committee of the University Hospital of Uppsala, and written informed consent was obtained from each patient. We studied 26 consecutive patients, ASA I or II, without cardiopulmonary diseases undergoing elective general, neurological or eye surgery (table 1). The refusal rate was 15%. Patients were allocated to group 1 ($n = 6$: premedicated, conscious patients breathing spontaneously, investigating inspiration and expiration), group 2 ($n = 10$: general anaesthesia with mechanical ventilation, investigating inspiration and expiration) or group 3 ($n = 10$: general anaesthesia with mechanical ventilation, investigating delayed changes after 60 min). Three separate groups were investigated in order to limit the radiation exposure to individual patients. The numbers of spiral CT were therefore restricted to two in each patient (see below).

Premedication comprised ketobemidone (Ketogan Novum) 0.07 mg kg^{-1} i.m. Patients were transported

to the X-ray department and positioned supine on the CT table. In group 1, spiral CT were performed in the premedicated, conscious patient before induction of general anaesthesia. In groups 2 and 3, general anaesthesia was induced with propofol 1–2 mg kg^{-1} and fentanyl 0.002 mg kg^{-1}, and muscular paralysis was produced with pancuronium 0.1 mg kg^{-1}. After intubation of the trachea, anaesthesia was maintained with a continuous infusion of propofol 6–8 mg kg^{-1} h^{-1} and fentanyl injections (0.05–0.1 mg) as necessary.

The lungs were ventilated mechanically at a rate of 12–14 bpm with 40% oxygen in nitrogen (FI_{O_2} 0.4) with a Servo Ventilator 900D or 710 (Siemens-Elema, Stockholm, Sweden). Minute volume was adjusted by changing *f* (frequency) to maintain end-tidal carbon dioxide concentration ($P\text{CO}_2$) at 4.5 and 4.9 kPa (CO_2 analyzer 5250 RGM, BOC Ohmeda, Louisville, CO, USA) with a tidal volume of 8 ml kg^{-1}. No additional changes in ventilation were made during the 60-min study.

SPIRAL CT OF THE LUNGS

Aeration of the lungs and distribution of atelectasis (see below) were studied by spiral CT of the lungs (Somatom plus, Siemens, Erlangen, Germany). Patients lying in their bed supine were lifted onto the CT table and the mean time between reclining on the table and the CT being undertaken was 30 min. Patients lay in the supine position with the arms alongside the body [8] while slowly moving through the gantry during exposure. While awake (group 1) or 10 min after induction of anaesthesia (groups 2 and 3), a frontal scout-view covering the chest was performed at end-expiration to define the borders of the lungs and to guide the settings of the succeeding spiral CT. The spiral CT were obtained during 10 s of breath-holding at end-expiration and end-inspiration in groups 1 and 2, covering the basal region of the lungs. In group 3, spiral CT were obtained during 20 s of breath-holding at end-expiration (= 0 airway pressure) from the left (= lower) most cephalad point of the diaphragm at least as far as the carina and further cranially, depending on the lung distance in each individual patient. There was a delay of 3 s before starting the spiral CT, allowing full expiration. The additional spiral settings were as follows: table speed 8 mm s^{-1}, 120 kVp tube voltage and 125 mA current, 8 mm slice thickness. After investigation, the scans were reconstructed in 4-mm increments. In group 3, a second spiral CT was performed 60 min after induction of anaesthesia. The maximum total amount of radiation (quantity) any patient received was 5 mSv, which does not exceed the effective dose equivalent per year for Swedish citizens. After the investigation, patients were transported to the operating theatre for surgery.

ANALYSIS OF THE SPIRAL CT SLICES

The interpolated, uncompressed 512 × 512 matrix scans, consisting of picture elements (pixels) of approximately 0.9 × 0.9 mm, were transposed to an 8-bit TIFF format (256 Gy values). Thus images were rendered legible for the image analysis software package Optimas, version 4.1 (Bioscan Inc, Edmonds, WA, USA). For each scan, the left and right lung contours were traced using a semi-automatic technique [9]. If possible, automatic tracing by an algorithm based on the standard formula for polygonal areas was performed. Manual tracing by eye, drawing the external boundary along the inside of the ribs and the internal boundary along the mediastinal organs (excluding large structures of the hilus) was performed if necessary to mask lung tissue densities. The following regions of interest (ROI) were studied: in groups 1 and 2, inspiratory and expiratory scans at a level just above the diaphragm dome were evaluated. Appropriate inspiratory and expiratory scans were chosen by identifying key anatomical landmarks in both. Thus the position of the scan with regard to the spine differed between scans. The vertical height of the basal CT section was measured as the distance between the ventral and dorsal surface of the lung. The section was divided vertically into five equal levels. Level 1 refers to the most ventral level and level 5 to the most dorsal, as modified from the method of Gattinoni and co-workers [10]. The attenuation values were measured in each interval in both the expiratory and inspiratory scans.

In group 3, the lung was divided into five areas, corresponding to the following attenuation values: −1000 to −900 Hounsfield units (HU) (over-aerated) [11], −900 to −500 HU (normal aeration), −500 to −200 HU (reduced aeration) (modified from [12]), −200 to −100 HU (poor aeration) and −100 to +100 HU (attenuation values corresponding to atelectasis) [13].

In one patient, a three-dimensional image was built up with an additional imaging software package (3 DE-Editor and 3 DE-viewer, Maidenhead.

CONTRIBUTION OF THE DIAPHRAGM TO TIDAL VENTILATION

In group 3, ventilation was partitioned into rib cage and abdomen–diaphragm components by respiratory inductive plethysmography (RIP) before and during general anaesthesia [14, 15]. The signals from the RIP were recorded on a microprocessor system (Respitrace, non-invasive monitoring systems, Miami Beach, FL, USA). Additionally, functional residual capacity (FRC) was measured during anaesthesia and mechanical ventilation by a multiple breath wash-in-wash-out sulphur hexafluoride (SF$_6$) technique according to Larsson and co-workers [16].

DATA TRANSFORMATION AND STATISTICAL ANALYSIS

The areas of different attenuation numbers at a given level (as indicated above) were expressed as percentages of the total lung parenchyma (cross-sectional area of the thorax excluding the chest wall and the manually traced hilar structures) to take into account the difference in quantity of lung tissue between basal and apical scans. Analysis of levels within the well defined region between the most cephalad point of the diaphragm (= base) and the carina, defined as 100% distance from the diaphragm, enabled comparison of regional variabilities of the patient's lungs. Thus an accurate volumetric comparison of the same lung regions was performed in different patients. As an appropriate transformation for percentage values, the arcsine of the square root of the mean was calculated for statistical analysis [17].

Unless otherwise stated, values are mean (SD) and range. In addition, 95% confidence intervals are given where appropriate. To compare data within groups, the Wilcoxon signed rank test and Friedman's analysis of variance (ANOVA) were used. For *post hoc* comparisons, Tukey's test was applied and probability values were calculated. To compare data between the groups, the Kruskal–Wallis ANOVA and the Wilcoxon rank sum test were used. Spearman's rank correlation coefficient (r_s) was used to analyse the relationships between variables. For all calculations, the Statistica/w 4.5 software package (StatSoft, Tulsa, OK, USA) was used.

Results

CONSCIOUS, SPONTANEOUSLY BREATHING AFTER PREMEDICATION

All lung densities were observed. However, regions with attenuation < -900 HU occurred only in one patient. They were located in the upper, non-dependent region and varied between 3% in the apex and up to 11% at the base. Few (less than 1%) areas with attenuation values of between -200 and $+100$ HU were scattered through the most dependent region of the lungs.

The mean expiratory attenuation value was -658 (SD 103) HU and the mean inspiratory value -789 (74) HU. Dependent lung regions showed more than twice as large variation in the attenuation during respiration than in non-dependent lung regions (fig. 1 (left panel), table 2). Assuming a gas distribution in proportion to the attenuation changes (expressed in HU), an almost two-fold increase in ventilation was calculated for the dorsal lung region, compared with the ventral, non-dependent one (table 2).

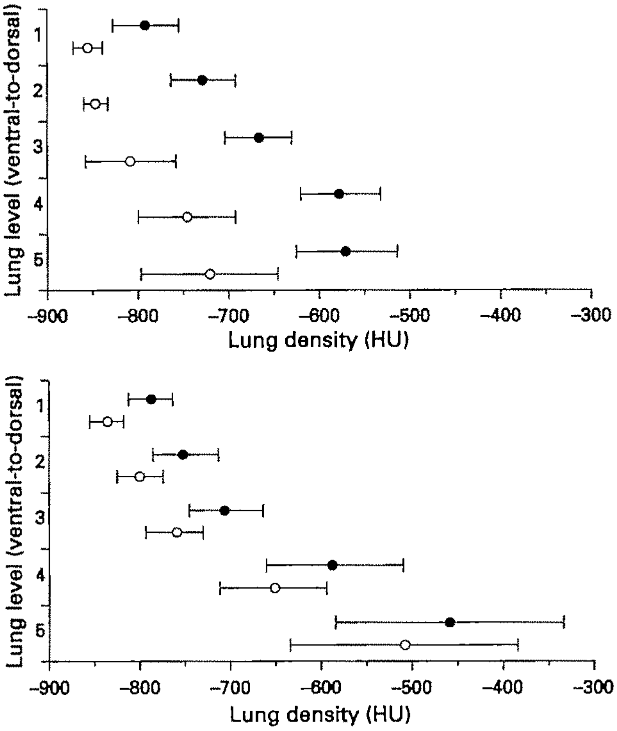

Figure 1 Distribution of ventilation in conscious, spontaneously breathing patients (top) and in patients 10 min after induction of anaesthesia (bottom) (mean, SD). Note the dorsoventral distribution of mean attenuation values (in Hounsfield units (HU)) in inspiration (○) and expiration (●). Data from the right lung are included (left lung is not shown but displayed similar values).

AERATION 10 MIN AFTER INDUCTION OF ANAESTHESIA

Densities defined as atelectasis were distributed over the whole distance between the diaphragm and the carina (fig. 2). However, atelectasis was larger in the basal part of the lung ($P < 0.05$) and decreased with increasing distance from the diaphragm ($r_s = -0.43$). In five patients, spiral CT included nearly the whole lung, from the diaphragm to the apex. In these patients, measurements of formation of atelectasis in more cranial parts of the scans were less reliable because of increasing scatter close to the rib cage. However, no or only small amounts of atelectasis (less than 0.5%) were detected in these regions. A significantly larger amount of attenuation values between -200 and -100 HU in dependent lung regions was found during anaesthesia compared with awake ($P < 0.05$) (table 2). These regions were of similar magnitude to those with atelectasis, and were located above the atelectatic areas. They also decreased in size with increasing distance from the diaphragm ($r_s = -0.38$). Regional analysis of accumulated data from the different slices showed the following: the quantity of both atelectatic and poorly aerated regions in the basal region (0–40% distance from the diaphragm) was significantly larger

Table 2 Increase in lung attenuation from inspiration to expiration (supine position) (mean (SD))

		Conscious, spontaneous breathing		Anaesthesia, mechanical ventilation	
Level	Lung	Increase (HU)	Distribution of ventilation (%)	Increase (HU)	Distribution of ventilation (%)
1	R	64 (41)	13	48 (19)	18
	L	93 (43)	13	51 (26)	17
2	R	118 (18)	17	50 (20)	19
	L	108 (79)	14	70 (36)	24
3	R	128 (11)	18	59 (23)	21
	L	121 (88)	17	56 (25)	19
4	R	170 (97)	28	67 (32)	24
	L	167 (84)	31	69 (39)	22
5	R	152 (109)	24	49 (29)	18
	L	179 (113)	25	48 (40)	18
All	R	127 (83)	100	54 (25)	100
	L	134 (84)	100	59 (33)	100

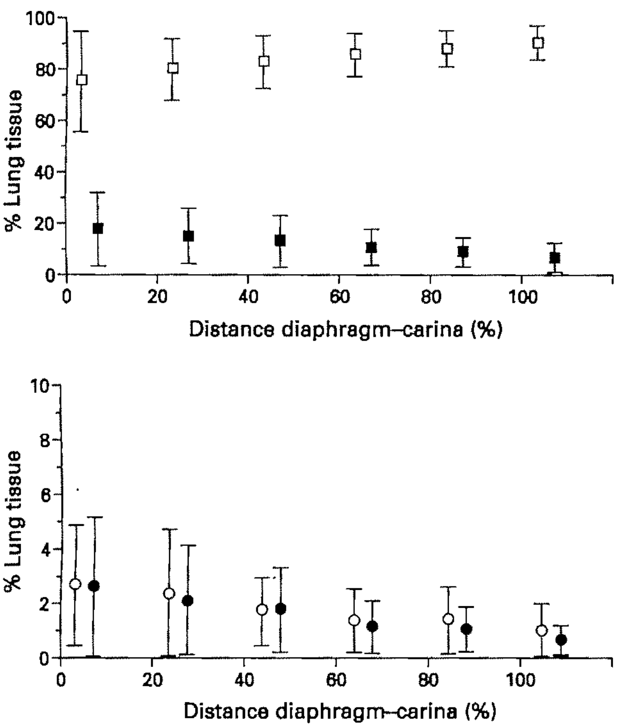

Figure 2 Aeration in the lungs between the diaphragm and the carina 10 min after induction of anaesthesia. The means (SD) for the areas with different densities are presented: values for normal (□) and reduced (■) aeration (top) and values for poor aeration (○) and atelectasis (●), (bottom). Data from the left and right lung are included.

than in the apical zone (60–100 % distance from the diaphragm) ($P < 0.05$). There was no correlation between atelectasis formation and height of the lung in the sagittal plane, cross-sectional height of the lung, body mass index, age, sex or smoking habit. There were no significant differences between the right and left lungs.

Areas with aeration between −500 and −900 HU were significantly more common in the apical region compared with the basal region ($P < 0.05$) (fig. 2). The correlation between the amount of densities between −200 and −900 HU and the distance from the diaphragm was calculated as $r_s = 0.46$ for densities between −500 and −900 HU ($P < 0.01$) and $r_s = -0.36$ for densities between −200 and −500 HU ($P < 0.01$). There was no significant difference in aeration between left and right lungs. FRC after 10 min of anaesthesia was 1390 (320) ml.

VENTILATION DURING ANAESTHESIA

In group 2, during anaesthesia, attenuation varied to a significantly lesser extent for the whole lung field than in the conscious subjects (group 1) ($P < 0.05$). Thus mean expiratory attenuation was −660 (140) HU, and the inspiratory value was −714 (136) HU (for inspiratory values, $P < 0.05$ compared with awake findings; no significant difference for expiratory values). The changes in attenuation over tidal volume were more similar over the lung field than in the awake state, with only a minor and insignificant increase from the ventral- to the dorsal-dependent segments (table 2). Attenuation values expressed as distribution of ventilation showed no significant difference between dependent and non-dependent segments. Thus ventilation was evenly distributed in the vertical, gravitational direction.

Table 3 Clinical data (time course). Data are mean (95 % confidence interval). For FRC comparisons, Wilcoxon matched pairs test: ns; for %RC comparisons, Friedman–ANOVA test: $^{**}P < 0.01$

	Conscious, spontaneous breathing	Anaesthesia, mechanical ventilation	
		10 min	60 min
FRC (10 *vs* 60 min)		1390 (1180–1610)	1430 (1190–1670)
%RC	41 (30–51)**	61 (52–69)	61 (52–70)
Distance (% of lung height) diaphragm – carina right/left		52 (49–55)/57 (53–62)	

The contribution of rib cage excursions to ventilation was significantly higher compared with the awake situation (61 (13)% *vs* 41 (15)%).

AERATION 60 MIN AFTER INDUCTION OF ANAESTHESIA

In group 3, there was no significant change in the amount or distribution of atelectasis or gas content when comparing lungs 10 and 60 min after induction of anaesthesia. There was no significant difference between left and right lungs. Mean FRC 60 min after induction was 1460 (350) ml and the mean percentage contribution of rib cage excursions to ventilation was 61 (13)%, and thus similar to the values after 10 min of anaesthesia (table 3).

Discussion

A volumetric approach to analysis of the lungs during general anaesthesia using spiral CT enables a more comprehensive description of aeration compared with one or more single exposures through the chest. The major findings in this study were that atelectasis was distributed from the base to the apex of the lung but was larger in caudal regions. It comprised, on average, 2% of the total lung volume which corresponds to approximately 10% of the normal aerated lung tissue. A similar amount of lung tissue, just above the atelectatic zone, was poorly aerated. Furthermore, ventilation was distributed more evenly from the top to the bottom of the lung (anteroposterior) during anaesthesia compared with the awake state. These findings are discussed below after some methodological aspects.

SPIRAL CT AND ANALYSIS

Conventional CT methods using multiple exposures through the chest, one after the other, with a time delay between, can lead to errors caused by differences in the depth of breathing and respiratory movements. Performing spiral CT leads to a reduction in these problems. Spiral CT implies volumetric scanning of the entire lung volume in a single breath hold and enables reconstruction of images at any chosen interval which results in improved detection of tissue and gas distribution. The total quantity of radiation is a limiting factor, and allows only two spiral CT with the settings described above. Despite not covering the entire lung distance in all patients, the most important areas of the lungs were analysed. Analysing the lungs caudal to the most cephalad point of the diaphragm was less reliable when scans included lung tissue and diaphragm. Partial volume effects of the diaphragm were enhanced by the additional transformations for image analysis [18]. Similar problems occurred between the carina and the apex, with scatter effects along the rib cage.

ATELECTASIS AND REGIONS WITH POOR AERATION

During anaesthesia, mean atelectasis formation in dependent lung regions was approximately 2% of the total lung volume between the diaphragm and the carina, as measured by spiral CT. As the amount of lung tissue per pixel element is four to five times larger in the atelectatic area than in aerated lung tissue in non-dependent parts of the lungs [6], the observed mean amount of atelectasis corresponds to 8–10% of the whole lung. A similar quantity of areas with poor aeration was seen, giving a mean value of 16–20% of the lung tissue being either collapsed or poorly aerated. These regions make a major contribution to shunt and regions with low ventilation–perfusion ratios ($\dot{V}\text{A}/\dot{Q}$), which have been shown in previous studies [19, 20]. During inhalation anaesthesia, shunt and perfusion of poorly ventilated lung regions (low $\dot{V}\text{A}/\dot{Q}$) have been estimated previously at 4–5% each [19]. The smaller perfusion values of these regions are reasonably explained by hypoxic pulmonary vasoconstriction (HPV) which still prevails, despite the use of anaesthetic agents. It has been shown by Marshall, Lindgren and Marshall that inhalation anaesthetics depress HPV by 20–30% at 1.0 MAC [21].

A progressive decrease in the amount of atelectasis was noted from the diaphragm to the apex, an observation suspected in previous studies using two or three CT scans through the chest [5, 19]. This finding is interesting in that it suggests another mechanism besides gravity. The latter reasonably explains the increased atelectasis in dependent regions but cannot explain the observed increase in atelectasis in regions near the diaphragm. Rather, relaxation of the diaphragm, and subsequent compression and collapse of underlying lung tissue, could be responsible for this non-homogeneous distribution of atelectasis and poorly aerated areas. This was suspected in earlier studies which observed rapid formation of atelectasis on induction of anaesthesia and on discontinuation of PEEP [1], and decreases in atelectasis after contraction of the diaphragm during phrenic nerve stimulation [22]. Also, the decrease in diaphragm movement during mechanical ventilation and muscle paralysis may be another factor that promoted atelectasis formation in dependent lung regions close to the diaphragm.

AERATION OVER TIME

We paid special attention to the differential aeration of the lung tissue as it may provide more information about the dynamics of the transition between aerated and collapsed lung regions. We believed that poorly aerated areas with attenuation values between −200 and −100 HU would be converted to atelectasis during the 60 min of anaesthesia that followed. However, none of these areas was altered in size or distribution over time. This suggests that areas with poor aeration remained stable during the observation period. These findings are supported by the unchanged FRC with time. The rapid development of densities after induction of anaesthesia contrasts with the lack of progression later in time. However, an additional increase in atelectasis during anaesthesia can be seen if the inspiratory gases are highly soluble in blood, as during oxygen–nitrous oxide anaesthesia [19], and ventilation with 100% oxygen [23].

VENTILATION DISTRIBUTION

The uneven distribution of ventilation in the awake subject with more air going to dorsal, dependent lung regions, has been shown previously in several studies using isotope techniques [24, 25]. The vertical inhomogeneity was proposed by Milic-Emili and co-workers to be caused by regional differences in pleural pressures [26].

Ventilation was affected significantly by anaesthesia and mechanical ventilation, with gas being more evenly distributed from the ventral to the dorsal parts of the lungs while patients were in the supine position. Rehder, Sessler and Rodarte demonstrated a similarly different distribution of ventilation during anaesthesia, using an isotope technique [27]. They suggested that altered ventilation was caused by changes in the shape of the chest wall. That such changes occur have been demonstrated by CT [28]. Krayer and co-workers used high-speed CT that enabled breath-by-breath analysis, providing evidence that changes in thoraco–abdominal motion could explain the altered ventilation distribution during anaesthesia [29].

The findings of atelectasis in dependent lung regions [1] and airway closure [30] during anaesthesia can also explain the impeded ventilation in dependent lung regions. However, the more even distribution of ventilation need not indicate a better ventilation–perfusion ratio, as perfusion is switched towards dependent lung regions which may cause or enhance ventilation–perfusion inequality [31, 32]. Also, poor ventilation of dependent regions may promote atelectasis formation by enhancing gas resorption [23, 32]. Furthermore, the increase in the rib cage contribution to tidal volume during mechanical ventilation and muscle paralysis decreases phasic passive diaphragmatic movement. This is in contrast with observations while spontaneous breathing is maintained [20] and may be a factor that promotes atelectasis formation in dependent lung regions close to the diaphragm.

In summary, a volumetric approach to CT analysis of the lungs provides a more complete description of changes in aeration during general anaesthesia. Induction of anaesthesia causes the formation of atelectasis in a gravitationally oriented fashion (i.e. in dependent lung regions), but also with a non-gravitational inhomogeneity (increasing atelectasis from the apex to the base). There is no evidence of change in regional aeration with time during the first hour of anaesthesia. Atelectasis comprises almost 10 % of the lung tissue. Another 8–10 % of the lung tissue, just above the atelectatic zone, is poorly aerated with less than 20 % of the volume being gas. Finally, the vertical ventilation distribution was more even during anaesthesia than in the awake state.

Sevoflurane–nitrous oxide or halothane–nitrous oxide for paediatric bronchoscopy and gastroscopy

O. A. MERETOJA, T. TAIVAINEN, L. RÄIHÄ, R. KORPELA AND K. WIRTAVUORI

Summary

We have studied 120 infants and children, in three age groups (3–11 months, 1–5 yr and 6–15 yr), to compare anaesthesia with sevoflurane or halothane for bronchoscopy or gastroscopy, or both. Premedication or i.v. anaesthetic agents were not used. Patients were allocated randomly to receive either 7% sevoflurane or 3% halothane in 66% nitrous oxide in oxygen for induction of anaesthesia. The same inspired mixture was continued during bronchoscopy while the concentration of the inhalation agent was reduced by 50% during gastroscopy. Induction times were shorter for infants than for children and shorter for sevoflurane than for halothane. Cardiac arrhythmias were significantly more frequent during halothane than during sevoflurane anaesthesia. Physiological and psychomotor recovery were more rapid after sevoflurane than after halothane. At 24-h follow-up, children who received sevoflurane had significantly less nausea and vomiting. We conclude that sevoflurane was superior to halothane for paediatric bronchoscopy and gastroscopy. (*Br. J. Anaesth.* 1996; **76**: 767–771)

Key words

Anaesthesia, paediatric. Anaesthetics volatile, halothane. Anaesthetics volatile, sevoflurane. Surgery, endoscopy. Children. Infants.

Paediatric bronchoscopy requires a deep level of anaesthesia of relatively short duration. Spontaneous breathing can be maintained if an inhalation anaesthetic is used and neuromuscular blockers are avoided. Paediatric gastroscopy also requires general anaesthesia and in most cases tracheal intubation. For this purpose inhalation anaesthesia can be used successfully if relatively high anaesthetic concentrations are used for tracheal intubation. We could not find any studies comparing different anaesthetic methods for paediatric endoscopies even though paediatric anaesthesia textbooks give recommendations [1–4]. Halothane has been the classic inhalation anaesthetic for paediatric patients, while sevoflurane has challenged its use recently in general surgery [5–9]. We have therefore compared sevoflurane–nitrous oxide to halothane–nitrous oxide anaesthesia in 120 infants and children for bronchoscopy and gastroscopy.

Patients and methods

After obtaining institutional Ethics Committee approval and written parental consent, we studied 120 ASA I–III boys and girls undergoing elective bronchoscopy, gastroscopy, or both. Patients were stratified into three age groups of 40: infants 3–11 months old, young children 1–5 yr old and older children 6–15 yr old. Exclusion criteria were unusual response to halogenated inhalation agents and significant cardiovascular, pulmonary, hepatic, renal or muscular disease.

No premedication was used. Anaesthesia was administered at one of two sites: the outpatient department where parents were present during induction of anaesthesia (52 children older than 1 yr), or the operating theatre. Anaesthesia, was administered by one of the staff anaesthetists with 4–14 years' full-time experience of paediatric anaesthesia. Before induction of anaesthesia, a sealed envelope was opened to allocate patients randomly to receive either sevoflurane or halothane anaesthesia. The inspired concentrations of these agents were approximately equipotent [10, 11]. An independent observer recorded all times and events during and after anaesthesia. The anaesthesia breathing system was either a Jackson-Rees T-piece (patients with a body weight of less than 30 kg) or a Bain system with a fresh gas flow equal to the square root of body weight. Induction of anaesthesia was commenced with inhalation of 66% nitrous oxide in oxygen and 7% sevoflurane or 3% halothane via a transparent silicone face mask applied at the end of a spontaneous expiration. If the children co-operated, they were asked to take a deep breath and maximal exhalation and then a mask was placed gently on the face. When consciousness was lost, an i.v. cannula was inserted and Ringer's acetate solution infused at a rate of 3–4 ml kg^{-1} h^{-1}. During induction of anaesthesia, spontaneous breathing was maintained and the time from application of the face mask to loss of the eyelash reflex (time to loss of eyelash reflex) and until the child had regular breathing and forward directed constricted pupils (time to end of induction) were recorded. Thereafter, tracheal intubation was per-

Correspondence to O. A. M.

formed or, in the case of bronchoscopy, a rigid bronchoscope (with a side-arm attachment for fresh gas) was introduced. No topical anaesthetics were used.

Inspired concentrations of sevoflurane or halothane were maintained unchanged during bronchoscopy and reduced by 50% during gastroscopy. At completion of endoscopy, nitrous oxide and the inhalation agent were discontinued simultaneously and the tracheal tube or bronchoscope removed. Thereafter, the child was taken to a postanaesthetic recovery unit until fully awake. Times from discontinuation of sevoflurane or halothane until the patient moved or responded to a non-painful stimulus (emergence time), and until the patient stated his or her name (time to orientation) were recorded.

Patient recovery was assessed at 10-min intervals by a modified Aldrete score according to which patients receive 0–10 points, that is 0–2 points for five physiological variables (motor activity, respiration, circulation, consciousness and temperature) with 2 points for each variable indicating full normal activity [12]. Patients were regarded as ready to be discharged from the recovery room when they scored 8 or more and communicated normally (time to discharge). In addition, psychomotor recovery in the oldest age group of patients ($\geq$ 6 yr old) was tested using the Trieger dot at 15-min intervals. In this simple pen and paper test, children connected as many dots as possible in 10 s, with the maximum number of points being 52. The results of this test were compared with individual pre-anaesthetic performance. If patients were too sleepy or tired, or had poor co-ordination which prevented them from performing the Trieger dot test, their points were taken as 0 at these times.

Routine patient monitoring included non-invasive arterial pressure, heart rate, oxygen saturation (Cardiocap, Datex, Finland), inspired and expired sevoflurane or halothane, and carbon dioxide measurement (Capnomac Ultima, Datex, Finland). Any untoward effects (e.g. cough, laryngeal spasm, breath-holding or excitement) were recorded. Most patients were outpatients and left for home within 2 h from the end of anaesthesia, while some patients remained in hospital for surgical reasons.

Patients were reviewed 24 h after anaesthesia by telephone call or by personal visit, for the incident of nausea and vomiting or other side effects during the 24-h post-anaesthetic period. In addition, a standard questionnaire was used to enquire about acceptance of induction of anaesthesia (a written question "How would you describe the experience when you lost consciousness?") graded as pleasant, indifferent, or unpleasant, and if a child would like a future anaesthesia carried out in the same way (a written question "Would you like to have the same anaesthetic administered if you return to hospital for further surgery?"). The answers to these questions were obtained from children, and in the event that they could not express an opinion themselves because of their young age, from their parents who were present during induction of anaesthesia.

For statistical analyses, a two-tailed unpaired Student's t test was used for patient characteristics. All induction and recovery data within one anaesthesia group were compared by a Kruskal–Wallis test followed by Mann–Whitney U tests. Between-group comparisons were made by a Mann–Whitney U test and the incidence of side effects by Fisher's exact test. Data are expressed as mean (SD) for patient characteristics and as median (10–90 percentile range) for induction and recovery data. $P < 0.05$ was regarded as statistically significant.

Results

Patient characteristics and duration of inhalation anaesthesia were similar for the two groups (table 1). Induction of anaesthesia was significantly shorter in patients anaesthetized with sevoflurane compared with halothane in the three age groups (table 2). Times to end of induction were shorter in infants than in older children for both anaesthetic groups.

Children in the sevoflurane group had a significantly lower incidence of clinically important side effects than those in the halothane group (table 3). The most frequent side effect was cardiac arrhythmia in 17 children (19 separate episodes). Two patients in the halothane group experienced two separate arrhythmias that were more than 10 min apart, and one patient in the halothane group experienced bigeminy during anaesthesia and laryngeal spasm after extubation.

Recovery from anaesthesia was significantly more rapid after sevoflurane than after halothane anaesthesia in all age groups (table 2). Time to recovery was similar in all age groups during sevoflurane

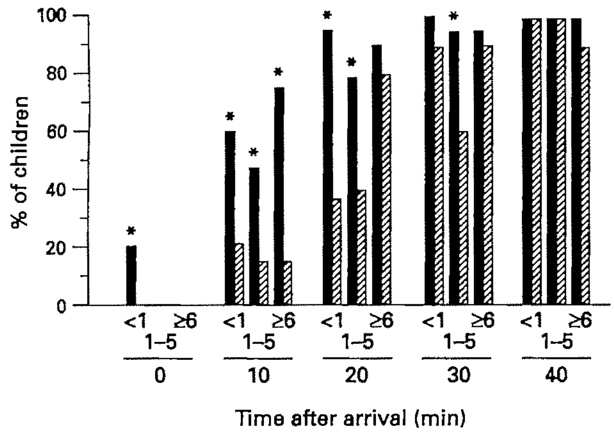

Figure 1 Percentage of children with modified Aldrete scores ≥ 8 at 10-min intervals after arrival in the post-anaesthetic care unit. ■ = sevoflurane and ▨ = halothane groups for the three different age groups (< 1 yr, 1–5 yr and ≥ 6 yr).
* Significantly different from halothane patients of the same age.

anaesthesia, whereas during halothane anaesthesia older children had an earlier recovery (emergence time and time to orientation) than younger patients (table 2). Modified Aldrete scores were significantly greater for sevoflurane than for halothane in several age groups up to 30 min after arrival in the post-anaesthetic recovery unit (fig. 1). Patients anaesthetized with sevoflurane did not express age-related differences in Aldrete scores, but in children anaesthetized with halothane, those aged 1–5 yr old had the slowest normalization of these scores ($P < 0.05$).

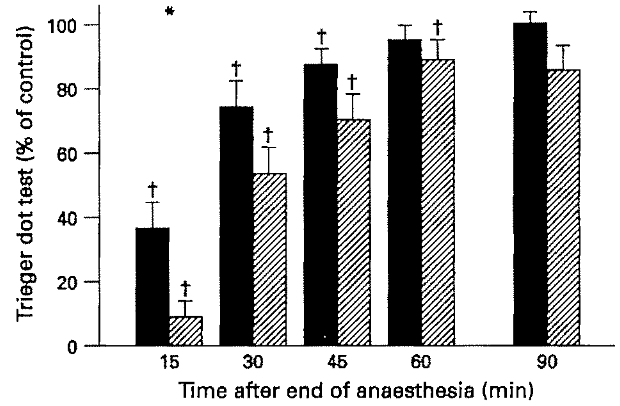

Figure 2 Trieger dot test results (mean, SEM) after sevoflurane (■) and halothane (▨) anaesthesia as a percentage of the pre-anaesthesia control performance in children aged 6–15 yr. * Between-group differences; † Significantly different from pre-anaesthesia performance.

Children in the sevoflurane group had significantly better results for the Trieger dot test at 15 min after anaesthesia than children in the halothane group, and at 60 min they expressed control performance while children in the halothane group failed to do this (fig. 2). Patients were ready to be discharged from the post-anaesthetic recovery unit sooner after the end of sevoflurane anaesthesia than after the end of halothane anaesthesia (table 2). Children of 6–15 yr old who received halothane remained longest in the post-anaesthetic recovery unit because of their slow final recovery from anaesthesia.

At 24-h follow-up, one child in the sevoflurane group had experienced nausea and vomiting, compared with six children in the halothane group ($P < 0.05$). No infant had nausea or vomiting. Children's own appreciation of the quality of induction of the inhalation anaesthesia was assessed in children older than 2 yr. Induction was rated significantly better after sevoflurane than after halothane anaesthesia (table 4). Children's or their parents' willingness to receive further anaesthesias by a similar method was significantly greater after sevoflurane than after halothane anaesthesia (table 4).

Discussion

This study highlighted several important findings. First, pure inhalation anaesthesia for procedures that do not require premedication or postoperative analgesia was rated significantly better by children or their parents when the volatile agent used was sevoflurane rather than halothane. Second, sevoflurane, even at relatively high concentrations, produced significantly less side effects than halothane. Third, children were anaesthetized more rapidly and recovery and discharge from the anaesthetic recovery area occurred earlier if sevoflurane rather than halothane was used.

Our induction technique simulated a vital capacity rapid inhalation induction [13] even though young children or infants were unable to take a deep breath and exhalation before application of a face mask. However, a concentration of 7% sevoflurane or 3% halothane in nitrous oxide and oxygen provided much greater speed of induction of anaesthesia than techniques of sevoflurane anaesthesia published previously [5–9]. One MAC of sevoflurane is 2.5–3.2% and that of halothane 0.8–1.2% in these age groups [10, 11]. As nitrous oxide potentiates halothane more than sevoflurane [11], we estimate that our inspired anaesthetic doses were slightly greater in the halothane than in the sevoflurane group (3.5 *vs* 3.0 MAC equivalents). However, because induction times were shorter in the sevoflurane group and time to loss of eyelash reflex was less than 1 min in these patients, we believe that effective brain concentrations occurred much earlier in the sevoflurane than in the halothane group. Two factors promoted this: low solubility of sevoflurane [11] and minimal airway irritation produced by sevoflurane compared with halothane [14].

We regard our results on children's or their parents' experience on the quality of anaesthesia as very important. Children are seldom asked for their own preference for any particular anaesthetic drug. Our results clearly indicate that sevoflurane is accepted more readily than halothane, even though halothane has been the traditional inhalation agent for children. Pleasant smell may be one of the factors favouring sevoflurane. Other valuable characteristics of sevoflurane anaesthesia include round and smooth induction, good physiological and psychomotor recovery, and a low incidence of side effects. Our anaesthetic method used a single volatile agent. Anticholinergic agents were not given as cardiac arrhythmias during bronchoscopy have been reported to be less frequent after placebo than after either atropine or glycopyrronium [15]. As premedication and opioids were also avoided, children did not have the drowsiness or nausea associated with these agents. Thus the children's experience of anaesthesia was related mainly to the particular volatile agent used.

We did not expect to find such a difference in the incidence of clinically significant side effects between the two anaesthetic groups. The most frequent side effect was cardiac arrhythmia and five episodes of bigeminy or ventricular premature beats required i.v. lignocaine for treatment. All cases occurred in patients receiving halothane. This result corroborates that of Johannesson, Florén and Lindahl [8] who reported that sevoflurane produced less cardiac arrhythmias than halothane during paediatric ENT surgery. However, these investigators used atropine for premedication, and this may have affected their results. We also found that the incidence of postoperative nausea and vomiting was less in the sevoflurane than in the halothane group (one of 40 sevoflurane patients compared with six of 40 halothane patients). Sevoflurane anaesthesia produced remarkably little nausea and vomiting; further studies are indicated to determine if sevoflurane has antiemetic properties.

Cricoid pressure applied after placement of the laryngeal mask prevents gastric insufflation but inhibits ventilation

T. ASAI, K. BARCLAY, C. MCBETH AND R. S. VAUGHAN

Summary

We studied 50 patients, in a blind, crossover study, to assess if cricoid pressure applied after placement of the laryngeal mask prevented gastric insufflation without affecting ventilation. After induction of anaesthesia and neuromuscular block, a laryngeal mask was inserted and confirmed to be placed correctly. The lungs were ventilated with a maximum inflation pressure of 15 cm H_2O. In the first 25 patients, expiratory volumes were measured with and without cricoid pressure (30 N). On both occasions, a free hand was placed under the patient's neck. In the next 25 patients, the effect of cricoid pressure on ventilation without support of the neck was also studied. The effect of cricoid pressure with support of the neck on gastric insufflation was then assessed using a stethoscope in all 50 patients, while the lungs were ventilated with a maximum inflation pressure of 30 cm H_2O. At the end of the study, the position of the mask was re-assessed. Cricoid pressure significantly decreased mean expiratory volume ($P \ll 0.001$). This inhibitory effect was significantly greater when the pressure was applied without support of the neck ($P \ll 0.001$). Cricoid pressure significantly reduced the incidence of gastric insufflation (12 patients *vs* one patient; $P \ll 0.001$; 95% CI for difference 10.5–33.5%). In no patient was the mask dislodged after these procedures. Thus, although cricoid pressure applied after insertion of the laryngeal mask prevented gastric insufflation, it also decreased ventilation. The inhibitory effect of cricoid pressure on ventilation without support of the neck was greater than cricoid pressure with support of the neck. (*Br. J. Anaesth.* 1996; **76**: 772–776)

Key words
Equipment, masks anaesthesia. Larynx, cricoid pressure.

The laryngeal mask has a potential role in patients with difficult airways. It has been used successfully to facilitate ventilation in patients in whom ventilation via a face mask, or tracheal intubation, or both, had failed [1, 2]. However, it cannot reliably prevent gastric insufflation, regurgitation or pulmonary aspiration [3, 4]. Cricoid pressure is thus necessary in patients with increased risk of pulmonary aspiration.

Cricoid pressure, when applied *before* insertion, impedes the correct positioning of the laryngeal mask and may prevent adequate ventilation [5–7]. Thus, it has been suggested that cricoid pressure should be released temporarily during insertion of the laryngeal mask and, when the mask has been inserted, cricoid pressure should be reapplied [5, 7].

Cricoid pressure applied *after* placement of the laryngeal mask effectively prevents regurgitation [8]. However, it is not known if cricoid pressure applied after placement of the laryngeal mask prevents gastric insufflation and if it affects ventilation through the mask. Therefore, in this study we examined if cricoid pressure applied after placement of the laryngeal mask effectively prevented gastric insufflation without inhibiting ventilation. It has been reported that there are differences in the various effects of cricoid pressure with and without support of the neck [7, 9]. We also studied if there was a difference in the effect on ventilation between these two methods of cricoid pressure.

Patients and methods

After obtaining approval from the local Research Ethics Committee and written informed consent, we studied 50 female patients, ASA I or II, aged 18–65 yr, undergoing elective surgery, in whom neuromuscular block was indicated. Patients were excluded if they had any pathology of the neck, upper respiratory or upper alimentary tracts, or were at risk of pulmonary aspiration of gastric contents. Patients with Mallampati class 3 [10] or class 4 [11] were also excluded.

Temazepam 20 mg was given orally as premedication. In the anaesthetic room, an electrocardiograph, pulse oximeter and arterial pressure cuff were attached. After preoxygenation, anaesthesia was induced with either thiopentone or propofol i.v. and neuromuscular block was produced with vecuronium. Neuromuscular block was confirmed with a peripheral nerve stimulator. Anaesthesia was maintained with either enflurane or isoflurane in oxygen during the study.

After neuromuscular block was achieved, pillows were replaced by a firm pad (6 cm in height). The pad was placed under the patient's occiput, but not under the neck. A size 3 or size 4 laryngeal mask was inserted using the method described in the manu-

facturer's instruction manual [12]. The cuff of the mask was inflated with the recommended maximum volume of air (20 and 30 ml, respectively). The breathing system was connected to the laryngeal mask.

ROUTINE ASSESSMENT OF VENTILATION VIA THE LARYNGEAL MASK

The adequacy of ventilation was assessed by manual ventilation. Ventilation was judged as adequate when the chest expanded with inflation with a satisfactory compliance. If it was not possible to ventilate the lungs adequately, one more attempt at placement of the laryngeal mask was allowed. If unsuccessful, the patient was withdrawn from the study. Any apparent airleak from the gap between the mask and pharynx was noted.

After successful insertion, a bite-block (a wad of gauze) was inserted and both the laryngeal mask and the bite-block were fixed to the patient's face with tape. The lungs were subsequently inflated using the ventilator (Siemens Servo-C) with a setting of square waveform in the pressure control mode. An inspiratory–expiratory ratio of 1:3 was used and the pressure was initially set to 15 cm H_2O.

ASSESSMENT OF INITIAL POSITION OF THE LARYNGEAL MASK

The position of the laryngeal mask was assessed using a fibreoptic bronchoscope, as described previously [7]. The mask was arbitrarily considered to be placed correctly when all of the following criteria were fulfilled: (1) the skin overlying both the thyroid and cricoid cartilages bulged mildly during inflation of the cuff; (2) neither the mask nor the tube was twisted; (3) the glottis was seen through the fibrescope; and (4) neither the tip of the mask nor the oesophagus was seen through the fibrescope [13].

EFFECT OF CRICOID PRESSURE ON VENTILATION VOLUME

In a random, crossover design, we assessed the adequacy of ventilation with and without cricoid pressure. In the first 25 patients, we studied the effect of cricoid pressure which was applied with a free hand placed under the patient's neck (i.e. bimanual cricoid pressure). On one occasion, cricoid pressure was applied with a cricoid yoke [7], at a force of 30 N [14]; on the other occasion, the yoke was placed on the cricoid cartilage, but pressure was not applied (sham pressure). The order of the test pressures was randomized by tossing a coin.

The investigator assessing ventilation volumes and the presence of gastric insufflation (see below) was blind to the application of cricoid pressure by placing a screen between the patient and the investigator. The other investigator, who applied a test pressure on cricoid cartilage, was also blind as to the volumes of ventilation and the presence of gastric insufflation. Expiratory volumes, as a reflection of ventilation volumes, were recorded from the sixth to the 10th breaths and mean values were calculated.

We found that cricoid pressure inhibited ventilation through the laryngeal mask in the first 25 patients (see results). Therefore, we studied another 25 patients to determine if there was a difference in the inhibitory effect on ventilation between two different methods of cricoid pressure. Three different methods were used in this part of the study: sham pressure, cricoid pressure with support of the neck (bimanual method) and cricoid pressure without support of the neck (single-handed method). These three test pressures were applied in turn. The order was randomized by choosing a card without replacement from three cards indicating the three test pressures. Expiratory volumes were recorded from the sixth to the 10th breaths for each circumstance.

EFFECT OF CRICOID PRESSURE ON GASTRIC INSUFFLATION

After assessment of the effect of cricoid pressure on ventilation through the laryngeal mask, we studied the effect of cricoid pressure on gastric insufflation in all 50 patients. The inflation pressure was increased from 15 to 30 cm H_2O. On one occasion, cricoid pressure was applied bimanually and on the other occasion, no pressure was applied. On each of the two occasions, the presence of gastric insufflation was assessed by auscultation over the epigastrium. The lungs were inflated for a maximum of five times for each situation. Lawes, Campbell and Mercer [15] have shown that a volume of gas, as little as 5 ml, entering the stomach from the oesophagus can be detected. We also confirmed that "bubbling" sounds were detected reliably by a stethoscope placed over the epigastrium during insufflation of 5 ml of air through a nasogastric tube into the stomach. Any apparent air leak from the gap between the laryngeal mask and the pharynx was also noted.

ASSESSMENT OF FINAL POSITION OF THE LARYNGEAL MASK

At the end of the procedure, the position of the laryngeal mask was re-assessed using a fibreoptic bronchoscope to examine if the mask had been dislodged by application of cricoid pressure and ventilation with an inflation pressure of 30 cm H_2O.

MEASUREMENTS AND STATISTICAL ANALYSIS

Ventilation volumes and the presence of gastric insufflation were recorded. The mean expired tidal volume between the sixth and 10th breath was calculated. Normal plots (plots of normal scores) showed that the data for the differences in expiratory volumes between the different test pressures were not normally distributed. The non-parametric Wilcoxon signed rank sum test was therefore used to compare mean expiratory volumes in patients in whom only bimanual and sham pressures were used. In patients in whom all three test pressures were used, Friedman's non-parametric two-way analysis of variance was used to compare mean expiratory volumes. If this proved significant, the Wilcoxon signed rank sum test was used to compare ventilation between single and bimanual cricoid pressure. Fisher's exact test was used to compare the incidence of gastric insufflation with and without cricoid pressure. $P < 0.05$ was considered significant. Confidence intervals (CI) for the difference in mean expiratory volume and the incidence of gastric insufflation with and without test pressure were also calculated.

A previous study has shown that without cricoid pressure, the incidence of gastric insufflation is about 30 % when the lungs are ventilated via the laryngeal mask with a maximum inflation pressure of 30 cm H_2O [3]. We considered that cricoid pressure would be effective if the incidence was decreased to less than 5 %. To detect this reduction, with a power of 85 %, 50 patients were required for $P = 0.05$ [16].

We studied 50 females, aged 22–67 yr, weight 51–86 kg, and with Mallampati class 1 and 2 (37 and 13 patients, respectively).

Results

ROUTINE ASSESSMENT OF VENTILATION VIA THE LARYNGEAL MASK

The laryngeal mask was placed easily at the first attempt and ventilation was considered adequate in all patients who were included in the study. In one other patient, however, placement of the mask failed after two attempts and thus this patient was withdrawn from the study. A size 4 mask was used in 44 and a size 3 in the remaining six patients. There was no detectable air leak from the gap between the laryngeal mask and the pharynx in any patient when the lungs were ventilated with a maximum inflation pressure of 15 cm H_2O.

ASSESSMENT OF INITIAL POSITION OF THE LARYNGEAL MASK

During inflation of the mask, the tissue overlying both the thyroid and cricoid cartilages bulged. The glottis was always seen directly below the grille of the laryngeal mask when the position of the mask was assessed using a fibreoptic bronchoscope. Neither the mask nor the tube was twisted; neither the tip of the mask nor the oesophagus was seen in any patient. Therefore, the position of the mask was judged as correct in all patients.

EFFECT OF CRICOID PRESSURE ON VENTILATION VOLUME

In the first 25 patients, median expiratory volume was 733 (range 438–1413) ml when no pressure was applied to the cricoid cartilage. Bimanual cricoid pressure decreased the expiratory volume to 501 (169–1133) ml, and this inhibitory effect was significant ($P \ll 0.001$) (95 % CI for difference 93–223 ml) (fig. 1).

In the second 25 patients, in whom the effects of both single-handed and bimanual cricoid pressures were studied, Friedman's two-way analysis of variance showed that mean expiratory volume was significantly different between the three test pressures ($P \ll 0.001$). The inhibitory effect of single-handed cricoid pressure was significantly greater than that of bimanual cricoid pressure ($P \ll 0.001$) (95 % CI for difference 88–290 ml) (fig. 1).

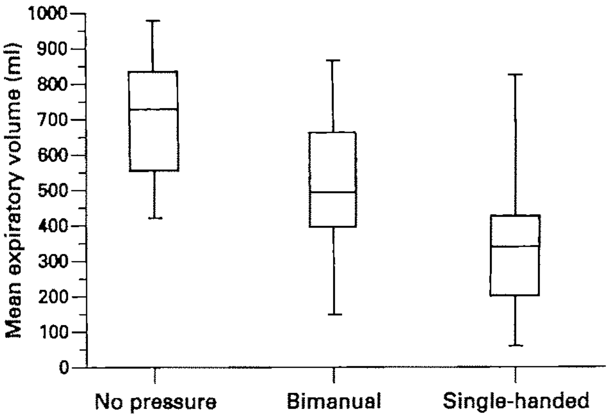

Figure 1 Box-and-whisker plots of the data for mean expiratory volume (calculated from the sixth to the 10th breaths) when either no, bimanual or single-handed cricoid pressure was applied. The box indicates the lower and upper quartiles and the central line is the median. The bars at the end of the "whiskers" are 2.5 % and 97.5 % values. The data for no pressure and bimanual cricoid pressure are for 50 patients, whereas those for single-handed cricoid pressure are for the last 25 patients.

EFFECT OF CRICOID PRESSURE ON GASTRIC INSUFFLATION

When inflation pressure was increased from 15 to 30 cm H_2O, gastric insufflation was detected in 12 of 50 patients (24 %) when no pressure was applied on the cricoid cartilage. In contrast, when bimanual cricoid pressure was applied, insufflation occurred in only one of 50 patients (2 %); it occurred under both circumstances in this patient. Bimanual cricoid pressure thus decreased the incidence of gastric insufflation by 22 % ($P \ll 0.001$) (95 % CI 10.5–33.5 %).

At a maximum inflation pressure of 30 cm H_2O, air leaked from a gap between the laryngeal mask and the pharynx in 23 patients (46 %) when no (sham) pressure was applied and in 26 patients (52 %) when bimanual cricoid pressure was applied.

ASSESSMENT OF FINAL POSITION OF THE LARYNGEAL MASK

At the end of the procedure, the position of the laryngeal mask was re-assessed. The position had not changed in any patient.

Discussion

EFFECT OF CRICOID PRESSURE ON VENTILATION

Cricoid pressure significantly decreased ventilation volumes through the laryngeal mask. The cumulative frequency of the expiratory volume per unit body weight (fig. 2) showed that the proportion of patients at a certain expiratory volume was always greater when cricoid pressure was applied compared with sham pressure. In addition, the proportion was also always greater when single-handed cricoid pressure was applied compared with bimanual cricoid pres-

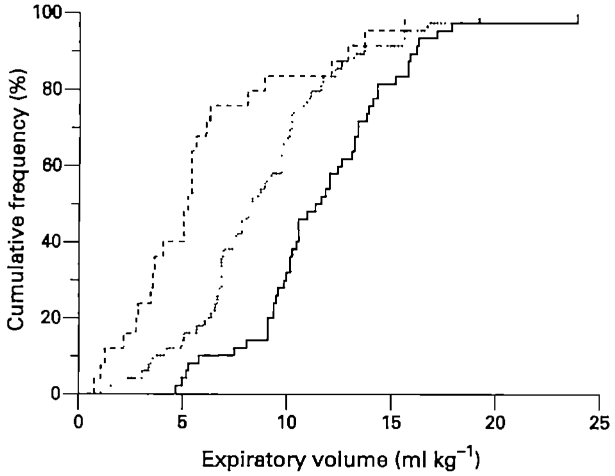

Figure 2 Cumulative frequency of mean expiratory volume (calculated from the sixth to the 10th breaths) when either no (—), bimanual (· · · ·) or single-handed (———) cricoid pressure was applied. The data for no pressure and bimanual cricoid pressure are for 50 patients, whereas those for single-handed cricoid pressure are for the last 25 patients.

sure (fig. 2). These results indicate that ventilation is more likely to be inadequate when cricoid pressure is applied and, in particular, when it is applied without support of the neck (single-handed cricoid pressure). For example, if we arbitrarily consider that ventilation was adequate when the expiratory volume was greater than 8 ml kg^{-1}, ventilation was adequate in most patients when no pressure was applied. In contrast, it was adequate in about 50 % of patients when bimanual cricoid pressure was applied and in only 14 % of patients when single-handed cricoid pressure was applied.

Several differences in the various effects of cricoid pressure with and without support of the neck have been reported [7, 9]. Cricoid pressure without support of the neck tends to flex the head on the neck. In contrast, support of the neck minimizes such flexion [9]. It has been claimed that flexion of the head on the neck may make both ventilation through the face mask and tracheal intubation more difficult [7, 9]. In addition, single-handed cricoid pressure prevents placement of, and ventilation through, the laryngeal mask more often than bimanual cricoid pressure [7]. The findings in this study confirm that support of the neck may reduce the untoward effects associated with cricoid pressure.

We assessed ventilation while the lungs were ventilated by a pressure control mode with a maximum inflation pressure of 15 cm H_2O. We used this mode as we considered that in clinical practice, ventilation wold usually be controlled by squeezing the reservoir bag, feeling the compliance of the lungs. We also considered that we would not inflate the lungs with an inflation pressure greater than 15–20 cm H_2O, to minimize air leak around the laryngeal mask. It is, however, not clear if cricoid pressure decreases ventilation volumes when the lungs are ventilated by a volume-controlled mode.

We used a firm pad to standardize the position of the patient's head and neck. Soft pillows are usually used to support the head and neck during induction of anaesthesia in the UK. This support of the neck by pillows may lessen the inhibitory effect of single-handed cricoid pressure on ventilation.

It has been recommended that cricoid pressure should be released temporarily during placement of the laryngeal mask and that it is re-applied immediately after placement of the mask [5, 7, 13]. From the results of this study we recommend that the patient's neck should be supported when cricoid pressure is applied after placement of the laryngeal mask to minimize the decrease in ventilation through the laryngeal mask.

GASTRIC INSUFFLATION

Cricoid pressure significantly decreases the degree of gastric insufflation while the lungs are ventilated via a face mask in both adults [15, 17, 18] and children [19–21]. We found that cricoid pressure was effective in preventing gastric insufflation even when the laryngeal mask was in place.

When the lungs were ventilated at a maximum inflation pressure of 30 cm H_2O (without cricoid pressure), gastric insufflation occurred in 24 % of patients, whereas air leaked from the gap between the mask and the pharynx in 46 % of patients. In a previous study, where a similar method of ventilation was used, the incidences of gastric insufflation and air leak were 35.4 % and 96 %, respectively, when the lungs were ventilated with an inflation pressure of 30 cm H_2O [3].

One possible reason for these differences between this and previous studies [3] is the difference in the size of the laryngeal mask. In the previous study, a size 3 laryngeal mask was used in females and a size 4 in males [3], whereas in this study, we used a size 4 in most female patients. Thus the incidence of both gastric insufflation and air leak might have been lower in this study because of a "better fit" mask. Brain states that a size 4 mask should be used in adults (both males and females) of average size, and a size 3 mask in small adults [12], although there is no study to confirm this recommendation. Our study may support the claim that the use of the size 4 mask is better than the size 3 mask in females of average size.

The incidence of apparent air leak from a gap between the laryngeal mask and the pharynx was greater than that of gastric insufflation. This finding is consistent with previous results [3]. The higher incidence of air leak around the laryngeal mask may indicate that the mask acts as a pressure-limiting ("pop-off") valve and reduces both the incidence and degree of gastric insufflation. When a face mask is used, gastric insufflation usually occurs at about 30 cm H_2O [15, 17, 21]. Thus the incidence of gastric insufflation is lower when the laryngeal mask is used compared with a face mask.

CRICOID PRESSURE DURING CARDIOPULMONARY RESUSCITATION

The laryngeal mask may be useful as an initial method of airway management during resuscitation until a person competent in tracheal intubation is available [22]. Although application of cricoid pressure during cardiopulmonary resuscitation has been advocated, it is not performed widely [23]. It is recommended that the airway should be maintained by two people when a face mask is used, one holding the mask and the patient's jaw and the other ventilating the lungs [24, 25]. Thus a third person may be required to apply cricoid pressure, which might be impractical. When the laryngeal mask is used, it may be practical to apply cricoid pressure, as one person can maintain both a patent airway and adequate ventilation and the second person can apply cricoid pressure.

In this study, although cricoid pressure decreased the incidence of gastric insufflation, it also inhibited ventilation through the laryngeal mask. It has been claimed from results of a multi-hospital study that the incidence of both gastric insufflation and regurgitation during cardiopulmonary resuscitation may be lower when the laryngeal mask is used compared with a face mask, even when cricoid pressure is *not* applied [22]. It is not clear if cricoid pressure would improve clinical outcome when the laryngeal mask is used during cardiopulmonary resuscitation.

POSITION OF THE LARYNGEAL MASK

The position of the laryngeal mask had not changed in any patient at the end of the experimental procedures. Thus application of cricoid pressure and ventilation of the lungs with an inflation pressure of 30 cm H_2O for a short duration after placement of the laryngeal mask did not usually dislodge the mask, when the mask was placed and fixed correctly to the patient's face. This finding is consistent with a previous observation [26]. However, it is not certain if cricoid pressure or ventilation with a high inflation pressure for a long duration would dislodge the mask. Dislodgement could be more likely to occur if the mask is not placed or fixed correctly. There is, however, no evidence to support these possibilities.

In summary, we have shown that although cricoid pressure applied after correct placement of the laryngeal mask significantly decreases the incidence of gastric insufflation, it also decreases the adequacy of ventilation. We also have shown that the inhibitory effect on ventilation by cricoid pressure without supporting the neck is greater than cricoid pressure with support of the neck. The patient's neck should thus be supported when cricoid pressure is applied after successful placement of the laryngeal mask.

Effects of surgical skin incision on respiration in patients anaesthetized with enflurane†

R. W. SUTHERLAND AND G. B. DRUMMOND

Summary

We measured ventilation in 12 subjects anaesthetized with enflurane (end-tidal concentration 1.25–1.45%) and nitrous oxide to assess the effect of surgical stimulation on ventilation in humans. Tidal volume and respiratory timing were measured by pneumotachograph before and just after a standardized surgical skin incision. Surgical stimulation increased ventilation by increasing tidal volume, which increased progressively over the first five breaths after incision. The first breath after the stimulus was prolonged, but the timing of the subsequent breaths returned rapidly to the duration observed before incision. Ventilation increased from median 3.6 (quartiles 2.9, 4.3) to 5.4 (3.8, 7.0) litre min^{-1} ($P < 0.01$). The increased tidal volume was not associated consistently with shortening of inspiratory duration. (*Br. J. Anaesth.* 1996; **76**: 777–779)

Key words

Anaesthetics volatile, enflurane. Ventilation, effects. Ventilation, pattern. Surgery, ventilatory response.

Traditional teaching is that depth of anaesthesia can be assessed by a variety of clinical signs [1]. Anaesthesia affects tidal volume and frequency of ventilation, and these variables are commonly used in clinical practice to assess depth of anaesthesia, although ventilatory frequency is influenced more by the volatile anaesthetic agent used than by depth of anaesthesia [2].

Spontaneous ventilation during surgery is influenced by both anaesthetic and stimulus. During anaesthesia with halothane or isoflurane, surgical skin incision is followed by an increase in the depth and rate of breathing [3, 4]. Stimuli in experimental animals cause similar increases in ventilation [5]. An increase in tidal volume, associated with a decrease in the duration of the respiratory cycle, suggests that respiration could be controlled in a manner proposed by Clark and von Euler [6]. The aim of this study was to demonstrate more exactly the pattern of response of respiration in anaesthetized patients after surgical skin incision, and to use this response to investigate the relationship between tidal volume and timing of the respiratory cycle.

Patients and methods

After obtaining local Ethics Committee approval and written informed consent, we studied 12 patients (eight female), ASA I or II, undergoing elective surgery for varicose veins. Patients were aged 30–63 yr and weighed 45–85 kg. No premedication was given. With the patient supine, anaesthesia was induced with propofol 2.5 mg kg^{-1} i.v., a laryngeal mask airway was inserted and anaesthesia maintained with enflurane and 66% nitrous oxide in oxygen. End-tidal enflurane concentrations were measured by sidestream sampling from a connector attached to the laryngeal mask airway using a Hewlett-Packard M1025 gas analyser, calibrated according to the manufacturer's instructions. The inspired enflurane concentration was adjusted to obtain a stable end-tidal value, within 0.1% for each patient, at 1.25–1.45%. Patients breathed spontaneously via a screen pneumotachograph (Mercury F100L) from a circle anaesthesia system. The pneumotachograph was calibrated on each occasion with a standard air syringe. The pneumotachograph output was digitized using a laptop computer fitted with an analogue-to-digital converter and recorded with Cardas software (version 6.1) (Oxcams, Oxford), which allowed instantaneous display of flow against time.

After surgical skin preparation and draping (skin clips were not used), each patient was allowed to breathe undisturbed for at least 2 min before a skin incision was made over the femoral vein in the groin for exploration of the saphenofemoral junction. The time of the start of incision was recorded onto the computer flow display. No attempt was made to synchronize the incision with the respiratory cycle.

The flow signal was later replayed and integrated using custom-written software to obtain a breath-by-breath volume signal, which was analysed to measure inspiratory duration (T_I), expiratory duration (T_E) and tidal volume (V_T). Instantaneous ventilation was calculated from tidal volume and respiratory cycle duration, and mean inspiratory flow rate was calculated as V_T/T_I.

Comparisons were made of these variables within individual subjects by paired comparison using the median values obtained from 10 breaths before

†Presented in part at the Anaesthetic Research Society, London Meeting, November 11–12, 1994 (*British Journal of Anaesthesia* 1995; 74: 497P–498P).

incision for each patient, with the median of 10 breaths after incision in the same patient (Wilcoxon paired test). $P < 0.05$ was considered significant. In addition, the first breath after incision was compared with the median value obtained from 10 breaths before incision, to assess the immediate responses. Individual V_T and T_I values in each subject before and after incision were plotted to assess the changes in breathing pattern. Statistical analysis was with Minitab release 8.2 using MS DOS version 6.2. Results are reported as median (quartile) values.

Results

Immediately before incision, mean end-tidal enflurane concentration was 1.39% (SD 0.06%). No patient showed limb movement on skin incision, but skin incision had an immediate effect on breathing pattern (fig. 1).

TIDAL VOLUME

Before stimulation, median tidal volume was stable with no significant trend in magnitude. Tidal volume of the first breath after stimulation had a greater volume (297, 178–437 ml) than the median of the values of the 10 preceding breaths (195, 151–211 ml). There was then a progressive increase in tidal volume over the next five breaths. Median tidal volumes for the 10 breaths after incision were significantly greater than the tidal volumes for the preceding 10 breaths (271, 225–363 ml compared with 195, 151–211 ml; $P < 0.01$).

MEAN INSPIRATORY FLOW RATE (V_T/T_I)

Surgical stimulation was associated with a small immediate increase in V_T/T_I in the first breath, and a progressive further increase over the next five breaths. The marked increase in tidal volume at the first breath was clearly not the result of an increase in inspiratory flow. The 10 breaths after stimulation had a significantly greater V_T/T_I than the preceding 10 breaths (10.6, 8.6–15.3 litre min^{-1} compared with 7.4, 6.9–9.0 litre min^{-1}; $P < 0.01$).

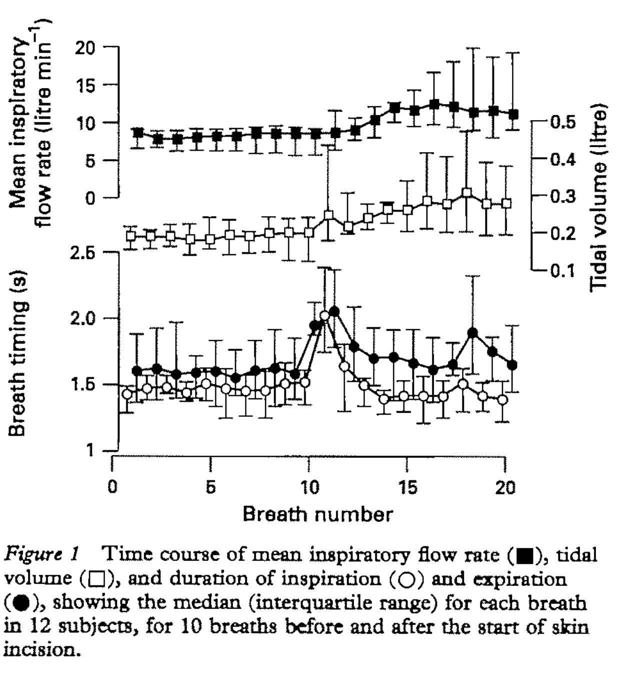

Figure 1 Time course of mean inspiratory flow rate (■), tidal volume (□), and duration of inspiration (○) and expiration (●), showing the median (interquartile range) for each breath in 12 subjects, for 10 breaths before and after the start of skin incision.

RESPIRATORY TIMING

The first breath after stimulation had a longer T_I (1.99, 1.55–2.42 s) and T_E (1.95, 1.63–2.28 s) than the preceding 10 breaths (1.49, 1.35–1.70 s and 1.60, 1.40–1.85 s, respectively) ($P < 0.05$). The timing of the subsequent breaths reverted to that before stimulation.

Minute volume had a pattern similar to mean inspiratory flow rate, and increased progressively for the first five breaths after stimulation. The 10 breaths after stimulation had a significantly greater minute volume (4.9, 3.8–7.0 litre min^{-1} compared with 3.6, 2.9–4.3 litre min^{-1} before stimulation; $P < 0.01$).

RELATIONSHIP BETWEEN V_T AND T_I

There was no clear relationship between V_T and T_I. Stimulation was associated with an increase in V_T in 10 subjects, of whom six showed a reduction in V_T and four an increase. Inspiratory duration decreased significantly in only two patients.

Discussion

Volatile anaesthetics in general, and enflurane in particular, are respiratory depressants [7]. Surgical stimulation can antagonize this depression, but little work has been done to assess the features of the increase in ventilation [3, 4]. Difficulties with standardizing the degree of stimulation have hampered studies of the effects of surgical stimulation on respiration. The intensity of the stimulus depends on the site of surgery and the degree of trauma. We attempted to standardize the stimulus by using a single skin incision in one body site. We also restricted our observations to breaths shortly after stimulation, so that secondary effects caused by changes in ventilation would have only small effects. The laryngeal mask may have caused some stimulation but our experience is that it is well tolerated at even very light levels of anaesthesia, in many instances better than the manipulations associated with conventional mask anaesthesia.

We found that stimulation had an immediate effect on the timing of respiration, followed by reversion to the timing before the stimulus. The speed of this response resembled the rapid responses in respiratory timing to stimuli mediated by nervous afferent activity, such as limb nerve stimulation [8], intercostal nerve stimulation [9], vagal stimuli [10] and peripheral chemoreceptor stimulation [11]. However, it is remarkable how respiratory timing reverts to the previous pattern after one breath. The remainder of the response to surgical stimulation was similar to that seen with a stimulus such as hypercapnia, which has a great influence on tidal volume, and less on respiratory timing [12].

Our findings do not support the possibility that lung volume affects inspiratory duration in these circumstances [2, 6].

Surgical stimulus caused a progressive increase in mean inspiratory flow rate over the first five breaths after the stimulus. Noxious stimuli result in extensive activation of brainstem reticular neurones [13], which can cause an increase in respiratory output, particularly in the rate of increase of inspiratory activity [8]. However, increased reticular system activity causes increases in both tidal volume and frequency [14], whereas in this study only drive increased. This resembles the response to a chemoreceptor stimulus [12].

Studies of other volatile anaesthetic agents with different effects on ventilatory frequency, such as halothane, would be of interest. It might also be that other forms of stimulation, in particular those carried from the viscera by the vagus, may result in different patterns of response, because vagal input in the nucleus tractus solitarius is related closely to respiratory reflex control.

In summary, we found that surgical stimulation during enflurane anaesthesia caused a slow increase in central respiratory drive and minute volume, but only a transient change in respiratory timing. Depth of respiration, or mean inspiratory flow rate, is therefore a useful index of respiratory response to surgical stimulation during anaesthesia with enflurane, but ventilatory frequency not.

Acknowledgement

We thank Dr P. K. Wraith who wrote the program to analyse the flow signal.

Efficiency of a circle system for short surgical cases: comparison of desflurane with isoflurane

D. J. H. LEE, D. L. ROBINSON AND N. SONI

Summary

Patients undergoing short surgical procedures but requiring ventilation of the lungs were allocated randomly to receive either desflurane or isoflurane by circle absorption system, initially at a high fresh gas flow. The inspired and expired concentrations of the volatile agent were measured and the fresh gas flows reduced to low flow (500 ml min^{-1} total when $F_E/F_I = 0.8$), as measured on a multigas analyser. In patients receiving desflurane ($n = 32$), the median time at which flows were reduced was 5 min (interquartile range (IQR) 1 min) while with isoflurane ($n = 32$), the median time was 19 (IQR 12) min. After the reduction in flow, expired concentrations of volatile agent decreased in both groups. In the isoflurane group the concentration continued to decrease during anaesthesia. In the desflurane group the initial decrease was followed by a slow recovery. We conclude that the circle system can be used efficiently for short anaesthetics using desflurane. (*Br. J. Anaesth.* 1996; **76**: 780–782)

Key words

Anaesthetics volatile, desflurane. Anaesthetics volatile, isoflurane. Equipment, breathing systems.

The advantages of circle systems compared with other breathing systems include conservation of gases, volatile agents, heat and moisture, and reduction in pollution [1]. These benefits are largely dependent on the use of low flows of gas. A large proportion of anaesthetics are of short duration and this does not lend itself to the use of low flows as traditionally it has been assumed to take 15–20 min at high flows to allow the achievement of adequate uptake of inhalation agent. Adequate uptake implies not only that an adequate alveolar concentration is achieved but that it is maintained at an acceptable level after flow reduction. While these initially high flows serve to reduce anxieties about nitrogen washout and nitrous oxide uptake, they also preclude efficient and effective use of the circle.

The advent of new agents with lower solubilities should enable more rapid uptake of agent and so potentially enable the flows to be reduced earlier [2]. Lower solubility also implies less ongoing uptake of the agent and so less risk of the alveolar concentrations decreasing progressively at the low flow rates. If the uptake of agent continues to be high, there is a risk that the alveolar concentration of volatile agent will diminish and result in a change in the depth of anaesthesia.

This study was undertaken to determine if an adequate end-expired concentration could be achieved earlier with desflurane than with isoflurane. We also wished to observe the changes in end-expired concentrations of volatile agents after reduction in flows.

Patients and methods

After obtaining approval from the Riverside Medical Ethics Committee, we studied ASA I or II patients, presenting for surgery, who required tracheal intubation and ventilation of the lungs for surgery. Patients were allocated randomly to receive either 8% desflurane or 1.5% isoflurane. These values were chosen as approximating to 1.5 MAC, so that at $F_E/F_I = 0.8$, the values would be 6% and 1.2%, respectively, which were of adequate magnitude to preclude awareness even if the expired concentrations decreased significantly after reduction in fresh gas flow. No premedication was given as these were short anaesthetics expected to last 20–30 min. Anaesthesia was induced in the anaesthetic room with propofol 3 mg kg^{-1} and fentanyl 2 μg kg^{-1}, and vecuronium 0.1 mg kg^{-1} was used to facilitate tracheal intubation. Anaesthesia was maintained with 66% nitrous oxide in oxygen and intermittent propofol administration while patients were moved to theatre and the tracheal tube connected to the circle system. The initial gas flows were set at 6 litre min^{-1}, with the vaporizers set to deliver 8% desflurane or 1.5% isoflurane. Initially the lungs were ventilated with a tidal volume of 10 ml kg^{-1} and a ventilatory frequency of 10 bpm. This was adjusted, as necessary, to maintain normocapnia.

The inspired and expired concentrations of desflurane or isoflurane were recorded at 1-min intervals. At the point where the expired concentration was 80%, or greater, of the set inspired concentration ($F_E/F_I = 0.8$, end-expired concentration/inspired concentration), the total

Correspondence to N. S.

fresh gas flow was reduced to 500 ml min^{-1} with a mixture of 50 % nitrous oxide and 50 % oxygen, and the time from connection to the circle absorption system was noted. The inspired and expired values of isoflurane or desflurane continued to be monitored until the end of anaesthesia. As this study was designed to evaluate short anaesthetics, a maximum time of 25 min was chosen arbitrarily. If the anaesthetic was shorter than 25 min and *F*E/*F*I failed to reach 0.8, then the time at the end of the anaesthetic was taken as the end-point. If the anaesthetic progressed beyond 25 min yet failed to achieve an *F*E/*F*I of 0.8, then 25 min was taken as the end-point.

The Mann–Whitney *U* test was used to test the difference in times at which the flow rates could be reduced.

An Ohmeda RGM 5250 multigas analyser was used to determine end-expired values. Accuracy is described as ±0.2 % over the range 0–5 % for isoflurane and ±0.5 % over the range 5.1–10 % for desflurane. This study was approved by the Riverside Medical Ethics Committee.

Results

We studied 64 patients, 32 in the isoflurane and 32 in the desflurane group. Median age was 35 (interquartile range (IQR) 11) yr and median weight 61 (IQR 14) kg. There was no significant difference between the ages in the two groups.

All patients in the desflurane group achieved an *F*E/*F*I = 0.8 during anaesthesia. In the isoflurane group, eight patients failed to achieve *F*E/*F*I = 0.8 by 25 min and were given an arbitrary value of 25 min. There was one patient in the isoflurane group where the anaesthetic time on the circle absorption system was only 20 min and who failed to reach *F*E/*F*I = 0.8. In that situation and for the purposes of this study, the time to reach *F*E/*F*I = 0.8 was given the arbitrary value of 20 min.

The median time to *F*E/*F*I = 0.8 in the isoflurane group was 19 (IQR) 12) min and in the desflurane group 5 (IQR 1) min. The difference in the time to reducing flow was significant ($P = 0.001$, Mann–Whitney *U* test). As nine patients failed to reach *F*E/*F*I = 0.8 and were given an arbitrary value of 25 min (except for one given 20 min), the isoflurane values were artificially low so that the difference between the two agents was greater than indicated.

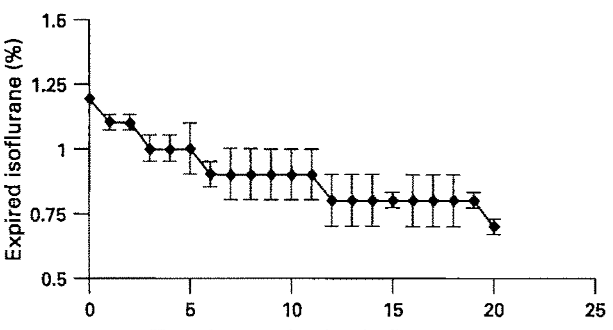

Figure 1 Expired concentration of isoflurane (mean, SD) after reduction in fresh gas flow rates to 500 ml min^{-1}. Time 0 = point at which flows were reduced.

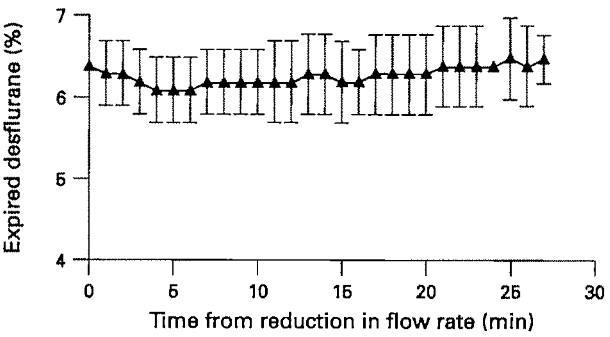

Figure 2 Expired concentration of desflurane (mean, SD) after reduction in fresh gas flow rates to 500 ml min^{-1}. Time 0 = point at which flows were reduced.

After reduction in flow rates, when *F*E/*F*I = 0.8 had been achieved, observations were made of the end-expired values of the volatile agents. The time at which the flow rate was reduced was termed time = 0 and the results plotted for isoflurane and desflurane at 1-min intervals (figs 1, 2).

Discussion

Previously it has been considered that the potential advantages of circle compared with non-rebreathing systems would be of benefit only in anaesthetics of long duration. In short anaesthetics, with the previous generation of soluble volatile agents, either high flows are required until the system has stabilized, negating the benefits of the circle, or complex and sophisticated techniques have to be used. The advent of new insoluble agents may enable the circle system to be used more efficiently in short anaesthetics, widening its effective application.

When *F*E/*F*I = 0.8 was used as an indicator to reduce the fresh gas flow into the circle system, the flows were reduced at a median time of 5 min with desflurane and 19 min with isoflurane. After the reduction in flows to a low flow of 500 ml min^{-1}, the pattern of change in the expired concentrations of desflurane and isoflurane were different. Desflurane decreased initially and then recovered while isoflurane decreased and then continued to decrease for the duration of time during which the concentration was measured, albeit a relatively short period of time in this study.

There are several aspects of this study which should be discussed. The time at which the flows were reduced was chosen in the absence of a specific indicator in the literature. An *F*E/*F*I of 0.8 was chosen for two reasons, First, it is a value which, using a multigas analyser, is easy to apply clinically with any volatile agent. Second, as it equates to 2–3 half-lives, it is an appropriate point on the uptake curve for volatile agents; the exponential curve is flattening at *F*E/*F*I = 0.8, indicating that the uptake of agent is reducing at this point (fig. 3). Uptake of agent beyond this point should be considerably less than earlier in the anaesthetic. Maintenance of the expired concentration depends on whether or not the

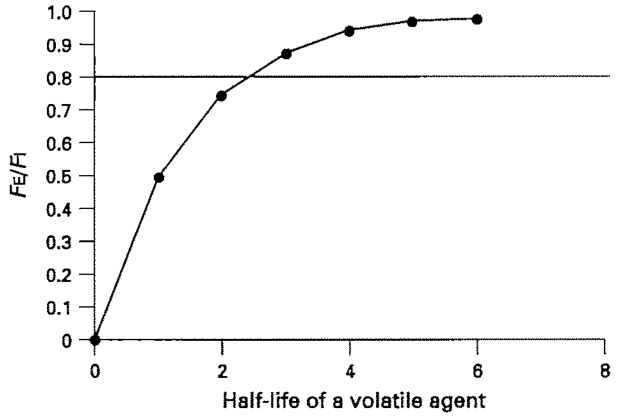

Figure 3 Theoretical curve of *FE/FI* against multiples of the half-life of a volatile agent assuming *FE* reaches *FI* eventually. *FE/FI* = 0.8 corresponds to the part of the curve with a reducing slope indicating a reduced speed of uptake.

dose of volatile agent administered in the new low flow is greater than, equal to or less than continuing uptake during the ongoing anaesthetic. In this study a flow rate of 500 ml min^{-1} was chosen as it is low by most standards, and also it delivers a small amount of anaesthetic agent accentuating any major difference in uptake between the agents. Higher flows deliver more agent and reduce the influence of flow rate on the expired values after the reduction in flow rate. The transient reduction and subsequent recovery of end-expired concentration with desflurane at low flow suggests that continuing desflurane uptake was satisfied by the small amount administered at low flow. The persistent reduction in expired values with isoflurane suggests that isoflurane uptake continued to be greater than that delivered by the low flow rates, over these relatively short-time periods. This is not unexpected given the comparative solubility of the agents and the low flow rates used.

The method of anaesthesia chosen is important when considering low-flow anaesthesia with a circle system for short anaesthetics. There are several potential problems. An adequate dose of anaesthetic agent has to be given to both prime the system and anaesthetize the patient. A continuing dose has then to be given to compensate for the continuing uptake and distribution of agent within the patient. As the volatile agent is administered as a percentage of the total fresh gas, low flows preclude a large dose being given unless a very high concentration is used. Consideration then has to be given to nitrogen washout of both the system and the patient, and the influence of nitrous oxide uptake, both early and late, on the concentrations of gases and vapours in the system. At low flows the volumes of these gases either being washed out or taken up have a relatively large impact, although any changes in concentration are easily monitored using the multigas analyser. Alternatively, the volatile agent can be injected into the circle system. The same potential difficulties with gas concentrations occur and there are technical and mathematical considerations regarding method and speed of administration [3, 4].

In this study high initial flows were used. This is in keeping with standard practice with other breathing systems. Nitrogen washout occurs rapidly and the uptake of nitrous oxide is relatively unimportant as the volumes of either gas taken up or released are trivial compared with flows into the system. The concentration of volatile agent set on the vaporizer is the concentration intended, and with the vaporizer out of circuit the set concentration represents the inspired value at high flows. When flows are reduced there is no alteration in the vaporizer settings and there is no risk of high concentration of volatile agent. The risk is of decreasing expired concentrations of volatile agents with a reduction in depth of anaesthesia. At total flows of only 500 ml min^{-1} (50% oxygen:50% nitrous oxide) the oxygen concentration must be monitored closely as over long periods it is possible for the inspired oxygen to decrease to less than 30%, even with a 50% oxygen mixture, as oxygen delivery may be close to oxygen consumption in some circumstances.

The method used in this study was deliberately attuned to anaesthesia for short surgical cases with the circle system. In patients receiving desflurane, the use of *FE/FI* = 0.8 to determine when flows could be reduced allowed the circle to be used as a low-flow system at a very early part of the anaesthetic. Using even very low flows (500 ml min^{-1}) did not cause clinical problems with decreasing expired desflurane values. With isoflurane, high flows were in use for most of the anaesthetic.

It is difficult to avoid the economic issue when discussing the circle system, in particular when using expensive agents, the cost of which prohibits introduction into many hospitals. Assuming an anaesthetic time of 20 min with the volatile agent used throughout, and fresh gas flows being reduced at the times suggested by the values obtained in this study, the cost of the volatile agents can be calculated. In this institution isoflurane would cost £3.60 and desflurane £2.60 for a 20-min anaesthetic. (At a fresh gas flow of 6 litre, the cost of desflurane would be £8.60.) The 30% difference, at low flow, has to be evaluated against the total cost of both the anaesthetic and the case [5, 6]. Of greater relevance to us is the ability to use the circle system efficiently and safely for day-case anaesthesia.

Oxygen consumption and delivery relationship in brain-dead organ donors

O. LANGERON, P. COUTURE, J. MATEO, B. RIOU, J.-L. PANSARD AND P. CORIAT

Summary

The oxygen delivery ($D\text{O}_2$) and consumption ($\dot{V}\text{O}_2$) relationship in brain-dead organ donors is unknown. Therefore, in a prospective study, we determined the $D\text{O}_2/\dot{V}\text{O}_2$ relationship in 21 consecutive brain-dead patients. Patients were allocated to one of two groups, according to plasma lactate concentration: normal (group NL, $n = 11$) or high (>2.5 mmol litre^{-1}) (group HL, $n = 10$). $\dot{V}\text{O}_2$ was measured independently, using indirect calorimetry, under control conditions, during low $D\text{O}_2$ challenge with PEEP administration, and high $D\text{O}_2$ challenge with inflation of medical antishock trousers and volume expansion or blood transfusion, as required. Under control conditions, there were no significant differences between groups NL and HL in haemodynamic or oxygenation variables, both groups having a low $\dot{V}\text{O}_2$ (mean 114 (SD 21) ml min^{-1} m^{-2}). In group HL there was a different $D\text{O}_2/\dot{V}\text{O}_2$ relationship pattern, with a dependent $\dot{V}\text{O}_2$ only. The mean slope of the $D\text{O}_2/\dot{V}\text{O}_2$ relationship was significantly higher in group HL than in group NL (0.12 (0.09) *vs* 0.04 (0.07), $P < 0.05$). We conclude that brain death was associated with a low $\dot{V}\text{O}_2$, and patients in group HL exhibited $D\text{O}_2/\dot{V}\text{O}_2$ dependency which was not observed in patients in group NL. *(Br. J. Anaesth.* 1996; **76**: 783–789)

Key words

Complications, brain death. Measurement techniques, calorimetry. Oxygen, consumption. Oxygen, delivery.

Transplantation of organs from brain-dead donors has become a common therapy for patients suffering from end-stage organ failure. Many physiological disturbances are associated with brain death, and management of the multiple organ donor is complex [1]. Failure to maintain cardiovascular and body homeostasis can induce sub-optimal organ perfusion and early graft dysfunction in the recipient [2]. However, in brain-dead patients, the optimal oxygen delivery ($D\text{O}_2$) required to meet the metabolic demand and provide appropriate tissue oxygenation is unknown. Oxygen consumption ($\dot{V}\text{O}_2$), calculated using the Fick method, has been suggested as being low in brain-dead patients [3–5]. This phenomenon could be related either to a decrease in oxygen requirements similar to that observed in anaesthetized patients [6–8] or to a deceased $D\text{O}_2$ because of hypovolaemia, left ventricular dysfunction, or both. Moreover, an abnormal $D\text{O}_2/\dot{V}\text{O}_2$ relationship could occur in brain-dead patients, as reported previously in critically ill patients [9–11]. Indeed, several studies have supported the hypothesis of a decrease in oxidative metabolism in brain-dead patients [4, 12], that could be explained by a $\dot{V}\text{O}_2$ supply dependency.

The aim of this study was to measure systemic $D\text{O}_2$ and $\dot{V}\text{O}_2$ in brain-dead patients before and after variation in $D\text{O}_2$, to determine the $D\text{O}_2/\dot{V}\text{O}_2$ relationship. To ensure an accurate and valid assessment of this relationship, $\dot{V}\text{O}_2$ and $D\text{O}_2$ were measured independently. Moreover, plasma concentrations of lactate may indicate if metabolism is predominantly aerobic or anaerobic, and has been used to assess organ donors [3, 5]. Consequently, we tested the hypothesis that the $D\text{O}_2/\dot{V}\text{O}_2$ relationship could differ, according to plasma concentrations of lactate.

Patients and methods

The study was approved by the Ethics Committee of Pitié-Salpêtrière Hospital and conducted according to French legislation concerning multiple organ procurement. Brain death was certified by: a neurological examination demonstrating the absence of brainstem reflexes; an apnoea test performed with intratrachael continuous high flow (15 litre min^{-1}) of oxygen and after 15 min of mechanical ventilation with an $F\text{I}_{\text{O}_2}$ of 100%; absence of spontaneous ventilation movement associated with an arterial $P\text{CO}_2$ greater than 8 kPa; no electrical activity during a 20-min electroencephalographic recording; absence of hypothermia (35 °C) and drugs known to depress the central nervous system [1, 5].

All patients had a stable haemodynamic state, characterized by a mean arterial pressure greater than 60 mm Hg without any change in requirements for fluids, inotropic support, or both, in the preceding hour, and without hepatic or renal failure. During the study, fluid therapy and inotropic

support were guided by haemodynamic monitoring with a pulmonary artery catheter, urinary output and laboratory estimation of plasma concentrations of electrolytes [5]. All patients were ventilated mechanically with an FI_{O_2} of 40% to maintain $Pa_{O_2} > 13$ kPa, Pa_{CO_2} at 4.5–5.3 kPa and pH at 7.35–7.45. Oesophageal temperature was maintained greater than 35.5 °C using heated blankets and perfusion warming.

MEASUREMENTS

Haemodynamic measurements were obtained via an indwelling radial artery catheter and a pulmonary artery catheter (SP5507 S, Viggo-Spectramed, Montigny le Bretonneux, France) connected to a haemodynamic monitor (HP 78354, Hewlett-Packard, Andover, MA, USA). The following haemodynamic variables were measured: heart rate (HR), mean arterial pressure (MAP), mean pulmonary arterial pressure (MPAP) and pulmonary capillary wedge pressure (PCWP). Cardiac output was measured in triplicate using the thermodilution method, and the mean was calculated. Systemic vascular resistance (SVR) and cardiac index (CI) were calculated according to standard formulae. Transoesophageal echocardiography (HP Sonos 1500, Hewlett-Packard, Andover, MA, USA) was performed by a trained echocardiographer and left ventricular ejection fraction area (LVEFa) was calculated.

Plasma concentrations of lactate (normal values $\leqslant 2.5$ mmol litre^{-1}) were measured in control conditions using an enzymatic method (Dimension apparatus, Dupont de Nemours, Wilmington, DL, USA). As an increase in plasma concentrations of lactate is thought to reflect a shift from oxidative to anaerobic metabolism with tissue hypoxia, brain-dead patients were divided into two groups based on whether they had a normal (NL) or high (HL) plasma lactate concentration, above 2.5 mmol litre^{-1}, in control conditions. This value was not known during the study, so that physicians performed the Do_2 challenge blinded.

Arterial and mixed venous blood was obtained to measure pH, partial pressures of oxygen (Po_2) and carbon dioxide (Pco_2), oxygen saturation (So_2) (BG Electrolytes Apparatus, Instrumentation Laboratory, Milano, Italy) and haemoglobulin (Hb) concentration (Cobas Argo, Apparatus, Roche, Basle, Switzerland). Do_2 was calculated using the following formulae:

$$Do_2 = \mathrm{CI}((1.34 \times \mathrm{Hb} \times Sa_{O_2}) + (0.003 \times Pa_{O_2})) \times 10$$

$\dot{V}o_2$ and Do_2 were measured independently to obtain reliable results, avoiding mathematical coupling of shared variables [13–16]. As reported previously [17–19], $\dot{V}o_2$ was measured using a portable indirect calorimetry system (Deltatrac, Metabolic Monitor, Datax Instrumentation Corp, Helsinki, Finland). This metabolic monitor measures carbon dioxide and oxygen concentrations in inspired and expired gases per minute and calculates carbon dioxide production and oxygen consumption during that minute. These measurements were performed on the ventilator circuit with a paramagnetic oxygen sensor, a carbon dioxide infrared analyser and a flowmeter. This system has been validated previously for accuracy, sensitivity and reproducibility in the measurement of $\dot{V}o_2$ [17, 18]. The mean error in the measurement of $\dot{V}o_2$ at baseline and after increasing $\dot{V}o_2$ is -2% (range -7 to 3%) [19]. Calibration of the apparatus was performed with a mixture of 96% oxygen and 4% carbon dioxide before each use.

For each patient, measurements were performed minute-by-minute over a 20-min period in which variation in minute-by-minute measurements of oxygen consumption was less than 5%. In each patient, during each period of the study, $\dot{V}o_2$ was determined as the mean of 20 measurements over a 20-min period. All patients were ventilated mechanically with a constant FI_{O_2} of 40% throughout the study. Oxygen extraction was calculated by dividing $\dot{V}o_2$ by Do_2:

$$\text{Oxygen extraction} = \dot{V}o_2 \times Do_2^{-1}.$$

EXPERIMENTAL DESIGN

The trachea was not suctioned and patients were not turned within the 30 min before acquisition of measurements and throughout the study. We performed a Do_2 challenge to obtain changes in Do_2 of at least $\pm 20\%$ from control Do_2.

To decrease Do_2, positive end-expiratory pressure (PEEP) was administered to decrease cardiac output. PEEP titration was performed to maintain MAP greater than 40 mm Hg. The level of PEEP was increased up to 10 or 15 cm H_2O (mean 12 (SD 4) cm H_2O). After a 15-min stabilization period, $\dot{V}o_2$ was measured.

To increase Do_2, inflation of medical antishock trousers (MAST, Jobst Ltd, OH, USA) was undertaken to increase venous return and thus cardiac output [20]. The inflation pressure was approximately 40 cm H_2O in the leg compartments and 30 cm H_2O in the abdominal compartment. These levels of inflation pressure induce venous compression without arterial compression, enabling an increase in Do_2 [20]. MAST inflation was followed by volume expansion of 500 ml of gelatin solution (Plasmion, Laboratories Roger Bellon, France) or transfusion of packed red blood cells if packed cell volume was less than 30%. This Do_2 challenge was monitored using a pulmonary artery catheter to avoid PCWP values greater than 20 mm Hg. After a 15-min stabilization period, $\dot{V}o_2$ was measured.

At the end of each 20-min period, haemodynamic and metabolic variables were recorded, and arterial and mixed venous blood was obtained for blood-gas analysis. We determined $\dot{V}o_2$ in the same order: control conditions, low Do_2 and high Do_2, with a recovery period between low and high Do_2 characterized by a stable haemodynamic and metabolic state, as in control conditions.

STATISTICAL ANALYSIS

Data are expressed as mean (SD or range). Comparison of control values between the two groups (NL and HL) was performed using the Student's *t* test and the Fisher's exact method. Comparison of several means was performed using repeated-measure analysis of variance and Newman–Keuls test. The relationship between $\dot{V}o_2$ and Do_2 was fitted to a two-regression line model. The two best-fit regression lines were determined by the sum of least squares technique [21]. The critical Do_2 represented the threshold, below which $\dot{V}o_2$ started to decrease with a further reduction in Do_2. All P values were two-tailed and $P < 0.05$ was considered significant. Statistical analysis was performed on a computer using PCSM software (V3.1, Deltasoft, Meylan, France).

Results

We studied 21 brain-dead patients (15 men), mean age 38 (range 16–53) yr. Eleven patients had a normal (group NL) plasma lactate concentration (1.9 (SD 0.4); range 1.25–2.5 mmol $litre^{-1}$), and 10 patients had an elevated (group HL) plasma lactate concentration (4.0 (0.9); 2.6–5.5 mmol $litre^{-1}$). There were no significant differences between the two groups in age, cause of brain death, mean time lapse between causal event and brain death, body temperature, haemoglobin concentration, LVEFa and the number of patients receiving dopamine throughout the study or dose of dopamine (table 1). Under control conditions, there were no significant differences in haemodynamic variables between groups NL and HL, except for cardiac index (table 2). There were no significant differences between groups for Do_2 (group NL, 428 (131); range 276–684 ml min^{-1} m^{-2} *vs* group HL, 450 (203); 190–733 ml min^{-1} m^{-2}), $S\bar{v}_{O_2}$, oxygen extraction, arterial oxygen content and the arteriovenous difference in oxygen content in control conditions (table 3). Moreover, a low $\dot{V}o_2$ was observed in the two groups (114 (21) ml min^{-2} m^{-2}) and $\dot{V}o_2$ was not significantly different between groups in control conditions (table 3).

During the Do_2 challenge, we observed a significant increase in Do_2 in both groups during MAST application (group NL, +24 (17)%, $P < 0.05$; group HL, +48 (25)%, $P < 0.05$), and a significant decrease in Do_2 in both groups during PEEP

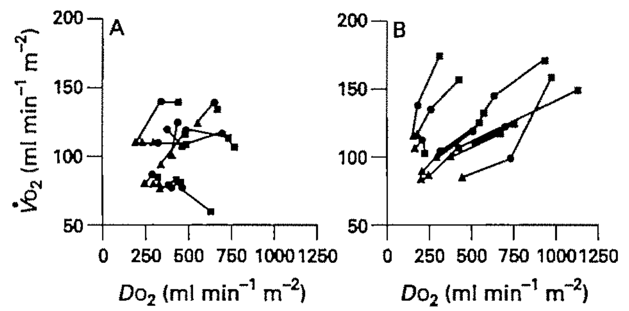

Figure 1 Individual relationship between oxygen consumption ($\dot{V}o_2$) and oxygen delivery (Do_2) during Do_2 challenge in patients with normal plasma lactate concentrations (group NL, $n = 11$) (A) and high plasma lactate concentrations (group HL, $n = 10$) (B) under three conditions: low Do_2 (▲), control Do_2 (●) and high Do_2 (■).

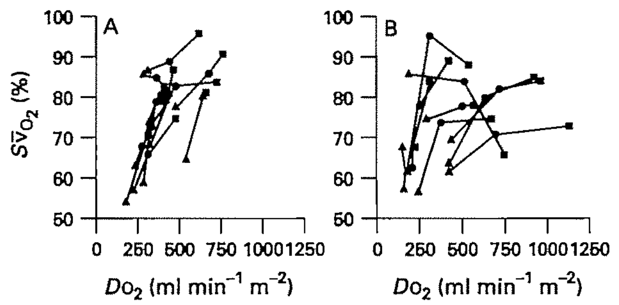

Figure 2 Individual relationship between mixed venous oxygen saturation ($S\bar{v}_{O_2}$) and oxygen delivery (Do_2) during Do_2 challenge in patients with normal plasma lactate concentrations (group NL, $n = 11$) (A) and high plasma lactate concentrations (group HL, $n = 10$) (B) under three conditions: low Do_2 (▲), control Do_2 (●) and high Do_2 (■).

administration (group NL, −24 (10)%, $P < 0.05$; group HL, −35 (12)%, $P < 0.05$). In group NL, $\dot{V}o_2$ did not increase significantly during high Do_2 challenge (−4 (8)%) and was moderately decreased during low Do_2 challenge (−9 (9)%, $P < 0.05$). In contrast, in group HL, $\dot{V}o_2$ increased significantly during high Do_2 challenge (+19 (17)%, $P < 0.05$) and decreased significantly during low Do_2 challenge (−16 (6)%, $P < 0.05$) (table 3).

There was a different pattern in the $Do_2/\dot{V}o_2$ relationship in groups NL and HL. $\dot{V}o_2$ increased with Do_2 throughout Do_2 challenge in patients in group HL, whereas patients in group NL exhibited small variations in $\dot{V}o_2$ ($\Delta\dot{V}o_2$) during control and high Do_2 conditions. Nevertheless, it should be pointed out that variations in Do_2 (ΔDo_2) were lower in group NL compared with group HL (48 (25)% *vs* 83 (26)%; $P < 0.05$). However, the magnitude of $\Delta\dot{V}o_2/\Delta Do_2$ was significantly higher in group HL than in group NL (0.13 (0.09) *vs* 0.05 (0.04); $P < 0.05$).

Individual analysis of the $Do_2/\dot{V}o_2$ relationship is depicted in figure 1. We observed a significant increase in the mean slope of the $Do_2/\dot{V}o_2$ relationship in patients in group HL compared with patients in group NL (0.12 (0.09) *vs* 0.04 (0.07); $P < 0.05$). This $Do_2/\dot{V}o_2$ relationship, either in NL or HL patients, impedes the use of a two-regression line model in each group and consequently the assessment of critical Do_2 could not be achieved in either group (fig. 1).

As shown in table 3 and figure 2, we observed a different pattern in the $S\bar{v}_{O_2}/Do_2$ relationship in groups NL and HL, with a significant correlation between $S\bar{v}_{O_2}$ and Do_2 in group NL ($r = 0.64$, $P < 0.05$), and no significant correlation in group HL ($r = 0.34$). The mean slope of the $S\bar{v}_{O_2}/Do_2$ relationship (fig. 2) was not significantly different between patients in groups NL and HL (0.07 (0.05) *vs* 0.05 (0.05) % ml^{-1} min m^2).

Discussion

In this study, we observed a low $\dot{V}o_2$ in brain-dead patients, both in group NL and group HL (table 3), and a different pattern in the $Do_2/\dot{V}o_2$ relationship between these two groups. Pathological $\dot{V}o_2$ dependency was noted in patients with elevated plasma concentrations of lactate and a physiological $Do_2/\dot{V}o_2$ relationship with a plateau was observed in patients with normal plasma lactate concentration.

Brain-dead patients had low $\dot{V}o_2$ values, as reported previously in normal humans at rest [8] (range of 110–150 ml min^{-1} m^{-2}) or in critically ill surgical patients undergoing mechanical ventilation at rest (114 (18) ml min^{-1} m^{-2}) or at a low level of activity (131 (21) ml min^{-1} m^{-2}) [22]. Moreover, in our study, $\dot{V}o_2$ values were close to those found in anaesthetized patients, where $\dot{V}o_2$ reached a plateau at 109 (16) ml min^{-1} m^{-2} or at 105 (13) ml min^{-1} m^{-2}, before and after cardiopulmonary bypass, respectively [6, 7]. During general anaesthesia, oxygen consumption decreased by 25–30% [8, 23], corresponding to the values found in our study during brain death. Mechanical ventilation decreases oxygen consumption and minimizes oxygen uptake. Consequently, similar $\dot{V}o_2$ values were observed during brain death and general anaesthesia [23].

The $Do_2/\dot{V}o_2$ relationship has been studied under many circumstances [24–27], but is often a source of controversy, mainly because an artefactual correlation between Do_2 and $\dot{V}o_2$ can occur by sharing common data for cardiac output and arterial oxygen content leading to mathematical coupling of these variables [13, 16, 28]. In our study, $\dot{V}o_2$ was measured independently in order to avoid this pitfall. We used the gas exchange method to measure $\dot{V}o_2$ with a metabolic monitor which had been validated previously [17, 18] and exhibits a small error in $\dot{V}o_2$ measurement when $F_{I_{O_2}}$ is less than the critical level of 75% [18]. In our study, $F_{I_{O_2}}$ was maintained constant at 40%. The second criterion for a reliable $Do_2/\dot{V}o_2$ relationship is to minimize spontaneous and provoked variations in metabolic demand with no muscle activity to keep $\dot{V}o_2$ constant. These conditions are achieved in brain death. Moreover, the $Do_2/\dot{V}o_2$ relationship may be influenced by body temperature [29]. In our study we did not observe any significant difference in temperatures between groups NL and HL which could explain the different pattern of the $Do_2/\dot{V}o_2$ relationship. Furthermore, we performed a Do_2 challenge with PEEP administration, fluid loading and MAST application, sometimes associated with blood transfusion. As reported previously, $\dot{V}o_2$ is not affected by any of these manoeuvres [16, 30]. Whereas the effects of catecholamines on cellular oxidative metabolism increase $\dot{V}o_2$ [10], dopamine is not thought to increase $\dot{V}o_2$ at the low doses used in our study [16, 31]. Moreover, we did not observe any significant difference in dopamine doses between the two groups. Finally, to ascertain that a reliable $Do_2/\dot{V}o_2$ relationship could be obtained it is necessary to have at least two data pairs for each patient over a wide range of Do_2 values. We collected three data pairs for each patient over a Do_2 variation of at least ±20% of control values, which was our minimal end-point in the Do_2 challenge (table 3). As reported previously, these different factors are essential to describe a reliable $Do_2/\dot{V}o_2$ relationship [15].

After Do_2 challenge, we observed that patients in group HL had a different $Do_2/\dot{V}o_2$ relationship pattern compared with patients in group NL (fig. 1). In group HL, the increased plasma lactate concentration suggested inadequate Do_2 and that tissue oxygen requirements were no longer satisfied, and $Do_2/\dot{V}o_2$ dependency was observed. Inadequate Do_2 usually implies either hypoperfusion or arterial desaturation, whereas impaired oxygen utilization by the tissues reflects abnormal oxygen metabolism or dysoxia [15]. However, the lack of significant differences in haemodynamic and echocardiographic data, and blood-gas analysis between the two groups suggest dysoxia in group HL, with a weak oxygen extraction and utilization by the tissues in group HL, as suggested by the non-significant difference in arteriovenous oxygen content difference between groups HL and NL. Furthermore, in group HL, the inability to obtain a critical Do_2 despite a wide Do_2 challenge with $\dot{V}o_2$ dependency would suggest a pathological $Do_2/\dot{V}o_2$ dependency [24]. In group NL, we probably did not decrease Do_2 as much as necessary to obtain critical Do_2 from which $\dot{V}o_2$ begins to decrease, with a further reduction in Do_2. Thus our results suggest that critical Do_2 in brain-dead patients with normal plasma lactate concentration was less than 330 ml min^{-1} m^{-2} which is the critical Do_2 reported in patients during general anaesthesia [6, 7]. Conversely, critical Do_2 in brain-dead patients with elevated plasma concentrations of lactate was not reached despite high Do_2 levels, and remains unknown at present.

This pathological $Do_2/\dot{V}o_2$ dependency has been reported in sepsis [10], adult respiratory distress syndrome (ARDS) [11], or both [9]. However, other recent studies in sepsis [13, 19, 20] and ARDS [14, 32] did not confirm this $Do_2/\dot{V}o_2$ dependency, probably because $\dot{V}o_2$ was measured and not calculated. Thus, this is the first time that a $Do_2/\dot{V}o_2$ dependency has been demonstrated using independent measures of Do_2 and $\dot{V}o_2$.

Our study indicated the occurrence of dysoxia in some brain-dead patients, but did not enable us to determine precisely the mechanism(s) of these abnormalities. However, several hypotheses might be suggested: (1) the event causing brain death or brain death itself is able to release mediators or induce neurohumoral dysfunction altering the microcirculation, with oxygen diffusion impairment or microcirculatory mismatch, such as during sepsis, causing dysoxia; (2) a switch from aerobic to anaerobic metabolism caused by haemodynamic deterioration occurring during brain death may induce an oxygen debt in some patients and this debt may be paid off with increasing Do_2. However, our study was conducted under stable haemodynamic conditions, several hours after resuscitation, and therefore this hypothesis is unlikely; (3) a reduction in circulating free triiodothyronine, as noted previously in brain-dead patients [3, 12], may result in decreased oxidative metabolism. Indeed, it has been shown recently that high plasma lactate concentrations are associated with mitochondrial impairment in oxygen metabolism in brain-dead patients [33].

Several limitations should be discussed to assess the clinical relevance of our study. First, systemic

$D\mathrm{o}_2$ does not assess the effectiveness of regional $D\mathrm{o}_2$ in different organs and vascular beds [26]. Local and regional blood flow redistribution are important determinants of the adequacy of both regional and systemic oxygen uptake, as reported previously [34]. Brain death is associated with loss of peripheral vasomotor tone and an inability to redistribute blood flow appropriately [1]. Consequently, brain death may also modify the local or regional $D\mathrm{o}_2/\dot{V}\mathrm{o}_2$ relationship, leading to potential organ impairment, despite appropriate systemic $D\mathrm{o}_2$. Second, elevated plasma lactate concentration might not always reflect tissue hypoxia, as lactate concentration results from the balance between lactate production and hepatic and renal clearance, the washout phenomenon after successful resuscitation, and from the activity of pyruvate dehydrogenase which may be inhibited as in sepsis. Nevertheless, in our study, none of the patients with elevated plasma lactate concentrations had hepatic or renal failure. Lastly, some authors [35] have supported the theory of obtaining supranormal values of $D\mathrm{o}_2$ to prevent dysoxia and organ system dysfunction in order to decrease mortality in critically ill patients. But a recent study failed to demonstrate any survival benefit from obtaining supranormal $D\mathrm{o}_2$ values [36]. In the management of organ donors, increasing $D\mathrm{o}_2$ in patients in group HL seems reasonable, but increasing $D\mathrm{o}_2$ to supranormal values has yet to be demonstrated. However, our results do not provide evidence that increasing $D\mathrm{o}_2$ may actually decrease plasma concentrations of lactate and that transplantation outcome could be modified by decreasing plasma lactate concentrations. Further studies are required to confirm this hypothesis.

Sepsis-induced vasoparalysis does not involve the cerebral vasculature: indirect evidence from autoregulation and carbon dioxide reactivity studies

B. F. MATTA AND P. J. STOW

Summary

We have studied cerebral autoregulation and vasoreactivity to carbon dioxide in 10 patients with the sepsis syndrome receiving intensive therapy. All patients were sedated with infusions of midazolam and fentanyl, and their lungs were ventilated mechanically with oxygen–air to maintain normoxia and normocapnia. Inotropic support and antibiotics were administered as necessary. During a period of constant level of sedation and stable haemodynamics, cerebral autoregulation was tested by increasing mean arterial pressure (MAP) by 23 (SD 2) mm Hg from baseline with an infusion of phenylephrine and simultaneously recording middle cerebral artery blood flow velocity (*v*mca) using transcranial Doppler ultrasonography. Carbon dioxide reactivity was tested by varying Pa_{CO_2} between 3.0 and 7.0 kPa and simultaneously recording *v*mca. There was no significant change in *v*mca (57 (22) and 59 (23) cm s^{-1}) during the increase in MAP (75 (11) to 98 (10) mm Hg). The mean index of autoregulation (IOR) was 0.92 (SEM 0.03), which was not significantly different from 1, indicating near perfect autoregulation. Although absolute carbon dioxide reactivity was lower than reported previously in awake subjects, relative carbon dioxide reactivity was within normal limits for all patients (11.6 (SEM 0.8) cm s^{-1} and 20.3 (3) % kPa^{-1}, respectively). We conclude that cerebral carbon dioxide reactivity and pressure autoregulation remained intact in patients with the sepsis syndrome, providing indirect evidence that at least in the early stages of the syndrome, the widespread sepsis-induced vasoparalysis does not involve the cerebral vasculature. (*Br. J. Anaesth.* 1996; **76**: 790–794)

Key words

Brain, carbon dioxide, reactivity. Brain, blood flow. Measurement techniques, ultrasound. Intensive care. Complications, sepsis syndrome.

Sepsis continues to be a common and frequently fatal illness in humans. Although the pathophysiology of generalized sepsis is complex and not yet fully explained, the syndrome is generally associated with multisystem organ impairment and decreased systemic vascular resistance as a result of widespread vasoparalysis [1, 2].

Cerebral pressure autoregulation and carbon dioxide reactivity are dependent on intact cerebral vascular tone and reactivity [3]. It is not known if the vasoparalysis in patients with sepsis involves the cerebral vasculature, and if so, what effect this has on these two important mechanisms for the control of cerebral blood flow (CBF). In this study we aimed to establish if there were disturbances in cerebral autoregulation and carbon dioxide reactivity in patients with the sepsis syndrome. If this were the case, it might explain the pathophysiology of the encephalopathy seen in up to 70% of patients with sepsis, which has been associated with higher mortality [4, 5]. Furthermore, the information may be beneficial in the management of these patients in whom involvement of the cardiovascular and respiratory systems often leads to arterial pressure instability and carbon dioxide retention.

Patients and methods

After obtaining Human Subjects Committee approval and informed consent from the next of kin, we examined cerebral autoregulation and carbon dioxide reactivity in 10 patients admitted to our intensive care unit with the sepsis syndrome (eight intra-abdominal sepsis, two pneumonias) and altered mental state (confusion or delerium). The sepsis syndrome was diagnosed according to criteria described previously by Bone and colleagues [2] (table 1). Patients who had a pre-existing neurological disease and those receiving psychotropic drugs were excluded. All studies were performed within 24 h of admission to the intensive care unit. Routine monitors included electrocardiography, invasive arterial pressure, central venous and pulmonary artery pressures, and pulse oximetry. All patients received infusions of midazolam 100–300 µg kg^{-1} h^{-1} and fentanyl 1–5 µg kg^{-1} h^{-1} to maintain adequate sed-

Table 1 Criteria for definition of the sepsis syndrome [2]

- A systemic response to infection with:
  - Hypothermia < 35.1 °C or hyperthermia > 38.3 °C
  - Tachycardia > 90 beat min^{-1} in the absence of hypovolaemia or beta-adrenergic block
  - Tachypnoea > 20 b.p.m. or requirement for ventilatory support
  - Clinical evidence of an infection site
- At least one end-organ showing evidence of inadequate perfusion or dysfunction:
  - Poor or altered cerebral function (inattention, confusion, disorientation, delirium, coma)
  - Hypoxaemia Pa_{O_2} < 10 kPa breathing room air, not caused by overt pulmonary disease
  - Elevated plasma lactate > 2.2 mmol $litre^{-1}$
  - Oliguria (urine output < 30 ml h^{-1}) without corrective therapy for at least 1 h

ation. The lungs were ventilated mechanically with oxygen–air to maintain normoxia and normocapnia. Inotropic support and antibiotics were administered as indicated clinically. During a period of constant level of sedation and stable haemodynamics, cerebral blood flow velocity (*v*mca) was measured by insonating the middle cerebral artery (MCA) using a transcranial Doppler probe (Scimed, Bristol, UK or Neuroguard, Fremont, CA, USA). One type of probe was used throughout the study for each individual patient. The methodology has been reported previously [3]. Briefly, the probe was secured in position so that the angle of insonation remained constant throughout the study. Doppler signals from the right MCA were identified and measured at a depth of 45–50 mm. The shift in frequency spectra of the Doppler signals converted into time-mean flow velocity (*v*mca) were displayed on a video monitor. A phenylephrine infusion (100 μg ml^{-1}) was used to increase mean arterial pressure (MAP) by approximately 20 mm Hg from baseline and *v*mca was recorded simultaneously. The infusion of phenylephrine was then discontinued and MAP was allowed to return to baseline. Carbon dioxide reactivity was then tested by varying Pa_{CO_2} between 3.0 and 7.0 kPa and simultaneously recording *v*mca. Arterial Pa_{CO_2} was varied, altering minute ventilation without significant change in airway pressure (changing ventilatory rate at constant tidal volume). A minimum period of 5 min was allowed for stabilization (unchanged end-tidal carbon dioxide) at each Pa_{CO_2} before measurements were made. Three paired Pa_{CO_2}–*v*mca data were obtained for each patient.

DATA ANALYSIS

The index of autoregulation (IOR) was calculated as the ratio of percentage change in estimated cerebral vascular resistance (CVRe) to percentage change in MAP, using the equations CVRe = MAP/*v*mca and IOR = %∂CVRe/%∂MAP, where MAP = mean arterial pressure at the time of *v*mca measurement [6]. Perfect autoregulation is present when the percentage change in CVRe is equal to the percentage change in MAP; no change in *v*mca with change in MAP, and IOR = 1. An IOR of 0 signifies complete absence of autoregulation. Based on studies published previously [6, 7], we considered a 15% change in IOR to be clinically insignificant. We then performed a power analysis which indicated that for a power of 0.80, an alpha value of 0.05 and a beta value of 0.20, the required number of patients to reject the null hypothesis was 10. The computed IOR and data recorded before and after the phenylephrine-induced increase in MAP were analysed using Student's *t* test. $P < 0.05$ was considered statistically significant.

To determine carbon dioxide reactivity, regression lines were constructed for paired Pa_{CO_2}–*v*mca data for each patient. Carbon dioxide reactivity was expressed in both absolute (change in *v*mca per kPa change in Pa_{CO_2}) and relative (percentage change in *v*mca at Pa_{CO_2} 5.3 kPa per kPa change in Pa_{CO_2}) values.

Results

Patient characteristics are shown in table 2. There were no significant changes in body temperature, haemoglobin concentration and partial pressure of oxygen (Pa_{O_2}) in arterial blood during the study (table 3). There was no change in Pa_{CO_2} during the autoregulation part of the study and no change in MAP during the carbon dioxide reactivity part of the study.

There was no significant change in mean *v*mca (57 (SD 22) and 59 (23) cm s^{-1}) during the increase in MAP (75 (11) to 98 (10) mm Hg). Mean IOR was 0.92 (SEM 0.03), which was not significantly different from 1, indicating near perfect autoregulation. The dose of phenylephrine required to increase MAP by approximately 20 mm Hg was 100–300 μg.

Linear regression analysis demonstrated a close relationship between *V*mca and Pa_{CO_2}, with correlation coefficients greater than 0.85 in all instances ($P < 0.001$). Although absolute cerebral vasoreactivities to carbon dioxide derived by linear regression analysis were lower than reported awake values, relative cerebral vasoreactivity to carbon dioxide was within normal limits for all patients (11.6

Table 2 Patient data (mean (SD or range))

Age (yr)	60 (21–86)
Weight (kg)	74 (17)
Sex (M:F)	4:6
Admission APACHE score	23 (18–34)

*v*mca (cm s^{-1})	57 (22)	59 (23)

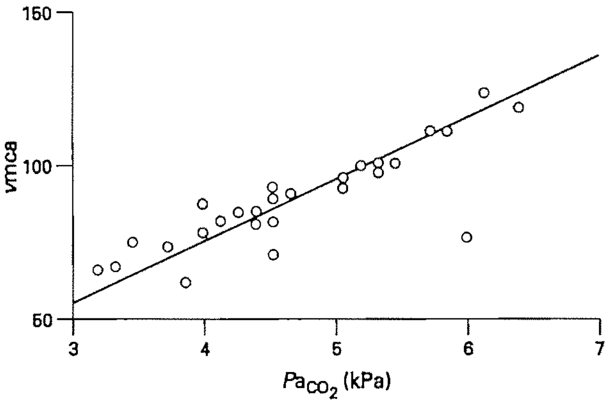

Figure 1 Relative middle cerebral artery velocity (*v*mca) *vs* corresponding Pa_{CO_2} for all patients. Relative *v*mca was calculated by expressing flow velocity values as a percentage of *v*mca at a Pa_{CO_2} of 5.3 kPa. The respective linear regression is shown.

(SEM 0.8) cm s^{-1} kPa^{-1} and 20.3 (3) % kPa^{-1}, respectively. Figure 1 shows the relative cerebral vasoreactivity for all patients (relative *v*mca *vs* Pa_{CO_2}).

Discussion

In this study, we have shown that cerebral pressure autoregulation and vasomotor reactivity to carbon dioxide remained intact in patients with the sepsis syndrome. This suggests that at least in the early stages of sepsis, the widespread sepsis-induced vasoparalysis does not involve the cerebral vasculature.

Steady-state conditions were maintained during both parts of the study. There was no change in patient body temperature or haemoglobin concentration; MAP was maintained constant during the carbon dioxide reactivity part of the study, and Pa_{CO_2} was unchanged between normotension and phenylephrine-induced hypertension phases. The drugs used for sedation (fentanyl and midazolam) have no direct cerebrovascular effects [8, 9].

Transcranial Doppler ultrasonography (TCD) is a particularly suitable tool for assessing cerebral vasoreactivity to carbon dioxide [10]. The device is inexpensive, non-invasive and non-radioactive. Multiple paired measurements can be obtained and linear regression lines constructed more accurately than with a limited number of conventional blood flow measurements [10–12]. Furthermore, despite TCD not providing a direct measure of CBF, it provides an accurate measure of relative changes in CBF [10–12]. There is now ample direct and indirect evidence to support the contention that MCA is a conductance vessel and its diameter does not change significantly with changes in arterial pressure, Pa_{CO_2} or the use of anaesthetic or vasoactive agents [11–16]. Changes in cerebral vascular resistance occur primarily through dilatation of arterioles and not the arteries of the circle of Willis [17].

Although the absolute carbon dioxide reactivity values in this study were slightly lower than reported awake values, they were consistent with values obtained during sedation and anaesthesia [6, 18, 19]. When the carbon dioxide reactivity values were normalized to *v*mca at Pa_{CO_2} 5.3 kPa, the percentage change in *v*mca per kPa approximated the awake value. Normalizing all *v*mca values by expressing them as a percentage of vmca at a Pa_{CO_2} of 5.3 kPa allows comparisons with previously published studies and reduces the dependence on the baseline *v*mca value, which is reported to vary between 30 and 90 cm s^{-1} in awake individuals [20]. Bowtón and colleagues have shown that in septic patients, CBF is reduced [21]. Although it is not possible to estimate absolute CBF accurately, *v*mca values obtained in this study were within the normal range.

We could only estimate cerebral vascular resistance (CVRe) because we measured *v*mca and not absolute CBF. This estimation of CVRe depends on our previous assumption that changes in CBF correlate with changes in *v*mca. We then calculated the index of autoregulation by dividing the percentage change in CVRe by the percentage change in MAP. An IOR of 1 indicates that the percentage change in CVRe is the same as the percentage change in MAP and no change in CBF results (complete autoregulation). Complete absence of autoregulation gives an IOR of 0. IOR was 0.92 (SEM 0.03), which indicated that near complete autoregulation was present in patients with the sepsis syndrome. This deviation from an IOR of 1 is clinically unimportant and within normal limits, as dynamic autoregulation in normal volunteers has been shown to have an SD of 15% [22]. Power analysis ensured that 10 patients were sufficient to reject the null hypothesis with a power of 0.80, an alpha error of 0.05 and a beta error of 0.20.

Although we only examined autoregulation in one direction (increase in pressure), we chose a level of MAP which normally lies in the middle of the autoregulation curve. Therefore, there is no reason to assume that a decrease instead of an increase in MAP would have yielded different results. This has been confirmed recently by Tiecks and colleagues who found that the ability of the cerebral circulation to autoregulate is similar whether MAP is increased or decreased [23].

Encephalopathy may be present in up to 70% of patients with sepsis [4]. The severity ranges from impaired attention and concentration to delirium and coma. The electroencephalograph (EEG) is a valuable tool in the intensive care of these patients. The EEG is a sensitive indicator of the severity of the encephalopathy. Four main patterns of increasing severity are seen: diffuse theta, intermittent rhythmic delta, triphasic waves, and suppression or burst suppression [24]. Although EEG patterns and the clinical grade of encephalopathy may be associated with a poor outcome, complete recovery is possible despite the presence of suppression and burst suppression EEG patterns [24, 25]. All patients in this study had a mild degree of encephalopathy and made a complete recovery. The size of the study does not allow speculation on the grade of the encephalopathy, autoregulation and carbon dioxide reactivity, and outcome.

The pathogenesis of septic encephalopathy is unknown. A reversible "metabolic" mechanism has been proposed to explain the presence of encephalopathy without direct infection of the brain and without consistent neuropathological changes [4]. Cytokines, the chemical messengers released from macrophages and lymphocytes, are likely to be responsible for this "metabolic" derangement, with increased permeability of the blood–brain barrier, increased capillary leakage and tissue oedema, interference with microcirculation, increased procoagulant activity, and direct effects on tissue metabolism [24–26]. Cytokines (interleukin-1 and-2) may also directly affect the brain [26–29]. There is evidence to suggest that at least in animals, there is differential impairment of pulmonary and systemic vascular contractility in hyperdynamic sepsis [30]. Robert and colleagues have shown that interleukin-1, a cytokine released during septic shock, reduces the noradrenaline-induced arterial vessel contraction in rabbit renal and pulmonary beds, but not in hepatic vessels [31]. This hyporeactivity may affect the mechanisms regulating cerebral blood flow, cerebral autoregulation and vasoreactivity to carbon dioxide, which are dependent on the ability of the cerebral vasculature to regulate its tone. In this study, we have shown that in patients without severe encephalopathy, these mechanisms remained intact. Although the exact mechanisms responsible for autoregulation and vasoreactivity to carbon dioxide remain unclear, this study suggests that cerebral vessels were not hyporeactive to changes in MAP or Pa_{CO_2}. However, carbon dioxide reactivity and autoregulation studies were performed during a period of optimal systemic haemodynamic state (table 2), with patients receiving vasoactive agents (dobutamine, dopamine and noradrenaline) that theoretically could have been responsible for restoring cerebrovascular reactivity. Although it is important to identify if these mechanisms are affected by the disease process, or if they can be restored by optimizing systemic haemodynamic state, it is at least reassuring that when systemic haemodynamics are optimized, the cerebral circulation is able to respond to changes in arterial pressure and carbon dioxide tension. This is important for the management of those patients in whom the involvement of the cardiovascular and respiratory systems often leads to arterial pressure instability and carbon dioxide retention.

Remifentanil reduces auditory and somatosensory evoked responses during isoflurane anaesthesia in a dose-dependent manner

I. Crabb, C. Thornton, K. M. Konieczko, A. Chan, R. Aquilina, N. Frazer, C. J. Doré and D. E. F. Newton

Summary

We studied 60 patients during stable isoflurane anaesthesia (0.4 MAC) after premedication with temazepam. Patients were allocated randomly to one of three dose regimens of remifentanil: 1 μg kg^{-1} i.v. over 1 min and an infusion of 0.2 μg kg^{-1} min^{-1} (low dose); 2.5 μg kg^{-1} and 0.5 μg kg^{-1} min^{-1} (medium dose); and 5 μg kg^{-1} and 1 μg kg^{-1} min^{-1} (high dose). The auditory (AER) and median nerve somatosensory (SER) responses were elicited throughout, and recorded before and after tracheal intubation, and surgical incision, together with systolic and diastolic arterial pressure and heart rate. Venous blood concentrations of remifentanil were measured at the above times. After administration of remifentanil, Pa and Nb amplitudes of the AER increased at the low dose, remained constant at the medium dose and decreased at the high dose. This dose-related effect was linear and significant ($P = 0.012$, $P = 0.05$). Pa amplitude correlated inversely with remifentanil blood concentrations before and after intubation and incision ($P = 0.002$, $P < 0.001$, $P < 0.001$ and $P < 0.001$). In the SER, P15–N20 amplitudes decreased after administration of remifentanil ($P < 0.001$), whereas P25–N35 and N35–P45 amplitudes increased at all dose concentrations ($P < 0.001$ and $P < 0.001$). After intubation, P15–N20 and N35–P45 amplitudes increased at the low dose, did not change at the medium dose and decreased at the high dose ($P = 0.001$, $P = 0.027$). After remifentanil, systolic and diastolic arterial pressure and heart rate decreased in a linearly dose-related manner ($P = 0.033$, $P < 0.001$, $P < 0.001$). At all doses the three variables increased after intubation ($P = 0.001$, $P < 0.001$, $P < 0.01$), and systolic and diastolic arterial pressure increased after incision ($P = 0.027$, $P = 0.039$). (*Br. J. Anaesth.* 1996; **76**: 795–801)

Key words

Anaesthetics volatile, isoflurane. Analgesics opioids, remifentanil. Monitoring, evoked potentials. Brain, evoked potentials.

Opioids supplement volatile anaesthetics [1, 2] and attenuate the stress response. In high doses they allow anaesthetics doses so low that cardiovascular effects are negligible. Respiratory depressant effects persist into the postoperative period, limiting the technique to major surgery where postoperative ventilation of the lungs is appropriate. The technique could be extended to routine surgery if a very short-acting drug were available. Remifentanil (GI 87084B), a new synthetic phenyl-piperidine opioid has a very rapid onset and a short duration of action because it is metabolized in both blood and tissues by ester hydrolysis. Its pharmacokinetic profile in volunteers and patients undergoing elective in-patient surgery has been described recently [3–6]. Titration of an infusion of remifentanil to produce a desired effect should be possible, making it attractive for use in anaesthesia.

We believe that evoked responses can separate the analgesic and hypnotic components of an anaesthetic. Changes in the early cortical waves of the auditory evoked response (AER) have been shown to be related to the degree of hypnosis with general anaesthetics [7, 8], and changes in the somatosensory evoked response (SER) waves that originate in the region of the thalamus [9, 10] have been shown to reflect the action of analgesic drugs during general anaesthesia [7, 11, 12].

We have examined the effects of three doses of remifentanil on the AER and SER recorded simultaneously during isoflurane anaesthesia. A clinically relevant nociceptive input was provided by tracheal intubation and surgical incision. This enables both testing of the direct effect of the drug during anaesthesia and its possible attenuation of arousal by stimuli.

Patients and methods

After obtaining approval from the local Ethics Committee and informed consent, we studied 60 patients, ASA I or II, undergoing elective surgery. We examined the effect of three regimens of remifentanil, administered in a random, double-blind manner during isoflurane anaesthesia. The

Table 1 Measurement times

		AER	SER	Remifentanil blood concn	Haemodynamics
Baseline 1	Immediately before baseline—no remifentanil	✓			
Baseline 2	Immediately before bolus—no remifentanil	✓	✓		✓
Post-bolus	Within 3 min of remifentanil bolus				✓
Pre-intubation	Steady state remifentanil, no stimulus	✓	✓	✓	✓
Post-intubation	Immediately after intubation	✓	✓	✓	✓
Pre-incision	Before incision	✓	✓	✓	✓
Post-incision	Immediately after incision	✓	✓	✓	✓

doses were: a bolus of remifentanil 1 μg kg^{-1} administered over 1 min followed immediately by an infusion of 0.2 μg kg^{-1} min^{-1} (low dose); a bolus of remifentanil 2.5 μg kg^{-1} followed by an infusion of 0.5 μg kg^{-1} min^{-1} (medium dose); and remifentanil 5 μg kg^{-1} bolus followed by an infusion of 1 μg kg^{-1} min^{-1} (high dose).

Premedication comprised oral temazepam 10–20 mg, approximately 1 h before anaesthesia which was induced with propofol 2–2.5 mg kg^{-1}, and a laryngeal mask airway was inserted when consciousness had been lost. Vecuronium 0.1 mg kg^{-1} was given, and paralysis was maintained with an infusion of vecuronium adjusted to allow a single response to the train-of-four stimulus. Patients' lungs were ventilated to achieve an end-tidal carbon dioxide concentration of 4.5–5 %, and anaesthesia was maintained with 0.4 % isoflurane (end-expiratory) in oxygen (measured using a calibrated Datex Ultima). When the end-tidal concentration of isoflurane was stable, typically 10–15 min after induction, glycopyrronium 0.6 mg was given followed 3 min later by remifentanil according to the study design. Ephedrine 10 mg was used when a reduction in arterial pressure was considered to require intervention. Nine minutes after the remifentanil bolus, the laryngeal mask airway was removed and the patient's trachea intubated. Surgical incision occurred at least 10 min after tracheal intubation. The study ended 10 min after incision, the remifentanil infusion was discontinued and nitrous oxide was introduced into the anaesthetic gas mixture.

EVOKED POTENTIALS

Recordings of the AER were started before induction of anaesthesia in all patients. The SER was recorded when consciousness had been lost. Responses were recorded continuously throughout the study. The auditory stimulus was a rarefaction click delivered to both ears simultaneously via close-fitting earpieces. It was presented at 75 dB above the average hearing threshold at a repetition rate of 6 s^{-1}. The somatosensory stimulus of the median nerve at the wrist was a 150-μs electrical pulse produced by a modified Duostim nerve stimulator fitted with an optically isolated trigger from the evoked responses apparatus. It was presented at a rate of 2.2 s^{-1}. The intensity was adjusted to just above the motor threshold before vecuronium was given.

The EEG was recorded for the AER using adhesive silver–silver chloride electrodes on the forehead and left mastoid, and for the SER silver–silver chloride cup electrodes attached with collodion glue at Fz and C3′ (20 mm back from C3) using the standard EEG 10-20 system. The EEG signal was analogue filtered on input with bandwidths of 25–500 Hz for the AER and 10–500 Hz for the SER. The evoked responses were displayed on two interlinked portable PCs using purpose-designed software, and the signals stored on the hard disks of these computers. After each study, the stored information was transferred onto optical disks and analysed off-line. During analysis additional digital filtering was used; a high pass filter of 20 Hz and three-point smoothing for the AER and a high pass filter of 20 Hz for the SER.

The evoked responses were averaged over a period of 2.8 min at steady state before administration of remifentanil and before and after intubation and surgical incision. From the AER, the latency and amplitude of the early cortical waves Pa and Nb were analysed. Latency is measured in milliseconds from time zero (the click). Amplitude is measured in μV as the vertical distance from a peak to a line joining two adjacent troughs, or vice versa. An index of the AER generated automatically from the mean second differential of the waveform at 30–60 ms was also recorded (the second differential gives a value which increases both with amplitude and with the number of peaks occurring in the window). The SER was analysed with respect to latency of the waves P15, N20, P25, N35 and P45, and the amplitude of P15–N20, N20–P25, P25–N35 and N35–P45. The amplitudes were measured as the vertical distance (μV) between successive waves.

Arterial pressure and heart rate were recorded every 3 min using a Dinamap, and throughout the procedure an ECG and pulse oximeter were attached to the patient.

REMIFENTANIL BLOOD CONCENTRATIONS

Venous blood samples were obtained in lithium heparin tubes from the contralateral arm for analysis of concentrations of remifentanil immediately before, and 3 min after intubation and correspondingly before and after surgical incision. Some of this sample (5 ml) was mixed with 20 μl of 50 % citric acid and vortexed for 10 s. Aliquots of 2.5 ml were then stored at −20 °C until analysis. Remifentanil analysis was carried out by Glaxo Inc. using the method of Selinger, Lanzo and Sekut [13]. The assay had a lower limit of resolution of 0.1 ng ml^{-1} and a coefficient of variation of < 11.5 %.

STATISTICAL ANALYSIS

Measurements of the following variables were made at the times shown in table 1. AER, SER and haemodynamic data were normalized by $\log_{10}$ transformation and analysis of variance was performed. Between-subject comparisons were made for the effects of dose, and within-subject comparisons for the effects of remifentanil infusion, intubation and incision. Regressions of the above variables and $\log_{10}$ transformed remifentanil blood concentrations were also carried out. All calculations were performed using Genstat 5 release 3.2 (IBM PC 3086/DOS).

Results

The relationship between blood concentrations and infusion rates is illustrated in figure 1. Concentrations increased slightly with time in all groups.

AUDITORY EVOKED RESPONSE

The effect of remifentanil on the AER is illustrated in figure 2 by group changes in Pa amplitude from baseline 1 to after incision. The three groups (low-, medium- and high-dose) showed similar values for baseline 1 and baseline 2 (fig. 2, table 2). There was a significant increase in all three groups between baseline 1 and 2 ($P = 0.024$). Comparing baseline 2 with the next period (before intubation), when the infusion of remifentanil was in progress, Pa amplitude increased at the low dose of remifentanil, remained constant at the medium dose and decreased at the high dose. This dose-related effect was linear and statistically significant ($P = 0.012$). Similar changes were seen in the AER index ($P = 0.001$) and Nb amplitude ($P = 0.05$).

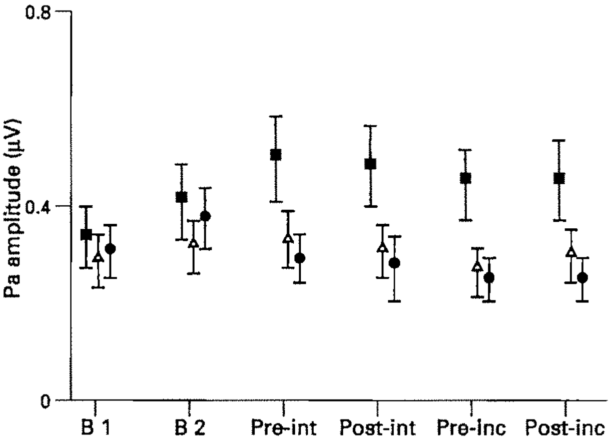

Figure 2 Pa amplitude (mean, 95 % confidence limits), 5 min (baseline 1 (B1)) and immediately before administration of remifentanil (baseline 2 (B2)), before (Pre-int) and after (Post-int) tracheal intubation and before (Pre-inc) and after (Post-inc) incision at the low- (■), medium- (△) and high- (●) dose regimens.

The differences in Pa amplitude between the three groups during administration of remifentanil were maintained throughout the study. There were no statistically significant differences caused by intubation or incision for any of the AER variables. The AER index and Nb amplitude (table 2) showed similar changes to Pa amplitude, which was not unexpected as they are related variables. The changes in these variables from baseline 1 to baseline 2 showed similar trends as Pa amplitude, but these were not significant. The changes with infusion rate were borne out when the AER data were plotted against blood concentrations of remifentanil. For example, there were statistically significant decreases in Pa amplitude (fig. 3) when individual values before and after intubation and before and after incision were plotted against blood concentration ($P = 0.002$, $P < 0.001$, $P < 0.001$ and $P < 0.001$, respectively).

SOMATOSENSORY EVOKED RESPONSE

The earlier wave P15–N20 and N20–P25 amplitudes (table 3) decreased with administration of remifentanil (baseline 2 to before intubation) at all dose

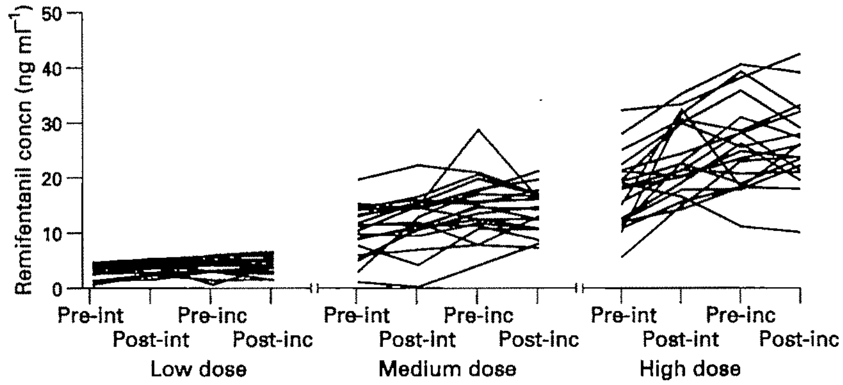

Figure 1 Blood concentrations of remifentanil at the three infusion regimens: remifentanil 1 μg kg^{-1} and infusion of 0.2 μg kg^{-1} min^{-1} (low dose); remifentanil 2.5 μg kg^{-1} and infusion of 0.5 μg kg^{-1} min^{-1} (medium dose); remifentanil 5 μg kg^{-1} and infusion of 1 μg kg^{-1} min^{-1} (high dose). Pre-int = before intubation; Post-int = after intubation; Pre-inc = before incision; Post-inc = after incision.

concentrations. This was significant for P15–N20 ($P < 0.001$) but not for N20–P25. In contrast, the later wave (P25–N35 and N35–P45) amplitudes increased significantly at all dose concentrations of remifentanil ($P < 0.001$ and $P < 0.001$, respectively). None of these changes was dose related.

There were significant linear dose-related changes in P15–N20 and N35–P45 amplitudes after intubation ($P = 0.001$, $P = 0.027$). The amplitudes increased in the low-dose group, were virtually changed in the medium-dose group and decreased in the high-dose group. This is in contrast with the AER variables where no such linear dose-related trends with intubation were observed. Figure 4 shows the differences before and after intubation for P15–N20 amplitude of the SER and Pa amplitude of the AER.

The SER observations were borne out in the

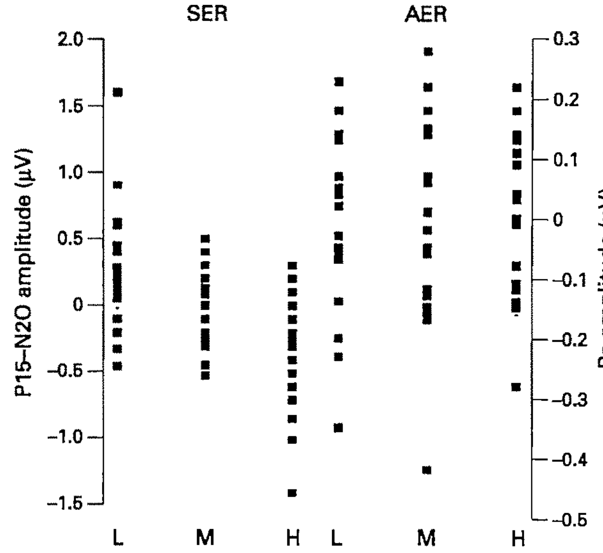

Figure 4 Change in somatosensory (SER) and auditory (AER) evoked potentials (P15–N20 amplitude and Pa amplitude) after tracheal intubation. There is a dose-related change in the SER response, and no change in the AER related to dose. L = low, M = medium, H = high dose.

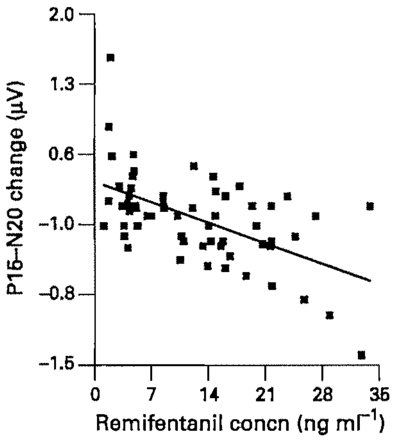

Figure 5 Change in the P15–N20 somatosensory response after tracheal intubation *vs* mean blood concentrations of remifentanil before and after intubation ($P < 0.001$).

relationship with blood concentrations (fig. 5). There were no significant relationships between any of the SER variables, before and after intubation and before and after incision, and remifentanil blood concentration, but there were significant relationships between the differences in P15 and P25 latencies before and after intubation which increased ($P < 0.001$ and $P = 0.04$), and P15–N20 (fig. 5) and N35–P45 amplitudes which decreased ($P < 0.001$ and $P = 0.04$), with increasing blood concentrations of remifentanil.

As with the AER variables there were no significant effects of incision on any of the somatosensory evoked response amplitudes.

HAEMODYNAMIC DATA

The haemodynamic effects of remifentanil are shown in table 4. After bolus administration of remifentanil, all three variables (systolic and diastolic arterial pressures and heart rate) decreased significantly in a linearly dose-related manner ($P = 0.033$, $P < 0.001$, $P < 0.001$, respectively).

Two patients in the high-dose group were given ephedrine to supplement fluids in maintaining arterial pressure within the clinical range 15 and 6 min after the bolus of remifentanil. The first of these and another different patient were given ephedrine after incision for the same reason.

Table 4 Haemodynamic variables. Group geometric means (95 % confidence limits) for low, medium and high doses of remifentanil

Dose	Baseline 2	Post-bolus	Pre-intubation	Post-intubation	Pre-incision	Post-incision
Systolic AP (mm Hg)						
Low	112 (108–117)	95 (92–99)	100 (96–104)	106 (102–111)	103 (99–107)	108 (104–112)
Medium	113 (109–118)	94 (91–98)	98 (94–102)	103 (99–108)	97 (93–101)	100 (96–104)
High	120 (115–125)	93 (90–97)	98 (94–102)	103 (99–107)	96 (92–100)	100 (96–104)
Diastolic AP (mm Hg)						
Low	62 (59–66)	50 (48–53)	51 (48–54)	57 (54–60)	52 (49–55)	57 (54–60)
Medium	67 (63–70)	51 (49–54)	55 (52–58)	57 (54–60)	55 (52–58)	55 (52–58)
High	68 (65–72)	46 (44–49)	49 (47–52)	55 (52–58)	52 (50–55)	55 (52–58)
Heart rate (beat min^{-1})						
Low	87 (83–90)	81 (78–84)	80 (77–83)	85 (81–88)	79 (76–83)	79 (76–82)
Medium	78 (75–81)	68 (66–71)	69 (66–72)	71 (69–74)	66 (63–69)	66 (63–69)
High	83 (80–86)	66 (63–68)	67 (64–69)	69 (66–72)	65 (63–68)	65 (62–67)

At the three dose concentrations of remifentanil, systolic and diastolic arterial pressures and heart rate increased significantly after intubation ($P = 0.001$, $P < 0.001$, $P < 0.01$, respectively), and systolic and diastolic arterial pressures increased significantly after incision ($P = 0.027$, $P = 0.039$). These changes occurred at all doses and were also reflected in the relationship with blood concentrations. Diastolic and systolic arterial pressures after intubation were inversely related to remifentanil blood concentrations ($P = 0.002$ and $P = 0.001$, respectively). Heart rate before intubation was significantly inversely related to blood concentrations of remifentanil ($P < 0.001$).

Discussion

As venous blood concentrations of remifentanil increased steadily with time at all dose concentrations (fig. 1), steady state was not reached during the study, and concentrations within a dose group were variable at each measurement time. The higher variability of pre-intubation concentrations and their lower mean values compared with subsequent measurements demonstrate that the loading bolus doses were not large enough. In a pilot study, greater bolus doses had produced unacceptable hypotension. We have presented the results in relation to dose, and measured blood concentrations, because it is not yet clear which has the closest relationship to the pharmacodynamic response. In this study there was no real difference in the results between dose and blood concentration. Although none of the doses used was able to completely suppress the cardiovascular effects of stimuli, the changes in cardiovascular variables were small and not clinically significant (table 4).

Studies which have compared remifentanil with alfentanil have reported greater haemodynamic stability with remifentanil, irrespective of the dose rate [6, 14]. In both of these studies the haemodynamic changes were also small. In one [6], the remifentanil infusion rate was increased before strong stimulation, which demonstrates that the short half-life of remifentanil [15] may allow greater control of haemodynamic state. The extent to which these doses are effective remains to be seen when the drug is studied in patients with greater cardiovascular instability.

As studies by other workers [16–18] have demonstrated little or no effect of opioids on the AER, we were surprised to see a dose-dependent effect on the AER variables. This would not have been detected with only one dose. In patients receiving the low dose, AER amplitudes increased. It is likely that this was the continuation of a trend which was occurring throughout the baseline period (see fig. 2) reaching a maximum at the pre-intubation measurement. The later SER wave amplitudes P25–N35 and N35–P45 (table 3) also increased after bolus administration of remifentanil, unlike the earlier waves P15–N20 and N20–P25 which decreased. One explanation for these observations is a decrease in depth of anaesthesia caused by factors such as reducing blood concentration of propofol, discomfort of the laryngeal mask and arterial pressure cuff. Until the pre-intubation measurement, the changes in Pa amplitude in the three patients groups were not significantly different from each other. From the post-intubation measurement onwards, the low dose of remifentanil arrested the trend, and the medium and high doses reversed it, resulting in the linear dose-dependent relationship.

The SER waves did not show a dose-dependent relationship. Previously, we observed later cortical SER waves behaving differently from the earlier pontine thalamic waves and in a similar manner to the cortical AER when we compared the effects of isoflurane and nitrous oxide [7]. We found that nitrous oxide decreased the amplitudes of the earlier complexes P15–N20 and N20–P25 more than isoflurane, suggesting that these subcortical waves may reflect analgesia. In contrast, isoflurane decreased the amplitudes of the later waves P25–N35 and N35–P45. The findings of this study support the suggestion that cortical waves reflect the hypnotic component of anaesthesia. Freye, Buhl and Ciaramelli [12] showed a dose-related decrease in the amplitude of N20 in response to alfentanil, and also that this response was related to the action of mu opioids, whereas opioids with a strong kappa activity affected the cortical SER waves.

This study was designed to demonstrate the effect of remifentanil on the changes in the evoked responses to strong stimuli which have been reported previously by us and others [8, 19, 20]. On this occasion both tracheal intubation and incision were included. There was no change in the AER variables in response to either stimulus (fig. 2). It would have been more impressive to show a graded attenuation of the effect of stimulation on the AER amplitudes such as was seen in the changes in SER amplitudes (fig. 4, table 3). Inclusion of a "no remifentanil" control or lower dose ranges of remifentanil had been contemplated but rejected because of the risk of awareness in patients undergoing tracheal intubation and incision receiving only 0.4% isoflurane after temazepam and propofol, and with no analgesic. In early experiences with a new drug, choice of dose range is a notoriously difficult decision and we were not prepared to give less than the low dose described here. In the light of our findings, future studies using the same background anaesthesia and lower remifentanil doses could perhaps be considered.

The SER showed a response to intubation but the AER did not. Sebel and colleagues [21] have previously reported a similar SER response to intubation in patients during thiopentone and nitrous oxide anaesthesia, and after administration of fentanyl a response to surgical incision. The mechanism of the response to one stimulus (the median nerve SER) being enhanced by another unrelated stimulus (surgery or intubation) requires explanation. One possibility is a local increase in available neurotransmitters in response to a large nociceptive insult. Another possibility is an effect regulated through the mechanism of CNS arousal. This effect is blocked by increasing concentrations of opioid. While the lowest dose of opioid was insufficient to inhibit the SER, no responses were seen in the AER.

The dose-dependent depressant effects of remifentanil on the early cortical AER in the unstimulated patient have yet to be explained. There are three possibilities: first that remifentanil has an interaction with isoflurane—a combined effect on the cortex; second, that deafferentation, that is a general dampening down of incoming stimulation, produces cortical depression; and third, that mu opioids may have a direct depressive effect on the cortex.

Effect of the addition of alfentanil to lignocaine during axillary brachial plexus anaesthesia

W. P. GORMLEY, J. M. MURRAY, J. P. H. FEE AND S. BOWER

Summary

Peripheral administration of opioids has been suggested as a means of improving regional block. We studied 60 patients receiving axillary brachial plexus anaesthesia, allocated randomly to receive either normal saline 10 ml or normal saline 10 ml with alfentanil 10 µg/kg body weight through an axillary cannula. All patients received 1.5% lignocaine at a dose of 7 mg/kg body weight with adrenaline 1 in 200000. The incidence of satisfactory block was similar in both groups. Although the percentage of patients with complete anaesthesia in the median nerve distribution was greater in the alfentanil group, there was no significant difference in any other distribution. The time to return of sensation and motor function was prolonged significantly in the alfentanil group ($P <$ 0.05). After return of normal sensation, there was no significant difference between groups in postoperative analgesia. In a second part of the study, there was no significant increase in plasma concentrations of alfentanil in 10 patients given lignocaine and alfentanil, as outlined above. These observations suggest that alfentanil may have a peripheral local anaesthetic action. (*Br. J. Anaesth.* 1996; **76**: 802–805).

Key words

Anaesthetic techniques, regional, brachial plexus. Anaesthetics local, lignocaine. Analgesics opioids, alfentanil.

Traditionally, antinociception has been associated with occupation of opioid receptors exclusively within the spinal cord [1]. Recently, opioid receptors have been discovered on immune cells, sympathetic nerve fibres and peripheral neurones [2, 3]. Animal behavioural studies have demonstrated antinociception after peripheral administration of opioids [4].

Peripheral effects of opioids may improve regional anaesthesia without centrally mediated side effects. This would clearly be of benefit during brachial plexus anaesthesia, a commonly used anaesthetic technique for upper limb surgery. However, clinical studies have shown results ranging from improved quality of anaesthesia and postoperative analgesia [5–7] to no effect [8, 9].

Ineffective opioid activity during brachial plexus anaesthesia may be because of the inability of the opioid to penetrate axonal myelin and the nerve membrane [4]. In this study, alfentanil was chosen as it is highly un-ionized (89%) at pH 7.4 [10]. Lignocaine is a commonly used short-acting local anaesthetic which may benefit from improvement in duration of action or postoperative analgesia.

Patients and methods

After obtaining local Ethics Committee approval and written, informed consent, we studied 60 patients, ASA I and II, aged 18–70 yr, weighing 50–100 kg. All were unpremedicated and undergoing elective upper limb surgery.

An 18-gauge i.v. cannula was inserted into the contralateral arm. Routine monitoring was used throughout the study. After sterile preparation, axillary brachial plexus block was carried out using a 20-gauge cannula, as described by Hill and Campbell [11]. Loss of resistance to saline was used to locate the axillary sheath. Having found the sheath, the needle was removed, the cannula advanced and secured in place. A length of primed plastic tubing was attached to the cannula and to a syringe. The patients were then allocated randomly to one of two groups using a sealed envelope technique. Group A received alfentanil 10 µg/kg body weight made up to 10 ml with 0.9% saline. Group S received 0.9% saline 10 ml. These solutions were prepared before use by a colleague who took no further part in the study. All patients received commercially prepared 1.5% lignocaine with adrenaline 1 in 200000 to a total dose of 7 mg/kg body weight. The pH of the mixed solutions in each group was measured later using a pH meter.

Sensory and motor observations were performed every 10 min for 30 min after injection by an observer who was unaware of the solution used. Anaesthesia was assessed using response to pinprick on a three-point scale: normal, impaired or absent sensation. The extent of motor block was assessed

Correspondence to J.M.M.

using hand grip with a modified Bromage scale: normal, impaired or absent motor function [12]. The block was judged overall to be satisfactory if anaesthesia involved at least two peripheral nerve distributions, including one of the following: median, ulnar, radial or musculocutaneous. The use of rescue adjuvants such as nerve blocks, infiltration or sedation was recorded. The return of sensory and motor function and the time to first request for analgesia were noted. A visual analogue pain score was obtained at hourly intervals for 6 h and at 12 and 24 h. Sedation, ventilatory frequency and peripheral oxygen saturation were also noted at these times. Systemic effects such as nausea, vomiting or pruritus were recorded.

In the second part of the study, 10 patients received axillary brachial plexus anaesthesia as described for group A. In addition, 10-ml samples of venous blood were obtained at 30 min, 1, 2, 3 and 4 h after injection. The samples were centrifuged and frozen to −40 °C. Plasma concentrations of alfentanil were measured later by a radioimmunoassay technique of sensitivity 2 pg ml^{-1} and coefficient of variation 7% [13].

Advice regarding statistical analysis was obtained from the Department of Statistics at the Queen's University of Belfast. Patient data and characteristics were compared using unpaired Student's *t* test and Mann–Whitney *U* test as appropriate. Onset times in the peripheral nerve distributions were categorized as 0–10, 10–20, 20–30 and greater than 30 min. The number of patients in each category was calculated for all peripheral nerve distributions and for motor function. They were compared using the chi-square test. The fact that complete anaesthesia failed to develop in certain peripheral nerve distributions precluded the use of analysis of variance. $P < 0.05$ was considered statistically significant.

Results

There were 32 patients in group S and 28 patients in group A. The type of surgery included correction of Dupuytren's contracture (57%), carpel tunnel median nerve decompression (26%) and others (17%). There was no significant difference between groups in age, weight, sex or duration of surgery (table 1).

There was a greater percentage of patients with complete anaesthesia in the median nerve distribution in group A at 30 min after injection ($P <$ 0.05). There was no significant difference between groups in any other peripheral nerve distribution or in motor function (fig. 1).

The overall incidence of satisfactory block was 91.7% and was not significantly different between groups. The use of rescue adjuvants was similar for both groups. The times to return of sensation ($P =$ 0.013) and motor function ($P = 0.001$) were prolonged significantly in group A compared with group S (table 2). The time to first request for analgesia was similar in both groups.

Table 1 Patient data (mean (SD or range) or number)

Group	Age (yr)	Weight (kg)	Sex (M/F)	Duration of surgery (min)
Saline	50.4 (18–69)	72.4 (11.2)	24/8	65.2 (18.7)
Alfentanil	44.1 (20–62)	75.5 (11.8)	20/8	74.6 (33.3)

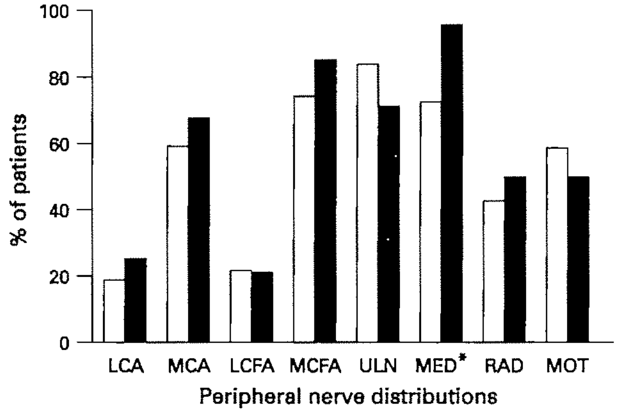

Figure 1 Percentage of patients with complete anaesthesia or motor block 30 min after injection of saline (□) or alfentanil (■). The peripheral distributions shown are the lateral cutaneous nerve of the arm (LCA), median cutaneous nerve of the arm (MCA), lateral cutaneous nerve of the forearm (LCFA), median cutaneous nerve of the forearm (MCFA), ulnar nerve (ULN), median nerve (MED) and radial nerve (RAD). Motor block (MOT) is also shown. $*P < 0.05$.

Table 2 Time to return of sensation and motor function, and time to first request for analgesia (mean (SD) minutes). $*P < 0.05$

Group	Return of sensation	Return of motor function	Time to first analgesia
Saline	189.7 (58)	191.6 (43)	335. 8 (171)
Alfentanil	231.7 (64.8)*	240.6 (61.9)*	320 (92)

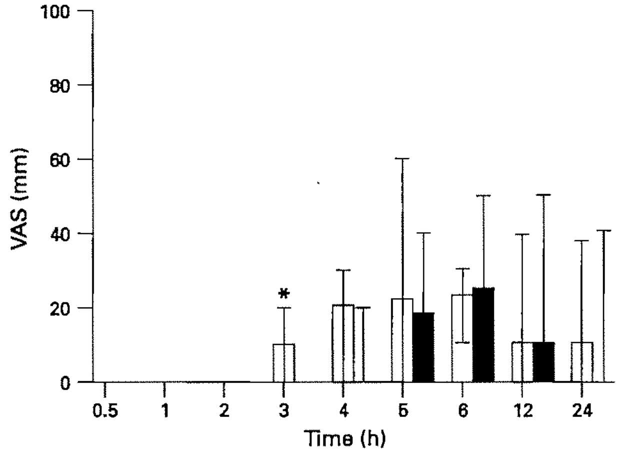

Figure 2 Postoperative visual analogue scores (VAS) in the saline (□) and alfentanil (■) groups (median, interquartile range). $*P < 0.05$.

There was a significant reduction in visual analogue pain scores (VAS) at 3 h in group A ($P =$ 0.019) but not at any other time (fig. 2). There were no significant differences between groups in sedation, peripheral oxygen saturation or ventilatory

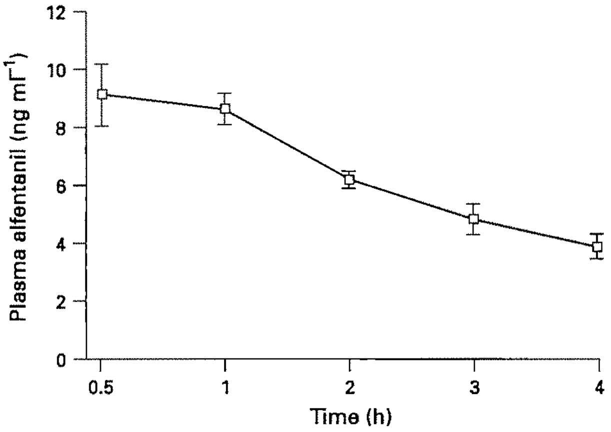

Figure 3 Mean (SEM) plasma concentrations of alfentanil for 10 patients.

frequency. Two patients in group A and one patient in group S developed pruritis. One patient in group A developed nausea.

Plasma concentrations of alfentanil did not increase significantly. Concentrations were greatest at 30 min after injection, with a decrease over the next few hours (fig. 3).

There was no significant difference in the pH of the anaesthetic solution between group S (4.01) and group A (4.08).

Discussion

Currently, there is significant cytochemical and behavioural evidence for the existence of peripheral opioid receptor sites. These have been demonstrated on sympathetic nerve fibres and primary afferent neurones [3]. In addition, endogenous opioids have been detected in peripheral terminals of sensory nerves [14]. Animal behavioural studies demonstrating peripheral antinociception have almost universally used response latency to pain inflicted on an inflamed paw [4].

Buprenorphine and morphine have been shown to improve postoperative analgesia after brachial plexus anaesthesia [5–7]. Faster onset of anaesthesia has been demonstrated in two studies with fentanyl [15, 16]. Other investigators have found no benefit from the addition of morphine or fentanyl [8, 9]. One suggestion for such inconclusive results is that certain opioids may be unable to penetrate layers of myelin [4]. These are particularly numerous on the proximal nerve axons found in the brachial plexus. It was thought that the use of a highly un-ionized opioid such as alfentanil may have facilitated penetration of the nerve sheath. The dose of alfentanil was chosen after a pilot study comparing 0, 5 and 10 µg/kg body weight, in which a clinical effect was demonstrated only with 10 µg kg^{-1}. In order to reduce any physical interaction, the alfentanil and lignocaine solutions were not mixed before injection. However, it is possible that acidic commercially prepared lignocaine and adrenaline solutions may alter the ionic equilibrium of alfentanil within the brachial plexus sheath.

Our study demonstrated improvement in the onset of anaesthesia in one peripheral nerve distribution. Improvement was not seen in any other distribution or in the development of paresis. These findings are therefore unlikely to be clinically important. However, there was a significant prolongation of sensory and motor block. These clinical observations would suggest that alfentanil may have a local anaesthetic action affecting both sensory and motor neurones. We demonstrated that the systemic absorption of alfentanil after injection into to the axillary sheath produces plasma concentrations unlikely to produce clinical effects [17].

Opioid receptors are thought to produce antinociception in a variety of ways. A local anaesthetic action on the excitability of nerve terminals and the propagation of nerve impulses is thought to be brought about by two distinct mechanisms. The first involves an early decrease in sodium conductance and a delayed decrease in potassium conductance [18]. This effect is not reversed by naloxone and has been demonstrated on peripheral mammalian nerves with fentanyl and sufentanil [19, 20]. Impaired nerve impulse conduction is seen only at high concentrations of opioid (greater than fentanyl 50 µg ml^{-1}) [19]. The second local anaesthetic action is reversible by naloxone and involves a decrease in sodium conductance alone [18]. This action occurs at lower opioid concentrations and would appear to relate best to the results of our study. It would have been interesting to observe the effects of naloxone in another group of patients. However, there is uncertainty over which route, how much and over what period naloxone should be administered.

Other mechanisms of action of peripheral opioid receptors involve inhibition of release of substance P from peripheral terminals of primary afferent neurones [21]. This effect is unlikely to have played a significant part in our study. The improvement in visual analogue pain score at 3 h is most likely because of prolonged anaesthesia as no improvement was seen after the return of sensation.

It is known that the peripheral effects of opioids are enhanced after inflammation [22]. This may be because of infiltration of immune cells which would produce a delayed analgesic response. There is evidence for the existence of endogenous opioids in a variety of immune cells infiltrating inflamed subcutaneous tissue [23]. An alternative suggestion is that both axonal transport and proliferation or activation of opioid receptors may be enhanced by inflammatory mechanisms [24, 25]. This inflammatory requirement may limit the usefulness of peripheral opioids in acute pain. Furthermore, axonal opioid receptors may be functionally less efficient than those located at peripheral nerve terminals [4].

In summary, this study has demonstrated prolongation of sensory and motor block suggestive of a local anaesthetic effect. However, the degree of improvement in anaesthesia is unlikely to render this technique clinically useful. In particular, we did not demonstrate a significant improvement in the quality of postoperative analgesia. The absence of a significant clinical effect is in keeping with the theoretical limitations of peripheral axonal administration of opioids in acute pain.

Analgesic and anti-inflammatory effects of lignocaine–prilocaine (EMLA) cream in human burn injury

J. L. PEDERSEN, T. CALLESEN, S. MØINICHE AND H. KEHLET

Summary

Pain relief may be improved by reducing sensitization of nociceptive pathways caused by tissue injury. Such a reduction depends mainly on inhibition of local inflammatory changes and the relation between duration of nociceptive block and nociceptive input. In this study we examined if prolonged topical treatment with local anaesthetics could reduce late hyperalgesia and local inflammation after burn injury in healthy volunteers. The effects of EMLA treatment for 8 h after burn on hyperalgesia, inflammation and wound healing were compared with the contralateral placebo-treated leg for 48 h after bilateral burn injuries (15 × 25 mm, 49 °C for 5 min) in a double-blind, randomized study in 12 healthy volunteers. Wound healing was studied 1 and 2 weeks after injury. Neither mechanical nor thermal primary hyperalgesia were affected significantly by prolonged EMLA treatment. Secondary hyperalgesia and skin erythema were also not changed. Seven of 12 placebo-treated legs developed blisters, in contrast with four of 12 EMLA-treated legs. Wound healing showed no apparent differences. Our data suggest that prolonged, topical treatment with local anaesthetics did not reduce local inflammation and late hyperalgesia. (*Br. J. Anaesth.* 1996; **76**: 806–810)

Key words

Burns. Anaesthetics local, EMLA. Pain, mechanism.

Injury causes inflammation and may lead to prolonged sensitization of nociceptive pathways. Primary and secondary hyperalgesia are well established aspects of this process. Hyperalgesia describes the phenomenon of increased pain intensity in response to normally painful stimuli [1], primary hyperalgesia refers to the changes in sensation within the injury, while secondary hyperalgesia refers to sensory changes in the undamaged tissue surrounding the injury. Several inflammatory mediators promote hyperalgesia by sensitization of nociceptors [2].

Many *in vitro* and animal studies have shown anti-inflammatory effects of local anaesthetics and these effects may potentiate the analgesic effect of these agents. The anti-inflammatory effects may impair the host defence, but may also improve conditions with destructive inflammation. In contrast, there are only few human reports on the anti-inflammatory effects of local anaesthetics and we have shown previously that brief (3.5 h) topical treatment with local anaesthetics before and after injury did not significantly affect inflammation after burn [3]. The aim of the study was therefore to examine if prolonged and intense treatment with lignocaine–prilocaine cream (EMLA) could reduce late hyperalgesia and other markers of local inflammation after burn injury in healthy volunteers. The treatment was initiated after the burn, as this mimics the clinical situation.

Subjects and methods

We studied 12 healthy volunteers, aged 22–47 yr (all male), after obtaining informed consent and approval from the local Ethics Committee and the Danish National Health Board. Subjects were not medically knowledgeable and were not aware of the purpose of the study.

Baseline measurements, which included assessment of skin colour, mechanical pain detection threshold (MPDT) and heat pain detection threshold (HPDT), were performed on the medial calf in both legs. After obtaining baseline measurements, thermal injury was induced on each leg. All measurements, that is skin erythema, blister formation, MPDT, secondary hyperalgesia and HPDT, were made in this order, 16, 20, 24 and 48 h after the injuries. Immediately after the injury, EMLA or placebo was applied, double-blind and randomized, to the skin and covered under occlusive dressing for 8 h after the injury. Experiments were performed in a quiet room, temperature 20–22 °C, with subjects in a relaxed and reclined position. Subjects were instructed to keep their eyes closed during all measurements so that they had no impression of the results of the measurements.

EMLA TREATMENT

EMLA cream 2 g (2.5% prilocaine and 2.5% lignocaine eutectic mixture, Astra, Södertälje, Sweden) or placebo (Astra; Södertälje, Sweden) was applied in a double-blind, randomized manner to the skin and covered under occlusive dressing (Tegaderm, 3M Health Care Ltd, Leicestershire, UK) for 8 h after the injury. The cream was renewed

3 and 5.5 h after initial application, and re-covered. Subjects were instructed to avoid physical activities that could displace the thick cream layer from the injury. The burns were performed in the afternoon and the cream was removed 8 h later (late evening). Subjects attended next morning for the first measurement, 16 h after the injury.

THERMAL INJURY

Thermal injuries were produced on the medial surface of the right and left calf with a 15 × 25-mm Peltier thermode (Thermotest, Somedic A/B, Stockholm, Sweden). The thermode (49 °C) was applied to the skin for 5 min under standardized pressure (34 mm Hg), causing first- and superficial second-degree burn injuries [4, 5]. The burn caused immediate intense stinging pain, which was followed by a moderate burning pain with a more diffuse quality during the remainder of the stimulation period. Spontaneous pain after the injury has not been observed in the model.

PRIMARY HYPERALGESIA

Mechanical pain detection threshold (MPDT) within the injured area was determined by pinprick with nine progressively rigid von Frey hairs (Somedic A/B, Stockholm, Sweden). We examined the force produced by each hair by pressing it against a balance and measured the weight it produced when it was slightly flexed. We confirmed that the steps from 1 to 9 represented logarithmic increases in force (hair no. 1 = 3 mN, 2 = 9 mN, 3 = 11 mN, 4 = 18 mN, 5 = 29 mN, 6 = 49 mN, 7 = 98 mN, 8 = 98 mN, 9 = 175 mN). MPDT was defined as the lowest force (pinprick) which produced a definite sensation of pain or discomfort. Pinprick was performed with *each* hair from the thinnest, 8–10 times in the area of the injury, until *some* of the 8–10 stimulations were reported to be painful or unpleasant. The number of the hair producing pain was recorded and the procedure was repeated three times at each measurement point. The median of three threshold measurements was reported as the MPDT. If hair No. 9 did not produce any pain or discomfort, we assigned this observation the value 10.

Thermal thresholds were determined with the computerized Thermotest (Somedic A/B, Stockholm, Sweden) in the area of the injury. Heat pain detection threshold (HPDT) was the lowest temperature perceived as painful. Subjects were instructed to press a button as soon as the specified sensation was reached. Thermal thresholds were determined from a baseline of 32 °C with a rate of change of 1 $°C\,s^{-1}$. The upper cut-off limit was 52 °C. HPDT was calculated as the average of three measurements, with intervals of 9 s between each stimulation.

SECONDARY HYPERALGESIA

The area of mechanical hyperalgesia that developed around the burn injury was assessed with von Frey hair No. 9 (175 mN). In most cases pinprick with this hair is a painful or unpleasant stimulus in distinct spots of the skin, although it is not universally painful. Thus areas of hyperalgesia were measured, not areas of allodynia. Borders of hyperalgesia were determined by stimulating along eight radial linear paths arranged from the centre of injury. Stimulation along each path began well outside the hyperalgesic area where slight or no pain was perceived and continued slowly towards the centre of the burn injury until the subject reported a definite change in sensation, most often to a more intense pricking with a burning after-sensation. This point was marked and the eight marks were later traced onto a clear acetate sheet. The area of secondary hyperalgesia was calculated from the eight marks using a vector algorithm.

INFLAMMATION

In order to estimate the severity of inflammation, the intensity of erythema inside the injury was assessed with a hand-held skin reflectance spectrophotometer (Dermaspectrometer, Cortex Technology, Hadsund, Denmark) [6, 7]. The spectrophotometer provided a skin erythema index based on the absorption characteristics of green and red light in the skin. Measurements were performed in six spots within the burn injury. All values were recorded and the mean calculated. The development of blisters was recorded as present or absent. Healing of the burns was documented using a questionnaire, 1 and 2 weeks after the injury.

STATISTICAL ANALYSIS

Distribution of data was evaluated with the Shapiro Wilk test [8]. Primary mechanical hyperalgesia and secondary hyperalgesia in EMLA- and placebo-treated legs were evaluated at separate times with multiple Wilcoxon tests for paired observation with Bonferroni correction and area under the curves (AUC) for the whole observation period with Student's t test for differences in a paired design [9]. Evaluation of primary thermal hyperalgesia and erythema was based on AUC values but analysed also using parametric two-way analysis of variance (ANOVA) for repeated measurements [8]. Minimal differences between treatments detectable in the present study with a power of 90 % and a type I error of 5 % were evaluated with Student's t test for differences in a paired design [8]. $P < 0.05$ was considered statistically significant.

Results

The area of hyperalgesia surrounding the injury was not significantly altered by EMLA treatment compared with placebo (fig. 1A). The effect of EMLA was evaluated at all times (16 h, $P = 0.68$; 20 h, $P = 0.37$; 24 h, $P = 0.14$; and 48 h, $P = 0.07$; Wilcoxon test). The level of significance was reduced to 1 % in these comparisons with Bonferroni correction, because of the multiple comparisons. The area under the curve (AUC) for hyperalgesia was applied as a

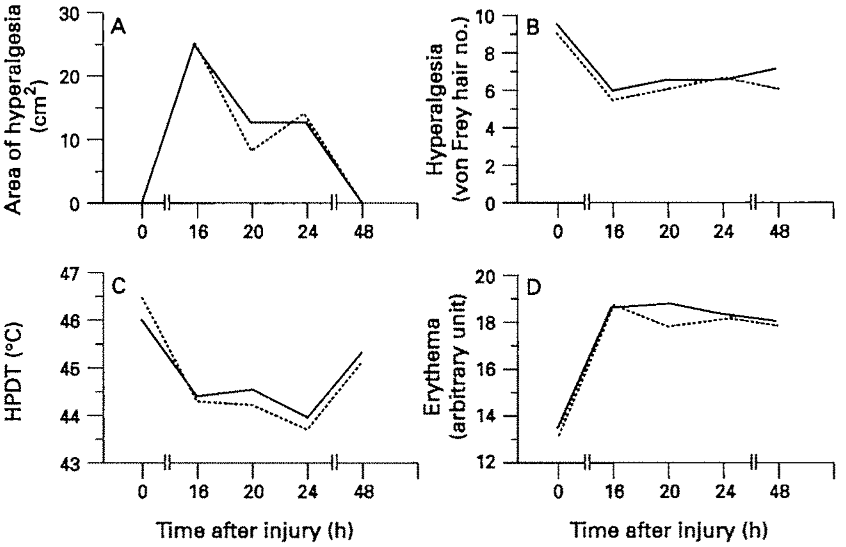

Figure 1 A: Secondary hyperalgesia, that is area of hyperalgesia to von Frey pinprick (175 mN) outside the injury, after burn injury in healthy volunteers treated with EMLA (· · · ·) or placebo (——). Time 0 h = measurements before thermal injury. Values are medians. Comparison of AUC values revealed no significant difference between secondary hyperalgesia in EMLA- *vs* placebo-treated legs ($P = 0.18$; Student's paired *t* test, $n = 12$). B: Primary mechanical hyperalgesia, that is mechanical pain detection threshold to von Frey pinprick, in the area of the burn injury. Values are medians. Comparison of AUC values revealed no significant difference between primary mechanical hyperalgesia in EMLA- (· · · ·) *vs* placebo- (——) treated legs ($P = 0.19$; Student's paired *t* test, $n = 12$). Von Frey hair no. (1–10) represents a rank scale, where 1 indicates a force of about 3 mN and 9 about 175 mN, whereas 10 indicates that 175 mN did not produce pain or discomfort. The steps from 1 to 9 are logarithmic increases in force (see text). C: Primary thermal hyperalgesia, that is heat pain detection threshold (HPDT) in the area of the burn injury. Values are means. Comparison revealed no significant difference between primary thermal hyperalgesia in EMLA (· · · ·)- *vs* placebo (——)-treated legs ($P = 0.61$; parametric two-way analysis of variance for repeated measurements, $n = 12$). D: Skin erythema, that is the intensity of erythema inside the burn injury assessed with a hand-held skin reflectance spectrophotometer. Values are means. Comparison revealed no significant difference between erythema in EMLA (· · · ·)- *vs* placebo (——)-treated legs ($P = 0.34$; parametric two-way analysis of variance for repeated measurements, $n = 12$).

Table 1 Positive answers out of 12, in a questionnaire (yes/no) completed by the 12 subjects

Changes in injury	Placebo (1 week)	EMLA (1 week)	Placebo (2 weeks)	EMLA (2 weeks)
Tenderness	1	0	0	0
Irritated by touch	2	0	0	0
Itch	3	2	3	1
Any colour change	7	9	6	5
Crusts	3	3	3	1
Blister	2	2	1	0
Skin erythema	6	6	4	0

Table 2 Minimum differences between treatments detectable with a power of 90% (type II error of 10%) and a type I error of 5%. Differences are presented as the weighted mean for the observation period (AUC divided by 48 h)

Secondary hyperalgesia (cm²)	Primary mechanical hyperalgesia (von Frey No.)	Primary thermal hyperalgesia (°C)	Erythema index (arb. unit)
13	0.9	2.4	1.3

summary measure of the total hyperalgesic response. AUC for secondary hyperalgesia after EMLA treatment was not significantly different from that after placebo ($P = 0.18$; Student's paired *t* test).

The effect of EMLA on primary mechanical hyperalgesia (fig. 1B) was analysed in the same way and there was no significant differences between EMLA and placebo (0 h, $P = 0.20$; 16 h, $P = 0.28$; 20 h, $P = 0.29$; 24 h, $P = 1.00$; and 48 h, $P = 0.25$; Wilcoxon test). Comparison of AUC values confirmed this finding ($P = 0.19$; Student's paired *t* test).

Data for primary thermal hyperalgesia (fig. 1C) and skin erythema index (fig. 1D) were analysed with both AUC summaries and parametric two-way ANOVA for repeated measurements. There were no significant differences between EMLA and placebo with both methods (primary thermal hyperalgesia: AUC, $P = 0.80$ and ANOVA, $P = 0.61$; and erythema: AUC, $P = 0.54$ and ANOVA, $P = 0.34$). Seven of 12 placebo-treated legs developed blisters in contrast with four of 12 EMLA-treated legs. With binomial data (yes/no), these small numbers precluded a sensible statistical analysis. There were no apparent differences in wound healing between EMLA and placebo treatment (table 1).

Minimal differences between treatments detectable in this study, with a power of 90 % and a type I error of 5 %, are presented in table 2. Differences are presented as the weighted mean for the observation period (AUC divided by 48 h).

Discussion

We examined if prolonged and intensive topical treatment with local anaesthetics reduced late hyperalgesia, blister formation or erythema after thermal injury in healthy volunteers in a double-blind, randomized study. We found that the local anaesthetics neither reduced local inflammation and late hyperalgesia nor produced apparent changes in wound healing, although the sample size does not exclude minor differences. This result may seem surprising, considering the known anti-inflammatory effects of local anaesthetics. Several *in vitro* studies have demonstrated reduced production of free oxygen radicals from polymorphonuclear leucocytes after treatment with local anaesthetics [10–14], and reduced adherence and migration of leucocytes have been documented in different *in vivo* models [15–18]. Furthermore, local anaesthetics inhibit movement of leucocytes and phagocytosis *in vitro* [14, 19–21]. Local anaesthetics have also been shown to reduce albumin extravasation in rats after burn injury and chemical peritonitis [22, 23] and to modify the inflammatory response to experimental colitis [24] and irradiation [25].

Local anaesthetics may alter release of inflammatory mediators, for example histamine release from mast cells *in vitro* [26], leukotriene B-4 and interleukin-1 release from polymorphonuclear granulocytes and mononuclear cells *in vitro*, respectively [27]. The flare reaction induced by trauma and injection of inflammatory mediators is diminished by local anaesthetics, in contrast with the weal and local red reaction [28–30]. Thus local anaesthetics block axon reflexes and sensory functions of nociceptors. Inhibition of axon reflexes reduces local, indirect release of inflammatory neuropeptides, but the clinical importance of diminished neurogenic inflammation is unclear. It is not known if the local effector function of directly stimulated nociceptors is affected by local anaesthetics [31]. Furthermore, local anaesthetics have been shown to inhibit substance P receptor binding [32]. Thus several anti-inflammatory effects of local anaesthetics have been demonstrated *in vitro* and in animal models, but evidence of effects in human studies is, to our knowledge, restricted to one uncontrolled study and one case report, where lignocaine improved ulcerative proctitis and severe interstitial cystitis, respectively [33, 34]. Topical lignocaine has been tested several times in asthmatic subjects with conflicting, but mainly negative results [35–37]. Topical lignocaine had no effects on allergen-induced nasal secretion, blood flow or obstruction, in allergic individuals [38]. We have shown earlier that short-lived topical application, or subcutaneous infiltration with local anaesthetics, did not affect inflammation after burn [3]. This study, with prolonged and intensive treatment, supports this conclusion. Our findings, and the lack of other clinical evidence, may therefore question the relevance of the anti-inflammatory effects of local anaesthetics.

There may be different explanations for our results. First, the response involves several inflammatory mediators and cell types, which may not be affected by local anaesthetics. Second, the timing of the treatment (before compared with after injury) may be important in modulating inflammatory responses, as early mediators release cascades of secondary mediators. In this study we preferred treatment after injury, as this mimics most clinical situations, while treatment was initiated before injury in our first study [3]. Apparently, this did not affect the results. Third, the effects of prolonged topical treatment were either too transient or incapable of altering the course of the inflammatory response. Although the analgesic effects did not last into the observation period (16–48 h after injury), we do not question the effectiveness of EMLA cream in pain relief, but effects on hyperalgesia should *not* be expected for prolonged periods (more than 8 h) after removal of the cream. The potential reduction of leukotriene B-4, interleukin-1, histamine, free oxygen radicals and activated leucocytes by local anaesthetics [27] should attenuate sensitization of nociceptors in the injury, but removal of EMLA cream 8 h before the first measurements may have returned the process to its natural course. Fourth, we studied only 12 subjects and we may have missed some real differences. The minimal differences between treatments detectable in this study, with a power of 90 %, are shown in table 2.

The consequences for wound healing after treatment with local anaesthetics are controversial. The synthesis of collagen and glycosaminoglycans by fibroblasts *in vitro* is reduced by local anaesthetics [39], as is the tensile strength of skin wounds in rats [40]. Other studies [41], including our own, have been unable to demonstrate adverse clinical effects on host defences and wound healing, but our study is less specific in this respect than the first mentioned studies, and prolonged use of local anaesthetics may threaten tissue defences.

Continuous extrapleural paravertebral infusion of bupivacaine for post-thoracotomy analgesia in young infants

M. K. KARMAKAR, P. D. BOOKER, R. FRANKS AND M. POZZI

Summary

We have studied the efficacy of a continuous paravertebral infusion of bupivacaine for the management of post-thoracotomy pain in 20 infants with a median age of 5.3 weeks (range 2 days to 20 weeks). Immediately before chest closure, 0.25% bupivacaine 1.25 mg kg^{-1} was injected into an extrapleural paravertebral catheter, inserted under direct vision. A continuous infusion of 0.25% bupivacaine 0.5 mg kg^{-1} h^{-1} was commenced 1 h later and terminated after 24 h. We found that extrapleural paravertebral catheter placement under direct vision was easy in neonates and infants. The technique provided effective postoperative pain relief in 18 (90%) patients and the failure in two (10%) infants was attributed to catheter block. Mean maximum serum concentrations of bupivacaine after the loading dose and during infusion were 1.03 (SD 0.56) and 2.00 (0.63) µg ml^{-1}, respectively. There were no major complications relating to the technique and we conclude that extrapleural paravertebral block is a simple and effective method for post-thoracotomy analgesia in young infants. (*Br. J. Anaesth.* 1996; **76**: 811–815).

Key words

Anaesthetic technique, regional, paravertebral. Anaesthetics local, bupivacaine. Anaesthesia, paediatric. Pain, postoperative. Surgery, thoracic. Infants.

Providing safe and effective analgesia after thoracotomy in infants is particularly difficult. Opioids are the mainstay of treatment of such pain [1, 2], although the potential for serious respiratory depression [3] may lead to inadequate prescribing or administration, or both, in young children [4–6]. Despite the increasing interest in regional anaesthesia to provide postoperative pain relief in children, the use of percutaneous paravertebral analgesia has only been reported recently in this age group [7, 8]. Insertion of the paravertebral catheter under direct vision at the time of thoracotomy [9, 10] appears to provide equally effective analgesia to the percutaneous approach but is an easier and safer technique. Prompted by these encouraging preliminary reports, we undertook a prospective, non-comparative study to assess the safety and efficacy of a continuous extrapleural paravertebral infusion of bupivacaine in young infants after thoracotomy. As a continuous infusion of bupivacaine into a vascular site, such as the paravertebral space, has the potential to lead to significant systemic absorption and accumulation, we measured serum concentrations of bupivacaine intermittently throughout the study.

Patients and methods

The study was approved by the local Ethics Committee and written informed parental consent was obtained before operation. We studied 20 infants less than 4 months of age (neonates included) who were > 38 weeks' gestational age undergoing elective or emergency thoracotomy for various cardiac procedures. Patients were excluded if they were < 2.5 kg in weight, their immediate postoperative care was anticipated to be other than in the intensive care unit (ICU) or if they were expected to require postoperative artificial ventilation.

No premedication was prescribed. I.v. cannulation was performed before anaesthesia which was induced with thiopentone 4–5 mg kg^{-1}. Atracurium 0.5 mg kg^{-1} was used to facilitate tracheal intubation. Anaesthesia was maintained with 0.5% isoflurane and 50–66% nitrous oxide in oxygen, and i.v. fentanyl 2 µg kg^{-1} was used to provide preoperative analgesia. Cannulation of the right radial artery was performed to facilitate arterial pressure monitoring and sampling for bupivacaine assays.

Immediately before chest closure, the parietal pleura was peeled medially starting at the thoracotomy space. The resulting pocket was extended from the posterior wound margin onto the vertebral bodies and for two intercostal spaces above and two below. A Lahey's forceps was used to create a tunnel in the paravertebral space. An appropriately sized Tuohy needle was inserted percutaneously at a site close to the angle of the rib of the thoracotomy incision to emerge near the extrapleural pocket created earlier. The needle was removed and either an end-holed (od 0.63 mm) or side holed (od 0.9 mm) extradural catheter (minipack, Portex Ltd) was advanced through the needle and positioned cranially under direct vision such that about 3 cm of its length lay against the costo-vertebral joints within the

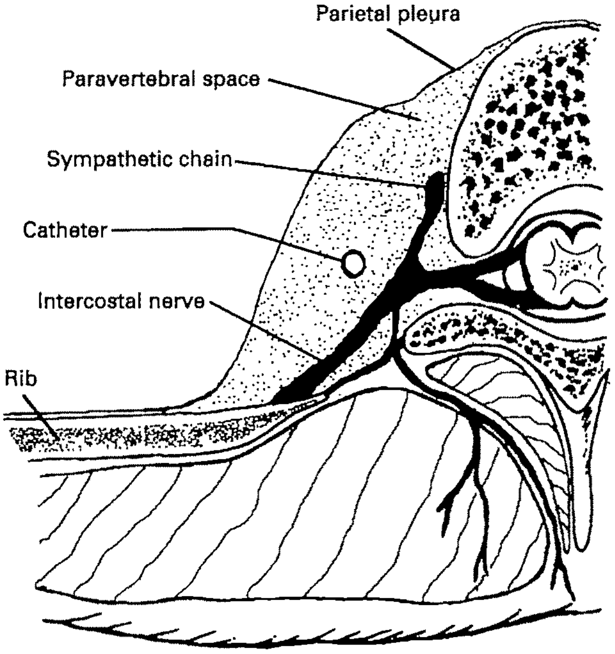

Figure 1 Position of the catheter in relation to the anatomy of the paravertebral space.

pocket (see fig. 1). The needle was removed and the parietal pleura was re-attached to the posterior edge of the wound before the thorax was closed. The catheter was affixed securely to the skin where it emerged through the chest wall and a bacterial filter attached.

The catheter was aspirated to examine for the absence of cerebrospinal fluid or blood. A test dose of 0.125% bupivacaine with adrenaline 1:400000 (1.0 ml) was injected and haemodynamic variables recorded for 5 min. When intravascular catheter placement had been excluded, a loading dose of 0.25% bupivacaine 0.5 ml kg^{-1} (1.25 mg kg^{-1}) was injected into the catheter. Haemodynamic variables were recorded 1, 3, 5, 10, 15 and 30 min after the loading dose. The infant was transferred to the ICU and the trachea extubated when clinically appropriate, usually within 1–2 h. One hour after administration of the loading dose a continuous infusion of 0.25% bupivacaine 0.2 ml kg^{-1} h^{-1} (0.5 mg kg^{-1} h^{-1}) was commenced and continued for 24 h, except in two patients where the infusion was continued for 36 h. Thereafter, paracetamol was prescribed in accordance with routine clinical practice. Hourly assessments of postoperative pain were made by a nurse not otherwise involved in the care of the patient, using a modified CRIES pain score [11]. An i.v. infusion of morphine 10 μg kg^{-1} h^{-1} was prescribed as "rescue analgesia", only if a pain score > 3 was recorded (maximum score = 10) and could not be reduced by a dummy or verbal soothing.

Arterial blood samples (1 ml) were obtained at 10-min intervals for 60 min after the loading dose and at 6-h intervals for 24 h after starting the infusion, for measurement of serum concentrations of bupivacaine. Blood samples were centrifuged, the serum separated and stored at −20 °C until assay. Serum concentrations of bupivacaine were measured by reverse phase high performance liquid chromatography using an Ultrasphere ods 5u, 150 × 4.6 mm column and 205 nm detector. The assay was calibrated with bupivacaine standard in methanol. Etidocaine or mepivacaine was used as the internal standard depending on the position of interfering peaks in the serum blank. A single extraction with methyl tert-butyl ether was performed. The limit of detection was 0.05 μg ml^{-1}. The coefficient of variation was ±4% at 0.05 μg ml^{-1} with a between-batch variability of 4%.

Results

The age, weight and operation performed on each patient are shown in table 1. Median age was 5.3 weeks (range 2 days to 20 weeks) and median weight 3.8 (range 2.5–6.2) kg. There were no difficulties related to insertion of the extrapleural paravertebral catheter under direct vision, even in the smallest neonate. The extrapleural fascia, which has been described in adults [12], was difficult to delineate in this age group, and therefore the catheters were inserted extrapleurally in the paravertebral space. There was no inadvertent intravascular catheter insertion in any patient, although blood-stained serous fluid, presumably from a collection in the extrapleural pocket, was aspirated before the test dose in almost every case. There were no adverse haemodynamic changes either after institution of the block or during infusion in any patient.

In 18 (90%) patients the mean hourly pain score was 0.52 (SD 0.33) and the median of the mean hourly pain score was 0.46 (range 0.0–1.4) (fig. 2); none of these patients required morphine as rescue analgesia after operation. Two patients (10%) had pain scores > 3 and therefore they both received morphine. In both of these patients the catheters were found to be either blocked or kinked, thereby preventing infusion of bupivacaine.

The maximum serum bupivacaine concentration ($C_S$max) measured during the first 60 min after the

initial injection and time to achieve this peak concentration (tC_Smax) are shown for 18 patients in table 2. Technical problems in two patients prevented sampling. Mean $C_S$max was 1.03 (0.56) μg ml^{-1} and median tC_Smax was 10 (range 10–60) min. A wide variation between individual patients was noted. After the initial peak after the first injection, there was a progressive increase in mean serum bupivacaine concentrations (fig. 3). Mean serum bupivacaine concentrations measured at 6, 12, 18 and 24 h (table 3) demonstrated wide variation between individual patients. Mean maximum serum bupivacaine measured at any time between 6 and 24 h after starting the infusion was 2.00 (SD 0.63) μg ml^{-1}.

There were no major complications relating either to the technique or the infusion. One patient had a transient ipsilateral Horner's syndrome which resolved after the infusion was stopped. Although there was evidence of accumulation of bupivacaine during the continuous infusion in many patients, none exhibited clinical signs suggestive of bupivacaine toxicity.

Discussion

We have confirmed that insertion of a paravertebral catheter, under direct vision at thoracotomy, is a safe technique, even in small neonates. A continuous infusion of bupivacaine into the catheter appears to provide effective postoperative analgesia for this procedure and this technique is now used routinely in our unit. However, we have shown that after 24 h there is evidence of significant accumulation of bupivacaine in some patients which, if the infusion had been continued for longer, may have reached potentially toxic concentrations [13–18]. The dose of bupivacaine used was the maximum safe infusion rate recommended for extradural block in children [15, 19]; preliminary results from an on-going study suggest that the concentration can be reduced without affecting efficacy.

Other regional techniques used to provide prolonged post-thoracotomy analgesia in children include continuous intercostal nerve block [20], thoracic extradural [21–23] and intrapleural catheter insertion [24, 25]. All of these methods have the disadvantages of either technical difficulty or unreliable efficacy. Advancement of a lumbar or caudal extradural catheter into the thoracic region, to avoid the possibility of spinal cord injury in the anaesthetized child having a direct thoracic extradural, has achieved some success [26, 27], although it may prove unreliable in infants [28]. Similarly, the use of continuous intercostal nerve block using catheters inserted during operation under direct vision [20] may fail to provide complete analgesia [29].

Paravertebral block should be more effective than more distal intercostal nerve block, as only the former reliably blocks the posterior primary rami and the ipsilateral sympathetic fibres [30], both of which are involved in the afferent inputs after thoracotomy. Paravertebral block, although originally described by Kappis in 1919 [31], received little attention until a continuous infusion technique was reported in 1979 [30]. This latter technique has since been used extensively in adults to provide safe, reliable and effective post-thoracotomy analgesia [10, 32–34]. The intercostal nerves, their collateral branches, especially the posterior primary rami and the thoracic sympathetic chain, pass through the paravertebral space making it an ideal site for afferent nociceptive block. Segmentation of the nerve into small bundles lying freely among the fat of the paravertebral space makes the nerves exceptionally favourable for block [35] and, furthermore, each space communicates superiorly and inferiorly, across the neck of the ribs, with the spaces above and below. This has been demonstrated in cadaver studies with resin [36], radiologically with contrast medium [37, 38] and clinically with the use of methylene blue at thoracotomy [10]. Although unilateral paravertebral spread of contrast medium without overspill into the pleural cavity or extradural space has been demonstrated [38], medial spread into the extradural space has also been shown [37, 39]. The role of this extradural spread remains unclear, but it may play a part in the extension of sensory block.

Paravertebral block has only recently been reported to provide effective post-thoracotomy analgesia in children, performed either percutaneously [8] or by inserting a catheter in the extrapleural paravertebral space under direct vision [9]. The technique has been shown to produce analgesia equal to or superior to extradural analgesia in children [7]. Although paravertebral block has been dismissed in many standard texts as being a hazardous technique [40, 41], these comments have been unsubstantiated by any evidence. In fact the complication rate for percutaneous paravertebral block in children (pleural puncture (2.08 %), vascular puncture (4.2 %) and an overall failure of rate of 6.2 % (3/48) [42]), can be compared favourably with other regional techniques used in this age group [43, 44]. Moreover, these complication and failure rates can be reduced further by performing catheter insertion under direct vision which we have found to be an effective technique in even the smallest neonate. We did not encounter any problem relating directly to the technique of catheter insertion; a similar lack of complications was reported in a study of six older children using this same method of analgesia [9].

In our study we found that the technique of continuous extrapleural paravertebral infusion of bupivacaine provided effective analgesia in 90 % (18/20) of our patients compared with the 100 % (6/6) success rate in older children reported by Eng and Sabanathan [9]. The 10 % (2/20) failure rate in our study was related to catheter blockage. The catheters used in both of these patients were designed to pass through a 19-gauge Tuohy needle, had only end holes and a tendency to kinking and blockage. The use of these particular catheters was therefore discontinued and slightly larger catheters (od 0.9 mm) with three lateral eyes, able to pass through an 18-gauge Tuohy needle, were used in all subsequent patients, however small, with a resultant 100 % success rate.

Surgical pain is followed not only by spinal sensitization but also by supraspinal antinociception

O. H. G. WILDER-SMITH, E. TASSONYI, C. SENLY, PH. OTTEN AND L. ARENDT-NIELSEN

Summary

Nociception can produce segmental spinal sensitization or descending supraspinal antinociception. We assessed both types of sensory change after surgery during isoflurane–nitrous oxide anaesthesia with or without fentanyl before nociception. Patients undergoing back surgery received fentanyl 3 μg kg^{-1} ($n = 15$) or placebo ($n = 15$) before anaesthesia in a prospective, randomized, blinded study. Sensation, pain detection and tolerance thresholds to electrical stimulation were measured before operation at the arm, incision and herniated disc dermatomes (HDD) and 1, 2, 4, 6, 24 h and 5 days after operation, together with pain scores and patient-controlled morphine consumption (duration 24 h). For segmental effects, thresholds were normalized to the thresholds at a distant dermatome (arm). Raw pain thresholds were increased after operation (fentanyl > placebo) and were maximal at 4 h (pain tolerance in HDD: fentanyl +5.2 mA (+62.7%), placebo, +3.8 mA (+44.2%); $P < 0.05$ *vs* baseline for both). Normalized sensation thresholds decreased for placebo only (HDD/4 h: placebo, −1.8 (−44.8%), $P < 0.05$; fentanyl, +0.1 (+5.5%) ns). All changes returned to baseline by 24 h except for the placebo group normalized HDD sensation (d5: placebo, −2.4 (−59.7)%, $P < 0.05$; fentanyl −0.1 (−5.5%) ns). Pain scores and morphine consumption were similar. The study demonstrated both supraspinal analgesia and spinal sensitization after surgery. Fentanyl administration before operation augmented the former while decreasing the latter, and hence sensitization, especially if neuropathic, may particularly benefit from pre-emptive analgesia. (*Br. J. Anaesth.* 1996; **76**: 816–821)

Key words
Pain, postoperative. Analgesia, postoperative. Analgesia, pre-emptive. Pain, threshold.

In an editorial discussing pain after surgery, Wall [1] noted, on the basis of animal experimentation, that nociception results in excitatory, segmental changes in central, spinal sensory processing (spinal sensitization). In animal experiments, it was found not only that opioids depress spinal sensitization, but that they were considerably more effective if given before rather than after nociception (pre-emptive analgesia) [2]. The clinical application of these findings has generated considerable debate, with the clinical reality of pre-emptive analgesia remaining controversial and the subject of intensive investigation [3, 4]. In particular, it has proved difficult to demonstrate clinically significant effects on analgesic consumption and clinical pain measures [3, 4].

Groups [5, 6] working on intact animals and with more intense nociceptive stressors described opposing, inhibitory and supraspinal phenomena, such as "stress-induced analgesia (SIA)" or "diffuse noxious inhibitory controls (DNIC)". These groups used nociception that was longer-lasting or more intense, or both, than that of spinal sensitization models (e.g. being forced to swim in hot water *vs* short-lasting electrical stimulation), and found analgesia and hyposensitivity in sensory testing afterwards [7]. Similar sensory inhibition was elicited by stimulation of various brain regions ("stimulation-induced analgesia") [6]. SIA operates via descending, inhibitory encephalinergic, α-adrenergic and NMDA systems [8].

Whether human surgery is associated with spinal sensitization or supraspinal inhibition has not been investigated in detail. Only few studies have examined the effect of pre-emptive analgesia on spinal sensitization; we have found none for SIA or DNIC. Richmond, Bromley and Woolf [9] and Collis and colleagues [10] found that mechanical secondary hyperalgesia was suppressed by pre-emptive morphine, but they did not give absolute thresholds. On a single occasion after operation, Lund, Hansen and Kehlet found an increased electric sensation threshold [11], while electric pain thresholds were decreased (and the nociceptive withdrawal reflex increased) in another study [12]. Both Willer, Bergeret and Gaudy [13] and Peters and colleagues [14] found increased thresholds in small postoperative studies. Thus data on postoperative changes in sensory processing with human surgery are scarce and contradictory.

The aim of this study was to investigate sensory processing after surgery using sensory skin thresholds. In particular, we were interested in

detecting and differentiating between generalized (e.g. supraspinal inhibition) and segmental (e.g. spinal sensitization) changes in sensory function. We also determined the effect of pre-emptive fentanyl analgesia on changes in sensory processing which might be present after surgery. Finally, we determined if altered sensory processing affects clinical measures of pain (analgesic consumption, pain scores).

Patients and methods

We studied 30 ASA I and II patients, undergoing elective herniated intervertebral disc surgery. The study design was prospective, randomized and double-blind. Institutional review board and Ethics Committee approval were obtained, and all patients gave informed written consent.

Patients were instructed on threshold measurement, pain verbal rating scores (VRS) and use of a patient-controlled analgesia (PCA) pump. They received no premedication on the morning of operation. Before insertion of a venous cannula, pain verbal rating scores (0 = no pain; 10 = worst pain imaginable) for the back and affected leg dermatome and sensation, pain detection and pain tolerance thresholds were determined. Thresholds were obtained using constant skin current stimulation (Digistim, Biometer A/S, Copenhagen/DK; tetanic stimulation at 100 Hz, 0.2 ms square wave pulses) via self-adhesive electrodes 3 cm apart. Measurements were carried out in the middle of the nerve root dermatome most affected by disc prolapse; on the flanks at the height of the back incision (T12–L1 dermatome), ipsilateral and contralateral to the side of the involved nerve root; and the proximal arm contralateral to the involved nerve root (C8–T1). Care was taken not to stimulate major nerves, and measurements were separated by 5 min. The three end-points, measured successively in a run, were the averages of the three runs.

Five minutes before induction of anaesthesia, patients received a blinded short infusion (0.9 % NaCL 100 ml) containing either placebo (placebo group) or fentanyl 3 $\mu g\ kg^{-1}$ (fentanyl group). Anaesthesia was induced with thiopentone 5 $mg\ kg^{-1}$, followed by vecuronium 0.1 $mg\ kg^{-1}$. After tracheal intubation, anaesthesia was maintained with isoflurane and 66 % nitrous oxide in oxygen. No other supplementation was given and the interventions usually lasted less than 1 h.

Thirty minutes after extubation, morphine by patient-controlled analgesia (PCA) was started (loading bolus 60 $\mu g\ kg^{-1}$, PCA bolus 25 $\mu g\ kg^{-1}$; lock-out interval 8 min in recovery room, 15 min on ward; background infusion 15 $\mu g\ kg^{-1}\ h^{-1}$ during the first 2 h in the recovery room). No other analgesics were given. Threshold and VRS measures, as before, and cumulative morphine consumption were assessed 1, 2, 4, 6 and 24 h after extubation. PCA morphine was discontinued 24 h after operation. Threshold and VRS values were obtained 5 days after operation. Observer sedation rating scores (5 = wide awake, 1 = unrousable) were also noted at measurement times.

Based on the data of Lautenbacher and Rollman [15], the study was designed to have the power to detect a difference of 20 % in sensation thresholds. To separate generalized from segmental (spinal) effects on thresholds, normalized (or relative) and raw thresholds were analysed. Thresholds were normalized relative to the arm [9, 10]. Thus normalized thresholds were calculated by dividing para-incisional and affected dermatome threshold values by the respective arm threshold values. All statistical analysis was performed using the software package Statistica for Windows (release 4.5, Statsoft Inc, 2325 East 13th Street, Tulsa, OK 74104, USA). Patient data were compared by unpaired *t* test. Analysis of thresholds, pain VRS or sedation scores and cumulative morphine consumption was by repeated measures ANCOVA, with the preoperative baseline values acting as covariant. *Post hoc* testing was by Tukey's honest significant difference test. Statistical significance was assumed if $P < 0.05$.

Results

The two groups were comparable (table 1), with similar preoperative (baseline) pain VRS and threshold values. There were no significant differences between groups for back or leg pain VRS, cumulative morphine consumption or observer sedation scores (table 2).

Raw thresholds were increased after operation (table 3, fig. 1). In both groups mainly the 4-h measurements of affected dermatome pain thresholds were increased significantly compared with baseline. Combining all thresholds, the fentanyl group values were significantly higher than the placebo values ($P < 0.02$). Overall, the thresholds at different measurement sites and the sensation, pain detection and pain tolerance thresholds were significantly different ($P < 0.008$ and 0.00001, respectively). Arm site thresholds overall were significantly lower than for the para-incisional site ($P < 0.024$), with no significant difference between para-incisional and affected dermatome thresholds. All three threshold test types differed from each other ($P < 0.0001$). For thresholds overall, values at 24 h and 5 days were generally lower than the preceding postoperative values ($P < 0.0001$). Baseline thresholds significantly affected subsequent values ($P < 0.0001$).

For normalized thresholds taken together (fig. 2), the groups or measurement sites did not differ. Only in the placebo group were sensation thresholds in the affected dermatome significantly lower than baseline at 4 and 6 h and 5 days after operation. Overall, the three threshold test types continued to be different ($P < 0.00001$), and day 5 threshold values together differed from those at 1, 2 and 24 h after operation. For sensation thresholds alone, the values in the placebo group were significantly lower than in the fentanyl group ($P < 0.003$) overall. Baseline values

influenced normalized thresholds only up to 4 h after operation.

Discussion

In this study, surgery was associated with generalized sensory inhibition and segmental sensitization in the immediate postoperative period. Changes in sensory processing generally returned to baseline within 24 h after operation. Compared with placebo, pre-emptive fentanyl inhibited segmental sensitization, and was accompanied by increased generalized sensory inhibition. These differences between groups were not significantly reflected in clinical measures such as pain scores or morphine consumption in our study, indicating the importance

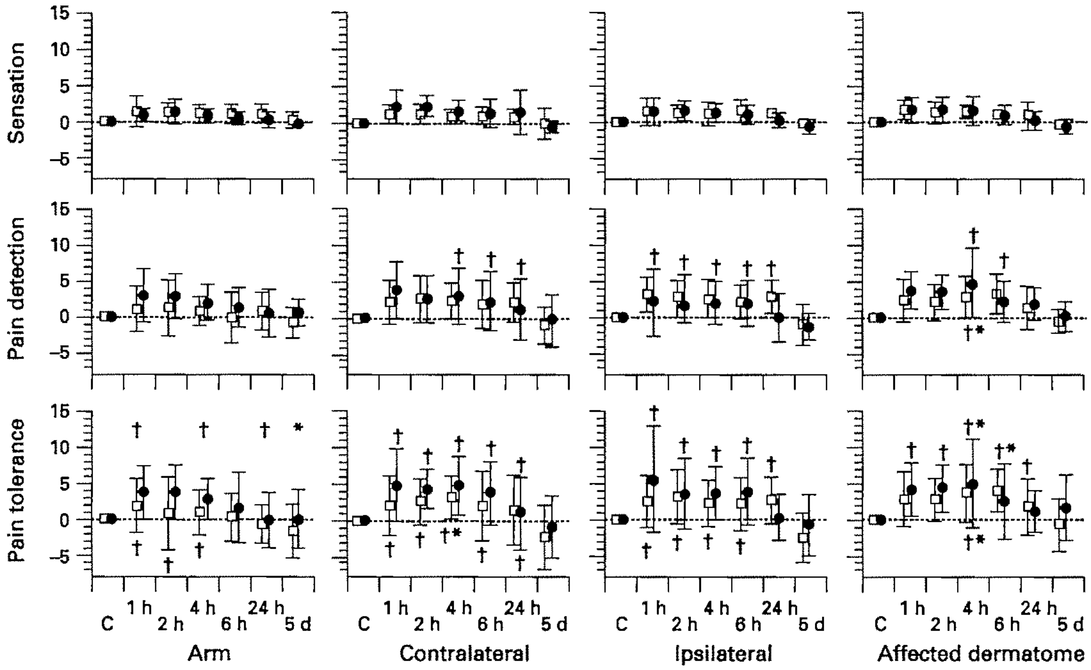

Figure 1 Changes from baseline of raw sensory thresholds (mean, SD mA). The dermatomes tested (X axis) and the types of threshold tests (Y axis) are indicated. *$P < 0.05$ *vs* baseline; †$P < 0.05$ *vs* day 5 value. The significances for the placebo group are marked above the zero line, those for the fentanyl group, below. Only differences at individual times within a given graph are marked (for other results, see text).

of sensory testing in assessing nociception after operation.

Measurement of pain thresholds by cutaneous electrical stimulation is easy to use and well validated [15]. While electrical thresholds do not represent a pure nociceptive activation, but a mixed nerve fibre population response, we consider its use acceptable in the surgical context because surgery also involves a mixed response. Additionally, use of the more complex equipment necessary for pure nociceptive stimulation (lasers, Peltier elements) is difficult if not impossible on the ward. Possible sensitization by threshold measurements was minimized by spacing the measures, doing only three runs and stopping on just reaching the pain tolerance threshold. In common with other groups [9, 10] we normalized thresholds relative to the arm. Because the arm was far away from the surgical site, it was unlikely to be affected by segmental or spinal sensory changes after operation, while still being subject to any generalized or supraspinal changes, making possible separation of the two types of altered sensory processing.

Extraneous factors which may have influenced thresholds include increased reaction times and analgesic or anaesthetic drugs. In order to decrease the effect of reaction times, electric stimulation was increased very slowly (approximately 0.1 mA s^{-1}). In addition, sedation scores were similar between groups throughout, and were normal by 4 h after operation. Isoflurane in subanaesthetic concentrations has no effect on pain detection thresholds [16]; nitrous oxide may increase pain detection thresholds for up to 30 min after its discontinuation [17]. Opioids such as morphine or fentanyl have no direct effects on sensation or pain detection thresholds [18]. The effects on pain tolerance thresholds are most visible if the stimulus is long or repeated, and are small for tolerance to single pain stimuli [18]. Thus direct drug effects on the thresholds can be expected to have been minimal, particularly with regard to sensation and pain detection thresholds.

Patients titrated themselves to similar pain levels in the groups using PCA morphine. The lack of difference in morphine consumption may primarily result from group size, or because back surgery is only moderately painful, or both. The group size had the statistical power to detect a difference of 50 % in morphine consumption at 24 h between the groups. These results suggest that sensory testing may be more sensitive in the assessment of change after operation than clinical measures such as morphine consumption or pain scores. The relevance of such sensory changes for long-term outcome needs investigation.

We have found no other studies which have systematically investigated sensory thresholds after surgery in humans with regard to spinal sensitization or supraspinal inhibition. Richmond, Bromley and Woolf [9] and Collis and colleagues [10], studying pre-emptive morphine for hysterectomy, found postoperative differential (i.e. forearm–abdomen) pain detection thresholds to mechanical stimulation to be smaller in the pre-emptive group, suggesting less spinal sensitization. There was no difference in sensation thresholds. No preoperative measures were given, however, making further interpretation difficult. The absence of threshold values in a dermatome distant to the surgical site precludes conclusions about the presence or absence of generalized sensory inhibition. The mainly raised thresholds in the studies of Lund, Hansen and Kehlet [11], Dahl and colleagues [12], Willer, Bergeret and Gaudy [13] and Peters and colleagues [14] have already been mentioned. Their results are difficult to compare with ours, as they involved different times, sites and methods.

The increased sensory thresholds after operation demonstrated in our study are likely to be the result of descending central inhibitory controls elicited by the nociception of surgery (e.g. SIA or DNIC [5–8]. Sensory inhibition in our study was generalized and detectable up to 24 h after operation. DNIC operates on convergent neurones and generally fades shortly after the conditioning stimulus [19], making it a less likely mechanism in this case than SIA. SIA is supported further by the fact that while DNIC is depressed by opioids [20], SIA has been described as being augmented by opioid supplementation [21, 22]. However, SIA mechanisms are complex, involving both opioid and non-opioid pathways, possibly mutually antagonistic [23], and a final understanding must await more complete elucidation of this phenomenon. The only possible alternative explanation could be the level adaptation theory, which postulates that pain thresholds change because of resetting of the reference point for pain thresholds [14]. This theory is unlikely to explain the shift in *sensation* thresholds also seen in our study, but definite differentiation would depend on measurement of the nociceptive withdrawal reflex [14] not performed in our study. It should however be remembered that the withdrawal reflex is affected by changes both in the sensory and motor system. Segmental spinal sensitization caused by nociception is also well described in the literature for animal models [2, 3]. Studies confirming spinal sensitization after nociception in human volunteers have now been performed [24], but formal clinical studies are still lacking, as are studies of the long-term implications of such changes for outcome after surgery.

The fentanyl supplemented group showed more supraspinal antinociception after operation than the placebo group. This would suggest that, as shown experimentally [21, 22], opioids act synergistically with descending inhibitory systems, providing another rationale for pre-emptive analgesia. Opioids are effective at preventing and treating spinal sensitization, particularly of the nociceptive system [4], as confirmed by our study. The fentanyl group showed no segmental sensitization; in the placebo group it was visible only for the somatosensory system. Expression of nociceptive system sensitization in the placebo group may have been suppressed by morphine analgesia in the context of only moderately nociceptive surgery, leaving only somatosensory sensitization visible [25]. This possibility needs further study using more painful surgical interventions and larger patient groups. In the placebo group, segmental sensitization was still present compared with the fentanyl group in the affected dermatome 5 days after operation, at a time when all other sensory changes had reverted to normal. This suggests that under special circumstances (e.g. the presence before surgery of neuropathic pain or sensitization associated with nerve damage), changes in sensory processing can persist long-term with poorly blocked pre- or intraoperative nociception, as also suggested by the amputation studies of Bach, Noreng and Tjellden [26]. Further studies are needed to confirm this.

Haemostatic changes caused by i.v. regional anaesthesia with lignocaine

T. T. NIEMI, A. H. KUITUNEN, E. M. VAHTERA AND P. H. ROSENBERG

Summary

The various components of i.v. regional anaesthesia (IVRA), that is ischaemia, tourniquet compression and the presence of high concentrations of local anaesthetics in the blood vessels of the extremity, may affect haemostatic mechanisms. We performed a cross-over study in 10 healthy male volunteers to examine the role of lignocaine in IVRA on several haemostatic variables, and those indicating fibrinolysis and platelet function in particular. Venous blood samples were obtained from the test arm and the opposite arm before IVRA, at the time of tourniquet cuff deflation and 30 min thereafter. Metal needle punctures were used, and for the sample from the test arm at the time of cuff deflation, cuff pressure was reduced from 300 mm Hg to individual mean arterial pressure. The IVRA technique included exsanguination by arm elevation and axillary artery compression, inflation of the tourniquet cuff for 20 min and deflation of the cuff in one step (after obtaining the venous sample). Each subject received, in random order, either 0.5% lignocaine 3 mg kg^{-1} or the corresponding volume of saline i.v. All fibrinolysis markers, that is, D-dimer, tissue plasminogen activator antigen (t-PA antigen), tissue plasminogen activator activity (t-PA activity), plasminogen activator inhibitor activity (PAI) and protein C indicated enhanced fibrinolysis by IVRA, but only t-PA antigen and PAI showed greater changes in the lignocaine compared with the saline group in the exposed arm at the time of cuff deflation. Platelet function tests (ADP-induced platelet aggregation, β-thromboglobulin and thrombelastogram (TEG)) indicated no differences between the lignocaine and saline groups. Although IVRA appeared to induce some platelet dysfunction, there was a small increase in TEG amplitude indicative of improved fibrin–platelet interaction in the lignocaine-exposed arm at the time of cuff deflation. We conclude that the presence of high i.v. lignocaine concentrations (median 144.4 μg ml^{-1} in cubital veins at the end of the tourniquet time) potentiated ischaemia-induced fibrinolysis activation during IVRA. Concomitant platelet dysfunction was not aggravated by lignocaine. (*Br. J. Anaesth.* 1996; **76**: 822–828)

Key words

Blood, haemostasis. Blood, coagulation. Anaesthetic techniques, regional. Anaesthetics local, lignocaine.

I.v. regional anaesthesia (IVRA) is used widely for minor operations of the extremities. The technique includes a pneumatic tourniquet and i.v. injection of local anaesthetic distal to the tourniquet. The various components of IVRA, such as ischaemia, tourniquet compression and intravascular local anaesthetic, may affect haemostatic mechanisms. Fibrinolytic activity increases both in the occluded limb and in the systemic circulation during tourniquet ischaemia [1–3]. This activity is associated with a low incidence of deep venous thrombosis in the exposed limb [2, 3]. However, there are reports of embolic events after tourniquet release [4, 5]. Embolic material is probably derived from fresh thrombi formed during tourniquet inflation [6].

A schematic representation of fibrinolysis is shown in figure 1. Tissue plasminogen activator (t-PA) is a primary activator which converts plasminogen to plasmin. It is produced by and released continuously from the vascular endothelial cells and after some local or systemic stimuli [7]. t-PA-mediated plasminogen activation is inhibited directly by plasminogen activator inhibitors (PAI), mainly PAI-1 (fig. 1) [8].

Clinically useful thrombosis prophylaxis by i.v. lignocaine has been demonstrated [9]. Lignocaine also has an antithrombotic effect when administered topically in rat microvascular injury [10]. Local anaesthetics are known to inhibit platelet aggregation but only at much higher concentrations that may occur normally during extradural or brachial plexus block [11]. In contrast, during IVRA, local anaesthetic concentration in the isolated limb may be 50–100 times higher than that associated with other types of regional anaesthetic techniques [12].

In this study, therefore, we evaluated the role of lignocaine on platelet function and fibrinolysis during and after IVRA, without surgery.

Subjects and methods

We studied 10 apparently healthy, male, non-smoking volunteers, aged 29–50 yr, in a randomized,

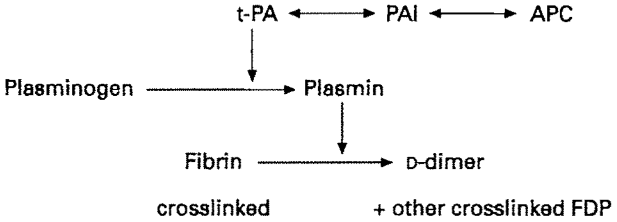

Figure 1 Schematic representation of fibrinolysis. t-PA = Tissue-type plasminogen activator, PAI = plasminogen activator inhibitor, APC = activated protein C, FDP = fibrin degradation products.

crossover study. The interval between the two experiments in one subject was at least 2 weeks. The study was approved by the Ethics Committee of Helsinki University Central Hospital and oral informed consent was obtained. Acetylsalicylic acid or other NSAID were not allowed for 1 week before the study. Individuals fasted for at least 3 h before the experiment. During the experiment subjects were in the supine position and monitored by five-lead ECG, non-invasive arterial pressure and pulse oximetry.

A vein of the dorsum of the hand was cannulated with a 20-gauge cannula (Venflon, BOC Ohmeda AB, Sweden) for administration of lignocaine or sodium chloride. Exsanguination was achieved by elevating the arm and occluding the axillar artery for 2 min so that no pulse could be detected in the periphery by a pulse oximetry. The brachial tourniquet was pressurized to and maintained inflated at 300 mm Hg for 20 min. In random order subjects were given preservative-free 0.5 % lignocaine 3 mg kg^{-1} for IVRA of the upper extremity or the same volume of 0.9 % sodium chloride. Lignocaine or sodium chloride was injected into the vein through the cannula at a rate of approximately 20 ml min^{-1}, immediately after pneumatic cuff inflation. In order to improve drug distribution and vascular filling, a small amount of physiological saline was injected immediately after lignocaine or sodium chloride (according to body weight: 3 ml for 60–69 kg, 4 ml for 70–79 kg, 5 ml for 80–89 kg and 6 ml > 90 kg). The cannula was then removed.

Blood samples were obtained from all subjects from an antecubital vein of the arm exposed to IVRA (IL = ipsilateral samples), and the contralateral arm (CL = contralateral samples) via a 20-gauge hypodermic metal needle directly into respective assay tubes. Control samples (IL-0 and CL-0) were obtained before IVRA. After 20 min of tourniquet inflation, the pneumatic cuff pressure was reduced to mean arterial pressure and a sample was immediately obtained from the first available dilated antecubital vein. This manoeuvre was necessary in order to obtain a sufficient volume of blood as rapidly as possible with a single venepuncture. As soon as the sample had been collected, the pneumatic tourniquet was released completely and a sample was obtained from the contralateral arm (CL-20). Finally, after 30 min from tourniquet release, samples (IL-50 and CL-50) from both arms were obtained with minimal stasis; an elastic, round 5-mm diameter rubber band on the brachium exerted low pressure on the skin.

ASSAYS

For assays of D-dimer, t-PA antigen, PAI and protein C, nine volumes of blood were mixed with 1 volume of trisodium citrate 0.129 mol litre^{-1}. For t-PA activity, blood collection tubes (Biopool Stabilyte tube, Umeå, Sweden) containing 0.5 ml of citrate buffer 0.5 ml litre^{-1}, pH 4.0, were used. After centrifugating at 1400 *g* for 30 min at 24 °C, plasma was aliquoted, snap-frozen and stored at −70 °C until assayed.

D-dimer was measured with an ELISA method according to the manufacturer (Asserachrom D-Di, Diagnostica Stago, Asnières, France). Expected values given by the manufacturer are < 400 ng ml^{-1} (expressed in fibrinogen equivalent units). Limits of detection (LOD) and quantitation (LOQ) for the method are 50 ng ml^{-1} and 100 ng ml^{-1}, respectively.

t-PA antigen was measured according to the manufacturer using an ELISA method (Imulyse t-PA, Biopool AB, Umeå, Sweden). The normal range at rest is 1.6–9.8 ng ml^{-1} and after 20 min of venous occlusion 22.8–83.5 ng ml^{-1} in the laboratory. t-PA activity was measured with a chromogenic method according to the manufacturer (Coaset t-PA, Chromogenix AB, Mölndal, Sweden). The range in 20 individuals at rest is 0.8–6.9 iu ml^{-1} and after 20 min of venous occlusion 21.3–128 iu ml^{-1} in the laboratory. LOD for the method is 0.1 iu ml^{-1}.

PAI activity was measured with a chromogenic method according to the manufacturer (Coatest PAI, Chromogenix AB, Mölndal, Sweden). The expected value is < 23 AU ml^{-1} and after a normal 20-min venous occlusion test < 5 AU ml^{-1} assayed in the laboratory. Because there are at least four immunologically different PAI [13] we measured functional PAI, that is PAI activity. LOD for the method is 5 AU ml^{-1}.

Protein C was measured with a chromogenic method using substrate S-2366 (Chromogenix AB, Mölndal, Sweden) and protein C-activator (American Diagnostica Inc, CT, USA). A pool of 33 normal donors was used as a standard. Reference values in the laboratory are 67–131 %.

For β-thromoboglobulin (an indicator of platelet activation and dysfunction) blood was obtained into Diatube H (Diagnostica Stago, Asnières, France). After centrifuging at 4600 *g* for 30 min at 8 °C, 33 % of the volume of the plasma supernatant, by aiming the pipette tip in the middle region of the liquid portion, was collected and stored at −70 °C until assayed. Plasma β-thromboglobulin was measured using an ELISA method according to the manufacturer (Asserachrom β-TG, Diagnostica Stago, Asnières, France). Normal values given by the manufacturer are 10–40 iu ml^{-1}. LOD for the method is 10 iu ml^{-1}.

Platelet count in whole blood and packed cell volume were measured using a Cell-Dyn 610 haematology analyser (Sequoia-Turner Corporation, CA, USA).

Platelet aggregation studies were based on the turbidometric method of Born [14]. For these studies (conducted only on samples from the arm exposed to IVRA) platelet rich plasma (PRP) was prepared by centrifuging citrate blood at 150 *g* for 10 min and platelet poor plasma (PPP) by centrifuging blood at 1400 *g* for 30 min. The platelet count of PRP was adjusted to 200×10^6 litre^{-1} with autologus PPP. Aggregation (Payton Aggregometer, USA) was induced with adenosine diphosphate and the concentration of ADP causing 50% of maximum aggregation (ADP–ED$_{50}$%) was calculated.

Thrombelastograph (TEG) tracings (Hellige Company, Freiburg, Germany) were obtained from citrate whole blood. Coagulation was initiated by adding calcium chloride to the cuvettes. TEG tracings were analysed by measuring reaction time (r), coagulation time ($r+k$), clot formation (k, α angle) and maximum amplitude (MA) [15]. Platelet aggregation measurements and TEG tracings were obtained only from the ipsilateral blood samples as equipment was available only for one sample at each sample time.

For lignocaine concentrations, plasma was stored at −70 °C until lignocaine concentrations were measured by gas chromatography [16].

STATISTICS

The Wilcoxon signed rank test was used for comparisons within groups and the Mann–Whitney *U* test for comparisons between groups. $P < 0.05$ was considered significant.

Results

PACKED CELL VOLUME AND PLATELET COUNT

There were no significant changes in packed cell volume (PCV) between samples obtained before, immediately after IVRA and 30 min thereafter. Also, there were no significant changes between groups. Therefore, no PCV-dependent corrections were made in the following results. Platelet count decreased in the saline group just after cuff deflation and 30 min thereafter compared with control values ($P < 0.05$) (table 1).

t-PA ANTIGEN, t-PA ACTIVITY, PAI

t-PA antigen in the sample at the end of IVRA was significantly higher in the lignocaine compared with the saline group ($P < 0.01$) (table 2). Thirty minutes later, values had normalized and t-PA antigen was slightly, but significantly ($P < 0.05$), lower than the control value in the saline group sample of the arm not exposed to the test. At the same time, also in the lignocaine IVRA arm, t-PA antigen was decreased significantly compared with control values ($P < 0.05$).

Compared with control values, t-PA activity in the test arm samples increased significantly in both groups after IVRA ($P < 0.01$) (table 2). Although values returned towards normal in the next 30 min, the small increase in t-PA activity in the lignocaine group was still statistically significant ($P < 0.05$). After lignocaine IVRA, t-PA activity was also increased in the contralateral arm compared with control ($P < 0.05$). There were no significant differences between groups. However, on the lignocaine exposed side, at the time of cuff deflation, there were only three t-PA antigen values and one t-PA activity value which exceeded the respective upper limit of the normal range.

PAI decreased significantly ($P < 0.01$) during IVRA in the lignocaine, but not in the saline group (table 2). There was a significant difference between the groups at the end of IVRA ($P < 0.05$). In the samples 30 min later, PAI values did not differ significantly from control values. All PAI values were within the normal range.

D-DIMER

In the lignocaine group, D-dimer concentrations increased significantly during IVRA in the sample from the exposed arm (table 2). Median concentrations of D-dimer were still higher than control values in the samples 30 min after IVRA, but this difference was not statistically significant. There was no difference between groups in the change in D-dimer.

ADP-INDUCED PLATELET AGGREGATION

In the saline group, ADP–ED$_{50}$% concentration increased significantly ($P < 0.05$) during and after IVRA (table 1). There was no significant change in the lignocaine group, and no differences between groups.

β-THROMBOGLOBULIN

β-Thromboglobulin concentration (table 1) increased significantly at the end of lignocaine IVRA in the sample from the exposed arm (median 25.6 iu ml^{-1}) compared with control values (median 19.7 iu ml^{-1}). In the saline group there were no significant changes in β-thromboglobulin concentrations. There were no significant differences between groups.

THROMBELASTOGRAPHY

In the saline group, there was a small (ns) increase in reaction (r) and coagulation ($r+k$) times after IVRA compared with control TEG. The increase in maximum amplitude (MA) was statistically significant immediately after IVRA in the lignocaine group ($P < 0.05$) while MA decreased slightly (ns) in the saline group (table 3). There were no significant differences between groups for any of the TEG variables during the test.

PROTEIN C ACTIVITY

Protein C activity (table 4) decreased significantly during lignocaine IVRA in the sample from the exposed arm (median 83%) compared with control values from the same arm (median 96%) ($P < 0.05$). Sodium chloride treatment caused an even greater decrease in protein C activity (median 63% *vs* 102%, respectively) ($P < 0.01$). There was a significant difference in protein C activity in samples immediately after IVRA between the two groups ($P < 0.01$).

Table 1 Platelet counts (PC), platelet aggregation (ADP–ED_{50}% concentrations) and β-thromboglobulin (β-TG) concentrations in ipsilateral (IL) and contralateral (CL) samples (median (range)). Significant differences ($P <$ 0.05) compared with: *IL-0 NaCl; †IL-0 lignocaine (Wilcoxon signed rank test). No significant differences between groups (Mann–Whitney U test)

ARTERIAL PRESSURE AND HEART RATE

There were no significant changes in systolic and diastolic arterial pressures before the test and immediately before tourniquet cuff deflation. Thirty minutes after saline IVRA, median diastolic pressure decreased to a value slightly below the control level ($P < 0.05$). Heart rate was stable (range 50–70 beat min^{-1} during lignocaine IVRA and 55–80 beat min^{-1} during saline IVRA), except in one volunteer who, during lignocaine IVRA, developed a transient (about 5 min) sinus tachycardia. However, his haemostatic data did not deviate from those of the others.

LIGNOCAINE PLASMA CONCENTRATIONS

Lignocaine concentrations were high (maximum 246.4 μg ml^{-1}) in the samples obtained from the exposed arm at the end of the tourniquet time (table 5). Seven of the 10 volunteers experienced symptoms of mild central nervous system toxicity (i.e. auditory disturbances, dizziness, lightheadedness) for 2–5 min after deflation of the tourniquet cuff. Thirty minutes after deflation, plasma concentrations of the exposed arm were still higher than those of the contralateral arm.

Discussion

The results of the study confirmed that fibrinolysis was activated in a limb isolated by a tourniquet [2, 3]. The presence of high i.v. concentrations of lignocaine in the ischaemic limb appeared to enhance further the fibrinolytic response, as indicated by changes in t-PA antigen and PAI. At the end of the experiment there were slightly increased t-PA activity values in the lignocaine exposed arm. At the same time t-PA antigen was decreased slightly which may have been because of rapid clearance by the liver [17].

The decrease in PAI activity by lignocaine IVRA was probably a consequence of complex formation between PAI and t-PA. This decrease in PAI is, in fact, a more logical result than the previous opposite finding of increased PAI associated with application of a tourniquet [3]. Complex formation between PAI and protein C [18] also contributes to low PAI values.

Protein C is a liver-derived glycoprotein that can neutralize PAI-1 and thus has a profibrinolytic effect [8]. When added to human and bovine endothelial cell cultures, activated protein C causes a decrease in the activity of PAI [18, 19]. The fact that PAI activity decreased more in the lignocaine group and protein C (test arm) decreased more in the saline group suggests that the effect of lignocaine is related mainly to the stimulation of t-PA release.

In blood samples from the contralateral arm there was no clear evidence of systematically enhanced fibrinolysis; a single index was the increase in t-PA activity in the sample from the contralateral arm after deflation of the tourniquet cuff. Also, in samples from the lignocaine exposed arm, 30 min after deflation, t-PA activity was still increased slightly when other fibrinolytic indicators had returned to near baseline. The results suggest short-lived enhanced regional fibrinolytic activity in the arm exposed to IVRA. Thus possible endothelial damage induced by a combination of ischaemia and high concentrations of local anaesthetic [20] does not result in any clear prolonged activation and release of fibrinolytic factors, which are known to originate in vascular endothelium [7].

Increased fibrinolytic activity is often associated with platelet dysfunction [21, 22]. Impaired platelet function was demonstrated by increased ADP-ED_{50}% concentration after IVRA with sodium chloride. A similar change was also seen after IVRA with lignocaine (median values after IVRA were almost identical), but because of greater variations between individuals, the change after lignocaine IVRA was not statistically significant.

PCV remained almost unchanged during the study. Although platelet counts showed a minimal decrease in the saline group they remained within the normal range. During IVRA, that is before tourniquet cuff deflation, venous blood in the isolated limb was diluted markedly by the added test solution (in pilot experiments, $n = 4$, median platelet count 83 (range 1–131) $\times 10^9$ litre^{-1}, median PCV 0.10 (range 0.09–0.19)). Our experimental design included releasing the cuff to a value equivalent to mean arterial pressure and thus the sampling veins in the antecubital region became filled with blood of normal PCV and normal platelet count. In this situation haemoconcentration may occur because of venous congestion which causes leakage of fluid into the extravascular space and compensates for the haemodilution effect on platelet count and PCV values. In addition to the potent fibrinolytic response (by ischaemia), dilution of blood during IVRA also contributes to prevention of coagulation in the tourniquet-isolated limb.

β-Thromboglobulin, an indicator of platelet activation and dysfunction [23], was also increased in the lignocaine group ($P < 0.05$) immediately after IVRA in samples from the exposed arm. Values remained above control, in some cases until 30 min, suggesting platelet dysfunction induced by contact of blood with the ischaemia-stressed veins. β-Thromboglobulin concentrations in the contralateral arm 30 min after IVRA were similar to baseline values indicating normal function of the majority of circulating platelets.

Interestingly, the amplitude of the TEG tracing was slightly, but significantly, increased in the lignocaine group samples of the exposed arm. In contrast with platelet dysfunction, this TEG finding suggests a stronger clot strength, that is greater fibrin–platelet interaction [15]. This change, compared with baseline, may be caused by lignocaine because *in vitro*, lignocaine has an inhibitory effect on endothelial cell-dependent antiaggregation of platelets [24].

Clinical concentrations of lignocaine (for example 2.5–4 $\mu g\ ml^{-1}$ in the circulation) are known to prevent the formation of deep vein thrombosis [11]. This beneficial effect is probably caused primarily by prevention of leucocyte adhesion, and prevention of transendothelial migration [25, 26]. In this study, resembling the clinical situation, venous lignocaine concentrations were large enough to cause local toxicity, including endothelial damage [20].

The function of platelets would also be expected to be inhibited because of the toxic actions of lignocaine [27]. Lignocaine concentrations of 10–25 $\mu g\ ml^{-1}$ inhibit platelet aggregation [28], which can be considered beneficial for the prevention of clot formation. In this study, venous concentrations in samples from the non-exposed arm were lower and thus a systemic platelet aggregation-inhibiting effect was not expected.

The neuroendocrine response to surgery has been shown to enhance haemostatic function [29], including decreased fibrinolysis [30] and increased platelet reactivity [31]. By excluding surgery and infusing stress hormones (adrenaline, cortisol and glucagon) to volunteers, Rosenfeld and colleagues [32] showed an increase in fibrinogen concentration and platelet aggregation. The haemodynamic responses to IVRA in volunteers were modest as tourniquet time was relatively short. Clinically, hypertension caused by tourniquet pain usually does not develop until after 1 h [33], but the increase in arterial pressure seems to be unrelated to changes in catecholamine or cortisol concentrations in plasma [34]. Even in those seven volunteers who developed symptoms of central nervous system toxicity, circulatory and haemostatic variables did not indicate stress.

In summary, our results confirmed that fibrinolysis was activated in a limb isolated by a tourniquet. The presence of high i.v. concentrations of lignocaine in the ischaemic limb appeared to enhance further the fibrinolytic response, as indicated by changes in t-PA antigen and PAI. The tourniquet ischaemia-induced platelet dysfunction was not enhanced by lignocaine.

Effect of systemic *N*-methyl-D-aspartate receptor antagonist (ketamine) on primary and secondary hyperalgesia in humans

S. ILKJAER, K. L. PETERSEN, J. BRENNUM, M. WERNBERG AND J. B. DAHL

Summary

Ketamine reduces nociception by binding non-competitively to the *N*-methyl-D-aspartate (NMDA) receptor, activation of which increases spinal hypersensitivity. We studied 19 healthy, unmedicated male volunteers, aged 20–31 yr. Burn injuries were produced on the medial surface of the dominant calf with a 25 × 50 mm rectangular thermode. On 3 separate days, at least 1 week apart, subjects received a bolus of either ketamine 0.15 mg kg^{-1}, ketamine 0.30 mg kg^{-1} or placebo, delivered by a mechanical infusion pump over 15 min. The bolus was followed by continuous infusion of ketamine 0.15 mg kg^{-1} h^{-1}, ketamine 0.30 mg kg^{-1} h^{-1} or placebo, respectively, for 135 min. Ketamine reduced the magnitude of both primary and secondary hyperalgesia, and also pain evoked by prolonged noxious heat stimulation, in a dose-dependent manner. In contrast, ketamine did not alter phasic heat pain perception (perception of transient, painful, thermal stimuli) in undamaged skin. The analgesic effects of ketamine in the burn injury model are in agreement with results from experimental studies, and can be distinguished from those of local anaesthetics and opioids. Side effects caused by continuous infusion of ketamine 0.15 and 0.30 mg kg^{-1} h^{-1} were frequent but clinically acceptable. (*Br. J. Anaesth.* 1996; **76**: 829–834)

Key words

Anaesthetics i.v., ketamine. Pain, mechanism. Pain, postoperative. Burns.

Peripheral tissue damage results in sensitization of dorsal horn neurones. One consequence is altered processing of afferent activity evoked by innocuous in addition to noxious stimuli, which is manifested clinically as allodynia (pain caused by a stimulus that does not normally provoke pain) and hyperalgesia (increased response to a stimulus that is normally painful) [1]. Injury-induced sensitization of dorsal horn neurones has been implicated as an important contributor to both acute and some chronic pain states [2]. In recent years the role of excitatory amino acids in nociception has been highlighted [3]. Glutamate and aspartate participate in the activation of nociceptive dorsal horn neurones as agonists for the *N*-methyl-D-aspartate (NMDA) receptor. There is substantial evidence that this receptor plays a significant role in spinal hypersensitivity, leading to renewed interest in NMDA receptor antagonists such as ketamine [3].

Ketamine has been used as an anaesthetic–analgesic agent for more than 30 yr. Its mechanism of action has been disputed [4] but it is now generally agreed that one pharmacological mechanism of the antinociceptive action is specific binding to the phencyclidine (PCP) site of the NMDA receptor-gated ion channel. This results in non-competitive, use-dependent NMDA receptor antagonism [5]. In experimental studies ketamine reduced NMDA-mediated nociceptive responses in dorsal horn neurones [6]. Clinical studies with ketamine indicated a role for NMDA receptors in acute postoperative [7–10], and also chronic neuropathic pain [11, 12].

A cutaneous heat injury evokes hyperalgesia for mechanical and heat stimuli within the injured area (primary hyperalgesia) and hyperalgesia for mechanical, but not heat, stimuli in an area surrounding the injury (secondary hyperalgesia) [13]. There is convincing evidence that secondary hyperalgesia is a result of altered central processing of afferent input because of sensitization of dorsal horn neurones, whereas primary hyperalgesia seems to be caused by a combination of sensitization of peripheral receptors and central neurones [14–18]. The burn injury model has been used previously to study the effects of various analgesics in human volunteers [19, 20].

The aim of this study was to investigate the effects of systemic ketamine, in clinically relevant analgesic doses, on pain and hyperalgesia after a burn injury in human volunteers.

Subjects and methods

We studied 19 healthy, unmedicated male volunteers, aged 20–31 yr, after obtaining informed consent and approval from the regional Ethics Committee and the Danish National Health Board. The study was performed in a quiet room with the subjects in a semi-supine position. Each subject had been familiarized with the burn injury and measurement procedures on a separate day.

HYPERALGESIA

Burn injuries were produced on the medial surface of the dominant calf (L3–4 dermatome), with a 25 × 50 mm rectangular thermode (Thermotest, Somedic A/B, Sweden), applied to the skin with a standardized pressure (8 kPa). The temperature of the thermode was 47 °C, and the application time was 7 min. This resulted in a first-degree burn injury, that is redness without blistering.

Pain ratings were performed continuously by the volunteer during the burn injury with an electronic visual analogue scale (VAS). The VAS was anchored with the descriptors "no pain" and "worst possible pain". Pain ratings were sampled at a rate of 2 Hz. The interpretation of "pain" was left to the subject, who was instructed to apply the same interpretation throughout the study.

Brief conditioning ("priming" of the central nervous system with afferent input in C-fibres) was produced with the same thermode placed on the centre of the anterior side of the thigh at 45 °C. After 3 min of heating, the border of hyperalgesia to punctuate stimuli was determined along four linear paths arranged radially around the thermal injury (see below). Immediately after these determinations the thermode was removed. These brief conditioning stimuli induced slight or no pain during heating and no spontaneous sensations after termination. The mechanical hyperalgesia induced by these brief conditioning stimuli never lasted more than a few minutes beyond the duration of the conditioning stimuli.

MEASUREMENT OF THERMAL THRESHOLDS

Thermal thresholds were measured with a computerized Thermotest (Somedic AB, Sweden). Heat pain detection threshold (HPDT) was defined as the lowest temperature perceived as painful. The thermode was identical to that used for production of the burn injury.

HPDT was determined from a baseline temperature of 32 °C with a rate of change of 1 °C s^{-1}. By pressing a button, subjects indicated when the pertinent threshold was reached. This value was recorded, and the stimulator returned to baseline. If the cut-off limit (52 °C) was reached before the pertinent threshold, the thermode automatically returned to baseline and a threshold of 52 °C was registered (this was the case in three of 570 threshold determinations). Each threshold was calculated as the average of three measurements with intervals of 10 s between each stimulation. Thermal thresholds were determined at the site of injury and at the corresponding site of the contralateral, unburned calf.

MEASUREMENT OF MECHANICAL HYPERALGESIA

The temperature of the injured site was stabilized at 36 °C, with the above described thermode, from 5 min before and throughout assessments of mechanical hyperalgesia. The border of hyperalgesia to punctuate and stroke stimuli was determined by stimulating along four linear paths arranged radially around the thermal injury in steps of 5 mm at intervals of 1 s, starting well outside the hyperalgesic area where neither stimulus type evoked pain. The stimulations continued towards the injury until subjects reported a clear change in sensation ("burning", "tenderness", "more intense pricking"). The areas of hyperalgesia were calculated using a vector algorithm [19]. Punctuate stimulation was performed with the von Frey technique using a nylon filament with a diameter of 1 mm and a bending force of 1.15 N. Stroke stimulation was performed by lightly stroking the skin with a gauze swab.

Table 1 Experimental design

Time	Actions/measurements
Baseline	Area of secondary hyperalgesia to pinprick during brief conditioning, thigh Heat pain detection threshold (HPDT), right and left calf
0–15 min	I.v. bolus of ketamine/placebo, followed by continuous i.v. infusion of ketamine/placebo
15–20 min	Side effects Area of secondary hyperalgesia to pinprick during brief conditioning, thigh HPDT, right and left calf
20–27 min	Burn injury, right calf; measurement of pain with electronic VAS during burn
60–80 min	Side effects Area of secondary hyperalgesia to pinprick during brief conditioning, thigh HPDT, right (burned) and left calf Secondary hyperalgesia to pinprick and stroke around burn injury, right calf
130–150 min	Side effects Area of secondary hyperalgesia to pinprick during brief conditioning, thigh HPDT, right (burned) and left calf Area of secondary hyperalgesia to pinprick and stroke around burn injury, right calf
150 min	Cessation of i.v. infusion with ketamine/placebo
200–220 min	Side effects Area of secondary hyperalgesia to pinprick during brief conditioning, thigh HPDT, right (burned) and left calf Area of hyperalgesia to pinprick and stroke around burn injury, right calf

ASSESSMENT OF SIDE EFFECTS

Drowsiness was assessed on an 11-point analogue scale (0 = completely awake; 10 = almost asleep). Discomfort was assessed on an 11-point analogue scale (0 = no discomfort; 10 = maximum discomfort). Hallucinations (yes/no) were registered after bolus injection. Finally, subjects were asked if they experienced other sensations (table 1).

EXPERIMENTAL PROCEDURE

On 3 separate days, at least 1 week apart, subjects received a bolus of either ketamine 0.15 mg kg^{-1}, ketamine 0.30 mg kg^{-1} or placebo, delivered by a mechanical infusion pump over 15 min. The bolus dose was followed by a continuous infusion of ketamine 0.15 mg kg^{-1} h^{-1}, ketamine 0.30 mg kg^{-1} h^{-1} or placebo, respectively, for 135 min. The time to administer the bolus injection and doses of ketamine were chosen on the basis of a small pilot study, performed in order to determine doses with acceptable side effects. The study was double-blind, and the order of treatments was randomized. The time course of the various assessments are shown in table 1.

STATISTICAL ANALYSIS

Data are presented as median (range). Variables were evaluated with non-parametric two-way analysis of variance for repeated measurements, Friedmann's analysis of variance and Wilcoxon's test for paired data, where appropriate. $P \leqslant 0.05$ was considered statistically significant.

Results

CONTROL (PLACEBO) DAY

Pain during burn injury increased rapidly during the first 15–30 s, reached a plateau and then remained relatively stable during the remaining 6 min (fig. 1). After injury, no spontaneous pain or other sensations were experienced from the site of injury.

HPDT inside the burn injury decreased from a baseline value of 45.9 (44.6–47.6) °C to 41.6 (39.0–44.8) °C, 100 min after the injury (Friedmann's ANOVA, $P < 0.00001$), and remained decreased throughout the study (fig. 2).

HPDT on the contralateral calf did not change during the study (fig. 2). The borders of secondary hyperalgesia for punctuate and stroke stimuli (fig. 3) surrounding the burn injury on the calf and the area of secondary hyperalgesia for punctuate stimuli evoked by brief conditioning on the thigh (fig. 4) were detected easily in all subjects.

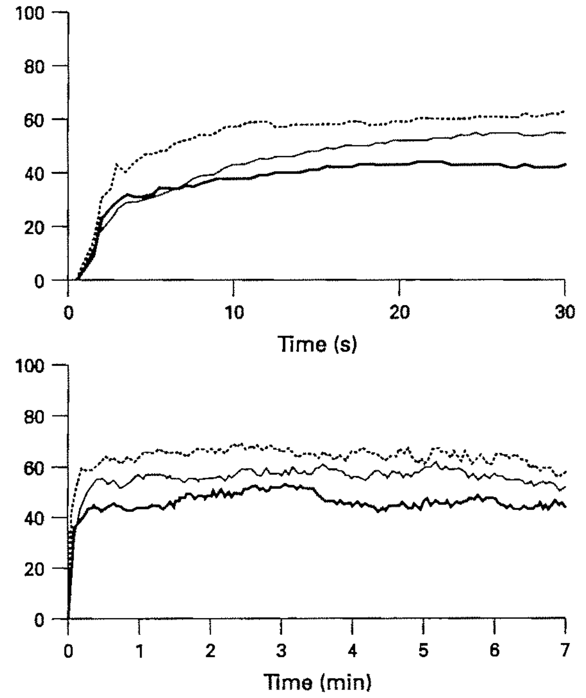

Figure 1 Pain (VAS) during burn injury during infusion of placebo (----), ketamine 0.15 mg kg^{-1} (——) or ketamine 0.30 mg kg^{-1} (——) (medians). The initial rapid increase in pain observed during placebo treatment (top) was diminished, and the plateau level was reduced (bottom) (ketamine 0.15 mg kg *vs* placebo: $P < 0.07$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P < 0.007$, Wilcoxon rank test).

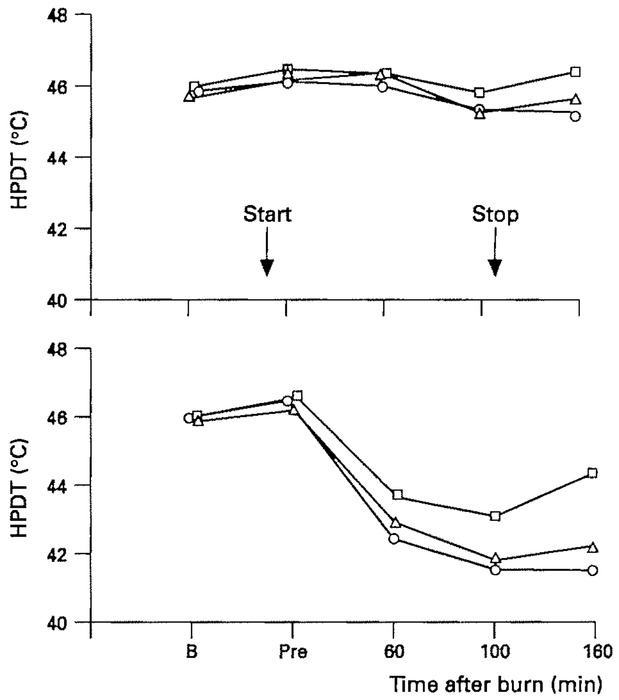

Figure 2 Heat pain detection threshold (HPDT) on the unburned (top) and burned (bottom) calf (medians) before (baseline (B) and before the burn injury (Pre)) during and after infusion of placebo (○), ketamine 0.15 mg kg^{-1} (△) or ketamine 0.30 mg kg^{-1} (□). Start, stop = Beginning and end of infusion of ketamine or placebo. Ketamine 0.15 mg kg^{-1} *vs* placebo: $P > 0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P > 0.05$, non-parametric two-way analysis for unburned calf; ketamine 0.15 mg kg^{-1} *vs* placebo: $P > 0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo; $P < 0.05$, non-parametric two-way analysis for burned calf. Filled symbols = significant difference from baseline (Friedman's ANOVA).

EFFECTS OF KETAMINE

Pain during burn injury was reduced in a dose-dependent manner by ketamine (fig. 1). The initial rapid increase in pain observed during placebo treatment was diminished, and the plateau level was reduced (low-dose *vs* placebo, $P < 0.07$; high-dose *vs* placebo, $P < 0.007$; Wilcoxon rank test).

At the site of injury there was no difference in the decrease in HPDT between placebo and low-dose ketamine treatments ($P > 0.7$; two-way ANOVA), whereas HPDT was reduced less during high-dose ketamine compared with placebo after injury ($P < 0.03$; two-way ANOVA). Hence, high-dose ketamine diminished primary hyperalgesia (fig. 2).

At the contralateral uninjured calf there was no difference in HPDT either between low-dose ketamine and placebo or between high-dose ketamine and placebo ($P = 0.43$ and $P = 0.07$, respectively; two-way ANOVA) (fig. 2).

The areas of secondary hyperalgesia for punctuate and stroke stimuli were both reduced by high-dose ketamine compared with placebo ($P < 0.004$ and

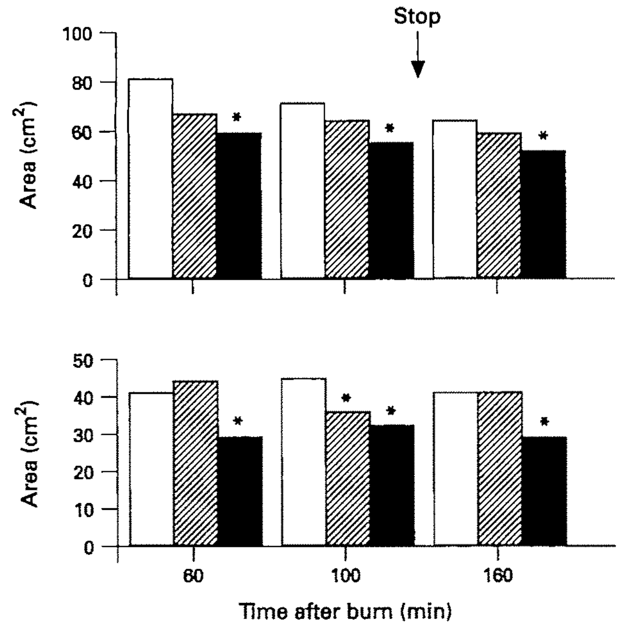

Figure 3 Top: Area of secondary hyperalgesia to punctuate stimuli around the burn injury during and after infusion of placebo (□), ketamine 0.15 mg kg^{-1} (▨) and ketamine 0.30 mg kg^{-1} (■) (medians). Ketamine 0.15 mg kg^{-1} *vs* placebo: $P > 0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P < 0.05$, non-parametric two-way analysis. $*P < 0.05$ compared with placebo. Bottom: Area of secondary hyperalgesia to stroke around the burn injury during and after infusion of placebo (□), ketamine 0.15 mg kg^{-1} (▨) and ketamine 0.30 mg kg^{-1} (■) (medians). Ketamine 0.15 mg kg^{-1} *vs* placebo: $P < 0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P < 0.05$, non-parametric two-way analysis. $*P < 0.05$ compared with placebo. Stop = End of infusion of ketamine or placebo.

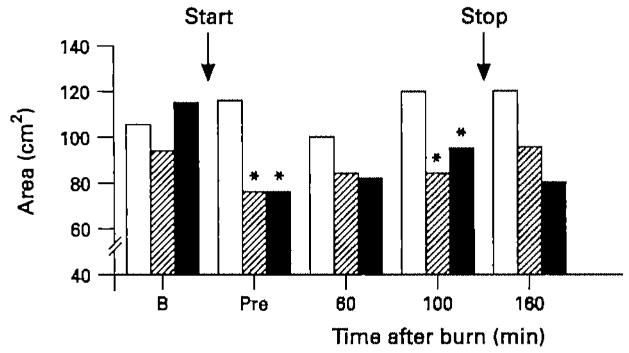

Figure 4 Area of secondary hyperalgesia to punctuate stimuli evoked by brief conditioning on the thigh before (baseline (B) and before the burn injury (Pre)), during and after infusion of placebo (□), ketamine 0.15 mg kg^{-1} (▨) and ketamine 0.30 mg kg^{-1} (■) (medians). Ketamine 0.15 mg kg^{-1} *vs* placebo: $P < 0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P < 0.05$, non-parametric two-way analysis. $*P < 0.05$, compared with placebo. Start, stop = Beginning and end of infusion of ketamine or placebo.

$P < 0.002$, respectively; two-way ANOVA) (fig. 3). Low-dose ketamine only reduced the area of secondary hyperalgesia for stroke ($P = 0.03$; two-way ANOVA) (fig. 3).

Both low- and high-dose ketamine reduced the area of secondary hyperalgesia for punctuate stimuli evoked by brief conditioning on the thigh ($P < 0.05$ and $P < 0.03$, respectively; two-way ANOVA) (fig. 4).

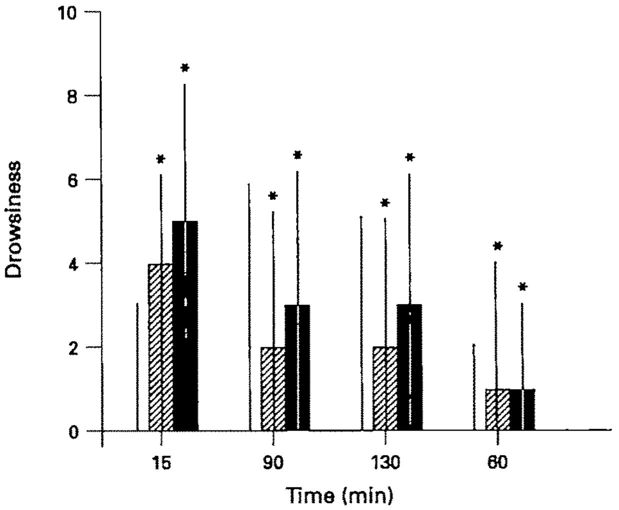

Figure 5 Drowsiness during and after infusion of placebo (□), ketamine 0.15 mg kg^{-1} (▨) and ketamine 0.30 mg kg^{-1} (■) (median, range) (15 = 15 min after ketamine bolus, 90 = 90 min after start of ketamine infusion, 130 = 130 min after start of ketamine infusion, 60 = 60 min after cessation of ketamine infusion). Ketamine 0.15 mg kg^{-1} *vs* placebo: $P < 0.05$; ketamine 0.30 mg kg^{-1} *vs* placebo: $P < 0.05$, non-parametric two-way analysis. $*P < 0.05$ compared with placebo.

SIDE EFFECTS

Ketamine induced drowsiness in all volunteers in a dose-dependent manner (fig. 5). Varying degrees of drowsiness (range 1–6 on the analogue scale), however, were also experienced by three volunteers during placebo treatment. Two volunteers experienced some degree of discomfort (range 1–6 on the analogue scale) after bolus injection of ketamine 0.15 mg kg^{-1} compared with five subjects after bolus injection of ketamine 0.30 mg kg^{-1} (range 2–9 on the analogue scale). No subject reported discomfort during continuous low-dose ketamine. Three subjects reported discomfort during continuous high-dose ketamine, although only one subject still experienced this discomfort towards the end of the infusion period. None of the volunteers experienced hallucinations. Most volunteers experienced other sensations such as "feeling drunk" or "dizzy" at one or several assessments during administration of ketamine. No volunteer wished to leave or was excluded from the study because of side effects. All volunteers were able to collaborate fully during the various assessments without problems.

Discussion

Experimental studies have demonstrated that dorsal horn neurones may display an altered response to both nociceptive and non-nociceptive afferent input after peripheral tissue damage or intense electrical C-fibre stimulation. These alterations include facilitation of the flexor motorneuronal responses, expansion of receptive fields and a decrease in the activation threshold of dorsal horn neurones [1,2]. The mechanisms of these alterations include induction of wind-up, whereby responses of dorsal horn neurones increase during repetitive constant intensity C-fibre stimuli, that is increased duration and magnitude of the cell responses [21]. There is substantial evidence that the NMDA receptor plays a significant role in wind-up and spinal hypersensitivity [1–3].

The mechanism of action of NMDA receptor antagonists differs from that of "classic" analgesics such as opioids. Opioids most probably reduce C-fibre input to the dorsal horn nociceptive neurones and consequently delay the onset and reduce the magnitude of wind-up and spinal hypersensitivity [22]. In contrast, the NMDA receptor antagonist ketamine has no effect on the initial input, but reduces wind-up [23]. Two recent studies in human volunteers confirmed these experimental observations [24, 25]. In one study, the NMDA receptor antagonist dextromethorphan reduced temporal summation of second pain, a psychophysical correlate of wind-up, whereas neither first nor second pain evoked by a single stimulus was affected by the drug [24]. In the other study, high-dose ketamine (bolus 0.5 mg kg^{-1}, followed by a 20-min infusion of 0.54 mg kg^{-1} h^{-1}) reduced central temporal summation to repeated nociceptive electrical stimuli, whereas reflex and pain ratings to a single stimulus were unaltered [25]. The high dose of ketamine used in the latter study [25], however, is clinically unacceptable because of significant side effects in the majority of patients [25].

Based on recent experimental and clinical studies, ketamine would be expected to have no or only minor effects on perception of non-noxious and phasic painful stimuli, such as thermal thresholds, in normal skin of human volunteers. Rather, ketamine is expected to exert its analgesic effects under conditions where tissue damage (e.g. a burn injury) or repetitive C-fibre stimulation has induced hyperexcitability of dorsal horn neurones. This study seems to confirm this assumption. Ketamine in clinically relevant, analgesic doses had no effect on thermal thresholds in undamaged skin, but reduced heat hyperalgesia at the site of injury. In contrast, HPDT in both normal and injured skin was increased after administration of extradural morphine 4 mg [20]. The differential effects of ketamine and morphine on thermal thresholds in normal and hyperalgesic skin are in agreement with the different mechanisms of action (see above).

Primary hyperalgesia is most probably caused by a combination of sensitization of peripheral receptors and central neurones, although the relative contribution of these components is not well established [13]. As ketamine increased HPDT in the primary hyperalgesic area, and as a peripheral effect of ketamine is not anticipated, the results of this study indicate that central sensitization contributes significantly to primary hyperalgesia. We observed further that pain during a prolonged noxious heat stimulus (which resulted in induction of secondary hyperalgesia and hence wind-up and sensitization of dorsal horn neurones), was reduced by ketamine in a dose-dependent manner. In accordance, Park and colleagues [26] reported reduction of ongoing pain evoked by intradermal capsaicin, and Arendt-Nielsen and colleagues [25] reduction of pain evoked by prolonged mechanical stimulation, by ketamine.

We observed that ketamine, in a dose-dependent manner, reduced secondary hyperalgesia for punctuate and stroke stimuli surrounding the burn injury, and secondary hyperalgesia for punctuate stimuli during brief thermal conditioning stimuli. In agreement with a previous study using higher doses of ketamine (bolus 5 mg, followed by infusion of 40 mg h^{-1}) [26], the reduction of the area of secondary hyperalgesia was only partial: 7–28% with low-dose ketamine and 25–28% with high-dose ketamine. Consequently, ketamine in clinically relevant doses should not by itself be expected to completely abolish pain or central sensitization [26, 27].

In experimental studies, NMDA receptor antagonists, including ketamine and dextromethorphan, have been shown to reduce tachyphylaxis and improve the analgesic effect of other analgesics such as morphine and local anaesthetics [28–32]. Data from clinical studies of postoperative pain are not uniform [7, 8]. In one study, the addition of ketamine 0.5 mg kg^{-1} to caudal bupivacaine provided better analgesia than bupivacaine alone in children undergoing inguinal herniotomy [7]. In another study, combined infusions of morphine and ketamine did not improve postoperative analgesia compared with morphine alone in patients undergoing elective upper abdominal surgery [8].

Side effects of the ketamine dose regimens used in this study were frequent but clinically acceptable in most volunteers. In general, side effects were most pronounced immediately after bolus injections, and substantially declined or disappeared during continuous infusions of both ketamine 0.15 and 0.30 mg kg^{-1} h^{-1}. Although ketamine in both doses produced drowsiness, HPDT in healthy skin was unaffected by ketamine. Consequently, we do not believe that drowsiness, or other side effects, introduced any significant bias.

In summary, ketamine reduced the magnitude of both primary and secondary hyperalgesia, and pain evoked by prolonged noxious heat stimulation. In contrast, ketamine did not alter phasic heat pain perception in undamaged skin. The analgesic effects of ketamine in the burn injury model can be distinguished from those of local anaesthetics and opioids [19, 20]. Side effects caused by continuous infusion of ketamine 0.15 mg kg^{-1} h^{-1} and 0.30 mg kg^{-1} h^{-1} were frequent but clinically acceptable in most human volunteers. These data provide a rationale for a systematic evaluation of the analgesic effect of low-dose ketamine in clinical pain states, such as postoperative pain.

Combination of ondansetron and dexamethasone in the prophylaxis of postoperative nausea and vomiting

L. LÓPEZ-OLAONDO, F. CARRASCOSA, F. J. PUEYO, P. MONEDERO, N. BUSTO AND A. SÁEZ

Summary

We studied 100 ASA I–II females undergoing general anaesthesia for major gynaecological surgery, in a prospective, double-blind, placebo-controlled, randomized study. Patients received one of four regimens for the prevention of postoperative nausea and vomiting (PONV): ondansetron 4 mg ($n = 25$), dexamethasone 8 mg ($n = 25$), ondansetron with dexamethasone (4 mg and 8 mg, respectively, $n = 25$) or placebo (saline, $n = 25$) There were no differences in background factors or factors related to operation and anaesthesia, morphine consumption, pain or side effects between groups. The incidence of nausea and emetic episodes in the ondansetron with dexamethasone group was lower than in the placebo ($P < 0.01$), ondansetron ($P < 0.05$) and dexamethasone ($P = 0.057$) groups. There were no differences between ondansetron and dexamethasone, and both were more effective than placebo ($P < 0.05$ and $P < 0.01$, respectively). Dexamethasone appeared to be preferable in preventing nausea than emetic episodes. Fewer patients in the ondansetron with dexamethasone group needed antimetic rescue ($P < 0.01$ *vs* placebo and $P < 0.05$ *vs* ondansetron). We conclude that prophylactic administration of combined ondansetron and dexamethasone is effective in preventing PONV. (*Br. J. Anaesth.* 1996; **76**: 835–840).

Key words

Surgery, gynaecological. Vomiting, nausea. Vomiting, antimetics. Pharmacology, ondansetron. Pharmacology, dexamethasone.

Recent reviews have reported that the incidence of postoperative nausea and vomiting (PONV) is 30% [1, 2], with little improvement in recent years, but it may be higher because of the influence of preoperative patient characteristics, factors related to operation and anaesthesia, and the intensity of pain and its management in the postoperative period [3, 4].

The introduction into clinical practice of the 5-HT_3 receptor antagonist, ondansetron, has provided effective antiemesis in surgical patients without significant drug-related side effects [5, 6]. Dexamethasone has been used as an antiemetic for more than 10 yr in patients receiving chemotherapy, with limited side effects [7–11]. The mechanism of action of dexamethasone as an antiemetic is not known.

None of the available antiemetics is entirely effective in all patients, perhaps because there is no single stimulus for PONV. The combination of drugs currently used in the treatment of nausea and vomiting in patients receiving chemotherapy [8], could be a solution to control situations with severe, frequent PONV. Recently, the combination of ondansetron and dexamethasone has been shown to be a highly effective prophylactic measure for patients receiving high-dose cisplatin chemotherapy [8].

In this prospective, double-blind, randomized study, we assessed the safety and efficacy of a single i.v. dose of ondansetron 4 mg, dexamethasone 8 mg, ondansetron with dexamethasone (4 mg and 8 mg, respectively) or placebo (2 ml of saline) in females undergoing elective major gynaecological surgery.

Patients and methods

After obtaining local Ethics Committee approval and written informed consent, we studied 100 ASA I – II women, aged 18–65 yr, weighing 45–90 kg, undergoing major elective gynaecological surgery. Patients who had received opioids, NSAID, steroids or antiemetic agents during the previous month or who had hypersensitivity to either ondansetron or steroids were excluded.

Patients were allocated randomly to one of four groups: P (placebo), O (ondansetron), D (dexamethasone) and O+D (ondansetron with dexamethasone). The study was prospective, conducted in a double-blind manner, with a stratified randomization to ensure an equal number of patients of the same age and weight undergoing the same type of surgery in each group (Table 1).

The night before surgery we recorded the following variables: age, weight and height, previous general anaesthesia and abdominal surgery, history

of motion sickness or headache, history of PONV after previous surgery, phase of menstrual cycle and grade of anxiety. All patients were taught to use the patient-controlled analgesia (PCA) pump for self-administration of morphine and were told to call the nurse as soon as they felt nausea or had any emetic episode in the postoperative period.

All patients had their last oral intake at least 8 h before the start of anaesthesia and were premedicated with bromazepam 0.1 mg kg^{-1} administered orally the night before surgery and atropine 0.01 mg kg^{-1} i.m., 30 min before induction of anaesthesia.

Each patient received two syringes with 2 ml of solution before induction of anaesthesia. Patients in group P received 0.9% saline, those in group O, ondansetron 4 mg and 0.9% saline, those in group D, dexamethasone 8 mg and 0.9% saline, and those in group O and D, ondansetron 4 mg and dexamethasone 8 mg.

Anaesthesia was induced with thiopentone 5 mg kg^{-1}, atracurium 0.5 mg kg^{-1} and fentanyl 5μg kg^{-1}. The trachea was intubated 3 min after administration of atracurium. A nasogastric tube and a urinary catheter were placed in all patients. Anaesthesia was maintained with 50% nitrous oxide in oxygen supplemented with isoflurane (0.5–1% expired concentration). Ventilation was adjusted to maintain end-tidal carbon dioxide pressure at 4.7 kPa. Neuromuscular blocking agents and fentanyl were used as required. All patients received morphine 0.1 mg kg^{-1} when it was predicted that surgery would end in 30 min. It was not necessary to antagonize residual neuromuscular block in any patient. No other sedative, analgesic or antiemetic drug was administered. The nasogastric tube and urinary catheter were left in place.

The variables recorded during the operative period included: type of incision (Pfannenstiel or midline laparotomy), type of surgery (hysterectomy, adnexectomy, reassessment laparotomy (second look) for ovarian cancer or myomectomy), total amount of atracurium and fentanyl administered, and duration of surgery and anaesthesia.

Postoperative analgesia was provided with i.v. ketorolac 30 mg/8 h and PCA (Pain Management Provider TM, Abbott, North Chicago, IL, USA) morphine 1 mg ml^{-1} (demand dose = 1 mg; lockout interval = 10 min; and maximum dose in 4 h = 0.25 mg kg^{-1}).

In the recovery room (2 h) and in the ward (12, 24 and 48 h after recovery from anaesthesia) we studied the following variables: in (1) incidence of PONV—we asked patients if they felt nauseated or sick in each period, with only two possible answers, "yes" if they did for at least 10 min, or "no". Retching and vomiting were grouped together under the common term "emetic episode" and were assessed as present or absent. The primary end-point was a complete response, as defined by no nausea or emetic episodes during the 48-h postoperative period. (2) Number of patients who needed rescue antiemetic treatment—if patients experienced nausea for 30 min or more than one emetic episode in 15 min, rescue antiemetic treatment was available with metoclopramide 10 mg/8 h. (3) Pain intensity scores, with and without active movement, were obtained with the VAS test. They were classified into three categories to allow easier statistical analysis. The pain categories were: severe if VAS score was greater than 7, moderate if VAS score was 3–7 and light if VAS score was less than 3. (4) Total amount of morphine consumed. (5) Sedation five-point scale: 4 = completely awake, open eyes; 3 = drowsy, closed eyes; 2 = asleep, responds to oral call; 1 = asleep, responds to touch or pain; 0 = does not respond). (6) Other side effects.

All observations were made by the same previously trained nurses as soon as the symptoms appeared. Nausea, retching and vomiting were also assessed by the same anaesthetist by questioning the patient 2, 12, 24 and 48 h after recovery from anaesthesia. Both the nurses and the anaesthetist were unaware of which antiemetic the patient had received.

We also recorded the following variables: postoperative comfort, postoperative analgesia and night rest (rated as bad, fair, good and very good), postoperative comfort compared with previous experiences (rated as worse, similar, better and not comparable), time before first postoperative oral intake, time before standing up and moment at which nasogastric tube and urinary catheter were removed (rated as less than 12 h, at 12–24 h, at 24–36 h, at 36–48 h and more than 48 h).

We used the chi-square test and Fisher's exact test for non-parametric analysis. Parametric data were analysed using analysis of variance (Fisher's PLSD correction was also applied), Kruskal–Wallis and Mann–Whitney tests. $P < 0.05$ was considered significant.

Results

The incidence of background factors and factors related to operation and anaesthesia, which may modify PONV, did not differ between groups (table 2).

A complete response (no nausea and no emetic episodes during the 48-h postoperative period) occurred in 84% of patients in the ondansetron with dexamethasone group and in only 20% of patients in the placebo group ($P < 0.01$). In the ondansetron

group, it occurred in 52% of patients and in 60% of patients in the dexamethasone group (fig. 1).

The incidence of nausea and emetic episodes in patients in group O+D was lower than in those in groups P, O and D during the whole study. There were significant differences between groups O+D and P at all times ($P < 0.01$), and between group O+D and groups O and D at some times only (table 3). There were no differences in the frequencies of nausea and emetic episodes between patients who received ondansetron or dexamethasone.

Only two patients (8%) in group O+D required antiemetic rescue ($P < 0.01$ *vs* group P and $P <$ 0.05 *vs* group O), compared with seven patients (28%) in group D ($P < 0.01$ *vs* group P), nine patients (36%) in group O ($P < 0.05$ *vs* group P) and 17 patients (68%) in group P.

There were no significant differences in pain intensity between groups at any time. At the end of the study only two patients at rest and 21 with movement had a VAS score greater than 3 (table 4).

Opioid requirements did not differ between groups, although in groups D and O+D, requirements were greater from 12 h after the end of operation. Mean total consumption of morphine at 48 h from the end of surgery was 32 (SD 14.8), (range 5–63) mg in group P, 32 (18.7), (4–68) mg in group O, 39 (22.4), (8–79) mg in group D and 38 (24.6), (4–94) mg in group O+D.

There were no significant differences in sedation. There was no patient with category 0, 1 or 2 at any

time during the study. At 12 h after the end of surgery, there were only seven patients with category 3, and all patients were in category 4 by 24 h (table 5).

The percentage of adverse events was similar between groups (table 4). The most commonly reported adverse event was headache. Perineal itching was reported during administration of a solution in groups that received dexamethasone, but disappeared spontaneously in 30 s. Itching was the only adverse effect associated with a high consumption of morphine.

No patient scored postoperative comfort as bad. Comfort was found to be greater in group O+D than group P at 24 h ($P < 0.05$) (Fig. 2). There were no differences between groups at 48 h and only 11 % of patients defined postoperative comfort as fair, most because of PONV.

Night rest was similar between groups. No patient considered night rest as bad. Four patients in group P, one patient in group O, one in group D and two in group O+D defined the first night's rest as fair mainly because of PONV. Fourteen patients (five patients in group P, three patients in group O, two in group D and four in group O+D) described rest as fair on their second night mainly because of lack of their usual hypnotics at home (10 patients) and PONV.

Postoperative comfort was similar to previous surgical experiences in 8 % of patients, not comparable in 20 % and better in 72 %. There were no significant differences between groups.

Discussion

We found that during the 48 h period after recovery from anaesthesia, ondansetron 4 mg and dexamethasone 8 mg were more effective than placebo in preventing nausea, although there were no significant differences in vomiting, perhaps because the groups were small. Moreover, there were no significant differences between dexamethasone and ondansetron and both drugs offered adequate control of PONV. But the major finding was that in the 48-h period, the combination of ondansetron and dexamethasone was more effective than placebo and ondansetron alone for nausea and vomiting, and better than dexamethasone for vomiting but not for nausea. No

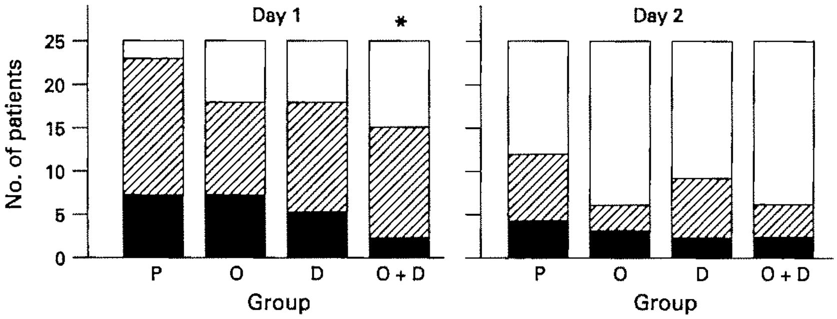

Figure 2 Grade of comfort after surgery. Number of patients who felt bad (none), fair (■), good (▨) or very good (□) in each treatment group. *$P < 0.05$ *vs* group P.

patient had vomiting in the recovery room (first 2 h) in the ondansetron with dexamethasone group, and only one patient during the 48-h postoperative period. Moreover, there was only one patient with nausea in the recovery room and only four had nausea during the 48-h postoperative period.

We chose patients at high risk of PONV: women aged 18–65 yr, in whom the incidence of PONV is three times higher [1, 2], undergoing major gynaecological surgery, a type of surgery associated with the highest incidence of PONV [2–4, 12]. We analysed factors that have been shown to affect the incidence of PONV such as patient weight [1, 2], history of motion sickness [3] or PONV after previous anaesthesia [12], grade of anxiety [1, 2] and phase of menstrual cycle [13]. In our study all of these factors were well balanced between groups. All patients underwent the same preoperative fasting and premedication, the same standardized balanced anaesthesia, without antagonism of neuromuscular block, and the same postoperative care, including the techniques and drugs used for postoperative analgesia. Type of incision, total amount of atracurium and fentanyl administered and duration of operation (none for more than 4 h) were similar in all groups. All of these factors also increase the incidence of PONV [1–4]. Postoperative factors involved in PONV [1–4], such as intensity of postoperative pain, morphine consumption, time to oral intake, time to stand up and time to remove nasogastric tube, were matched equally between groups.

Ondansetron is a selective 5-HT_3 receptor antagonist, effective in preventing PONV [6, 12, 13, 14–17]. The effectiveness of i.v. ondansetron as a prophylactic postoperative antiemetic was evaluated by McKenzie and colleagues in a dose ranging study [15], and it was demonstrated that a single 4-mg i.v. dose appeared to be the lowest acceptable dose to prevent PONV. Since then, most authors have agreed that this i.v. dose before induction is effective antiemetic prophylaxis [6, 18].

Dexamethasone was first reported to be an effective antiemetic agent in patients undergoing cancer chemotherapy in 1981 [7]. Since then randomized, placebo-controlled studies have shown that dexamethasone and other steroids are significantly better than other agents (metoclopramide, prochlorperazine, droperidol, domperidone) in preventing nausea and vomiting associated with chemotherapy. The mechanism of dexamethasone-induced antiemetic activity is not fully understood, but may involve central inhibition of prostaglandin synthesis [19]. Another theory involves a decrease in 5-HT turnover in the central nervous system [20] or changes in the permeability of the blood CSF barrier to serum proteins [21]. However, there is no experimental proof to support these hypotheses. The plasma elimination half-life of dexamethasone is approximately 4–4.5 h, similar to that of other antiemetics usually administered in a single dose [22] (for instance, ondansetron has a plasma half-life of approximately 3 h) [23]. A dose ranging study by Drapkin and Sokl [9] evaluated the effectiveness of i.v. dexamethasone in patients undergoing chemotherapy. An 8-mg i.v. dose appeared to be as effective as 32 mg in preventing nausea and vomiting in cancer chemotherapy. These are reasons why we chose dexamethasone as an antiemetic in a single 8-mg dose. A retrospective study by Mataruski and colleagues [24] showed that 34 patients who received intraoperative steroids were less likely to experience PONV than 27 who did not. Recently, Yoshitaka, Hiroyoshi and Hidenori [25] found no differences between placebo, granisetron and dexamethasone in women undergoing general anaesthesia for major gynaecological surgery. The lack of differences between the groups could be because of the low incidence of PONV and the small number of patients in the study.

McKenzie and colleagues [26] studied ondansetron and ondansetron with dexamethasone in women undergoing major gynaecological surgery and the results showed that the combination was more effective than ondansetron alone, as our results confirmed. More recently, Yoshitaka, Hiroyoshi and Hidenori [25] found differences between granisetron with dexamethasone and placebo, granisetron and dexamethasone alone, in women undergoing general anaesthesia for major gynaecological surgery.

All groups had a similar percentage of patients reporting adverse events. Perineal itching was present only in groups who received dexamethasone, and it appears to be related to the vehicle [11]. Chronic treatment with large doses of steroids has been implicated in postoperative complications such as infection and delayed or poor wound healing [27]. Many complications are dose related, and with low dose or discontinuation of steroids, their frequency decreases rapidly [28]. Furthermore, we did not find that giving a single large dose of steroid interfered with wound healing after surgery or produced other major side effects.

There were no significant differences between groups in sedation. The small number of patients with grade 3 sedation at 12 h had a higher consumption of morphine.

Pain and PONV are the most common, unpleasant postoperative events. As pain was similar in all groups, the lower incidence of PONV in our study was the main reason for the better results in group O+D compared with group P at 24 h. Both ondansetron and dexamethasone provided adequate control of PONV. If our results are confirmed in larger studies, dexamethasone will be more advantageous than ondansetron in terms of cost and resource allocation. The combination of ondansetron with dexamethasone was the most effective in reducing PONV. This combination could be useful in day-case surgical procedures because of the absence of side effects and sedation.

LABORATORY INVESTIGATIONS

Differential effects of desflurane and halothane on peripheral airway smooth muscle

A. J. MAZZEO, E. Y. CHENG, Z. J. BOSNJAK, R. L. COON AND J. P. KAMPINE

Summary

Volatile anaesthetics have been shown to have direct relaxant effects on airway smooth muscle. We have examined the effects of 0.9, 1.9, and 2.8 dog MAC of desflurane and halothane on isolated proximal and distal canine airways precontracted with acetylcholine. The proximal and distal airway smooth muscle relaxed with increasing concentration of each anaesthetic in a dose-related manner. Desflurane had a greater relaxant effect than halothane on the proximal airway only at 2.8 MAC. Desflurane relaxed the distal airway to a greater extent than halothane at 1.9 and 2.8 MAC. The distal airway smooth muscle was more sensitive to volatile anaesthetics than the proximal airway smooth muscle with either halothane or desflurane at all concentrations tested. This effect may be a result of differences in cartilage content, myosin content, epithelium-dependent effects, receptor density, myofilament sensitivity to Ca^{2+}, sarcoplasmic reticulum Ca^{2+} control, or ionic fluxes in the proximal airway compared with the distal airway. The increased sensitivity of airway smooth muscle to desflurane compared with halothane is not known but may be related to possible differences in the effects of Ca^{2+} homeostasis. (*Br. J. Anaesth.* 1996; **76**: 841–846)

Key words

Anaesthetics volatile, halothane. Anaesthetics volatile, desflurane. Airway, muscles. Receptors, cholinergic. Dog.

The bronchodilator effects of desflurane on intraparenchymal airway have not yet been determined. Adverse effects such as coughing and laryngospasm on induction have been associated with desflurane [1]. Although these effects appear to occur in the upper airway, it is not known if they are associated with a detrimental bronchospastic effect distally.

In this study we examined the direct effects of desflurane and halothane on the third- and sixth-generation airway. These segments of the peripheral airway are likely to be main sites of airway resistance [2] and airflow regulation [3, 4]. The clinical importance of direct effects of volatile anaesthetics on peripheral airway smooth muscle is not known. However, the direct effects on peripheral airway smooth muscle may be relevant clinically because of the diminishing innervation of airway smooth muscle when proceeding along the bronchial tree distally [5]. In addition, the airway at this level of the bronchial tree is more sensitive and more reactive [3, 6, 7], and therefore the distal airway requires less circulating agonist for a given response than proximally located airway. These factors may allow better control at the peripheral site of airflow regulation through a hormonal component rather than a neural component. This site of airflow regulation may therefore be affected predominately by the direct effects of anaesthetics, thereby altering airflow distribution. In this study we have determined the effects of halothane and desflurane on the portion of the airway believed to have a significant role in airflow regulation.

Materials and methods

All experimental procedures were approved by the Animal Care Committee of the Medical College of Wisconsin.

TISSUE PREPARATION

The right upper lobe was obtained from 15 mongrel dogs of both sexes (10–15 kg) after halothane anaesthesia and exsanguination. The right upper lobe, chosen to maintain consistency and ease of dissection [8], was placed in ice-cooled Krebs–Ringer bicarbonated solution aerated with 95% oxygen and 5% carbon dioxide. The first intraparenchymal bronchial segment is the third-generation airway and in this study is considered the proximal airway. This airway was dissected carefully and cleaned of lung parenchyma and pulmonary vessels under a binocular microscope. The proximal airway was dissected down to its first bifurcation. The middle third of this proximal airway was cut

Correspondence to A.J.M.

sequentially into 2-mm segments (od 4–6 mm) that excluded side branches. This section of the proximal airway was chosen because it gave the most uniform outer diameter. These segments were then mounted on two tungsten wires (od 0.1 mm), each shaped into an isosceles triangle with the base passing through the lumen.

The distal airway was also selected from the same animal. This airway, obtained after the fifth or sixth bifurcation from the trachea, was dissected carefully and cleaned of lung parenchyma and pulmonary vessels. The airway after the fifth or sixth bifurcation, corresponding to the fifth and sixth airway generation, respectively, was selected based on which airway generation had an outer diameter closest to 1.0 mm. The distal airway was also cut sequentially into 2-mm segments (od 0.7–1.8 mm) that excluded side branches. Based on outer diameter [9] and histology on randomly selected 1-mm segments, these airways were considered bronchioli. These distal segments were then mounted on tungsten wires as described for the proximal airway. During placement of the wires, special care was taken not to damage the luminal surface.

The mounted bronchi and bronchioli were suspended in jacketed baths, temperature controlled at 37 °C. The apex of one triangle was fixed at a point located at the bottom of the bath and the apex of the other triangle was attached to a force transducer (Grass Model FT103, Grass Instruments, Quincy, MA, USA) for measurement of isometric force. All responses were measured by the force transducer and are reported as isometric tension in grams. These rings were then allowed to equilibrate at 37 °C for 1 h in baths containing a 15-ml solution of Krebs–Ringer bicarbonate of the following composition (mmol litre^{-1}): glucose 11.1; NaCl 118.3; KCl 4.7; $CaCl_2$ 2.5; $MgSO_4$ 1.2; KH_2PO_4 1.2; $NaHCO_3$ 28.0; and Ca^{2+} disodium edetate 0.026. This solution was aerated with 95 % oxygen and 5 % carbon dioxide to maintain pH 7.40 with a $P\text{CO}_2$ of 5.3 kPa and $P\text{O}_2$ greater than 66.7 kPa. These values were assessed by radiometric (ABL 30 Radiometer; Copenhagen, Denmark) methods and verified before electrical field stimulation, before construction of the dose-reponse curve, during the ED_{50} response, and during desflurane or halothane administration. In addition, $P\text{CO}_2$, $P\text{O}_2$ and anaesthetic concentrations were monitored continuously by an infrared absorption technique (Poet II, Criticare Systems Incorporated, Waukesha, WI, USA, for halothane and Datex Capnomac, Tewksbury, MA, USA, for desflurane). No residual halothane administrated from the initial procurement of the lung tissue was detected from the infrared absorption technique at this time. A minimum of 3 h elapsed from the time of tissue procurement to the tissue equilibration, which would be sufficient for any unmeasurable halothane to be dissipated.

DETERMINATION OF OPTIMAL LENGTH

Optimal length of the airway was determined by the response to transmural nerve stimulation after incremental changes in airway smooth muscle length. For transmural nerve stimulation, two platinum-plate eletrodes were placed parallel to the airway ring (1 cm distance between the electrodes). Electrical impulses were generated by a high current constant voltage stimulator (designed and tested by the Biomedical Engineering Section, Department of Anesthesiology, Medical College of Wisconsin, WI, USA). Based on preliminary experiments, the variables of the voltage stimulator used in this study (15 V, 0.5 ms, 25 Hz) produced maximal indirect airway smooth muscle contraction. This maximal response was abolished by atropine 1 µmol litre^{-1}, indicating that the contraction was not a result of direct electrical stimulation of the muscle [10].

The airway rings were allowed to equilibrate for 1 h after mounting in the jacketed baths. The airway rings were stretched progressively every 10 min, by 0.5-g increments for the proximal airway and 0.25-g increments for the distal airway, until the contractile response to a standard electrical stimulus (15 V, 0.5 ms, 25 Hz) of 30 s duration was maximal. The maximum response was obtained when two consecutive readings were equal. When this maximal response was reached, the airway ring was considered to be at optimal length.

After an additional hour of equilibration, resting tension at optimal length was measured. To block ganglionic nicotinic receptors, hexamethonium chloride 10 µmol litre^{-1} was then added to each bath and allowed to equilibrate for 30 min before acetylcholine challenge [11].

ACETYLCHOLINE AND ANAESTHETIC DOSE–RESPONSES

Acetylcholine cumulative dose–response curves were obtained for both proximal and distal airways by increasing the concentration in log increments every 2 min [12]. The dose range for the proximal airway was 0.01 µmol litre^{-1} to 10 mmol litre^{-1}, and 0.01 µmol litre^{-1} to 1 mmol litre^{-1} for the distal airway. The dose required to reach the maximal plateau response determined the maximum dose (ED_{max}) required for each airway group. After obtaining the maximal response in each tissue, a minimum of three bath rinses were performed to wash out the acetylcholine. The tissue rings were allowed to reach baseline resting tension and equilibrate for at least 1 h. The ED_{50} was calculated from the linear portion (20–80 % of maximum response) of the dose–response curve by linear regression analysis. This dose was then administered to each tissue to obtain a baseline control response before administration of anaesthetic. The control response to the ED_{50} was allowed to stabilize for 10 min.

After stabilization, the halothane or desflurane dose, equivalent to 0.9, 1.9 or 2.8 dog MAC, was selected randomly and allowed to equilibrate in each bath for a minimum of 15 min. After the response stabilized or the minimum equilibration time elapsed, whichever was longer in duration, the response was measured. The anaesthetic vaporizer was then turned off and the tissue was allowed a wash-out period of at least 15 min. A calibration curve with carrier gas flows (oxygen, carbon dioxide) and volatile anaesthetic concentrations used for the

Table 1 Characteristics of proximal and distal airway smooth muscle (mean (SD))

	Desflurane		Halothane	
	Proximal	Distal	Proximal	Distal
od (mm)	5.1 (0.5)	1.1 (0.3)	4.8 (1.4)	1.1 (0.8)
Applied length (mm)	3.6 (0.5)	1.2 (0.3)	4.1 (1.7)	1.8 (1.9)
Optimal length (mm)	8.7 (0.8)	2.3 (0.8)	8.9 (1.4)	2.9 (2.6)

Response to EDmax of acetylcholine (g)	5.00 (1.27)	1.91 (0.56)	5.34 (0.65)	1.92 (0.45)
Response to ED_{50} of acetylcholine (g)	2.50 (1.83)	0.85 (0.50)	2.37 (0.91)	0.99 (0.56)
ED_{50} acetylcholine (μmol $litre^{-1}$)	40.3 (32.5)	5.4 (7.9)	26.2 (24.3)	1.9 (1.2)

Table 2 Responses to the ED_{50} of acetylcholine for proximal and distal airway smooth muscle before and after recovery from halothane and desflurane (mean (SD) percentage of maximal contraction)

Anaesthetic	Concentration	Airway	Pre-anaesthetic	Post-anaesthetic
Halothane	0.9 MAC	Proximal	40.6 (1.5)	39.4 (2.2)
	1.9 MAC		41.9 (2.2)	38.3 (1.6)
	2.8 MAC		45.4 (2.3)	40.3 (2.4)
	0.9 MAC	Distal	48.9 (1.3)	48.1 (2.2)
	1.9 MAC		47.7 (2.7)	48.9 (3.1)
	2.8 MAC		48.6 (1.5)	50.7 (1.8)
Desflurane	0.9 MAC	Proximal	49.0 (2.3)	49.9 (3.4)
	1.9 MAC		47.1 (2.1)	47.9 (2.8)
	2.8 MAC		48.9 (2.4)	47.9 (3.2)
	0.9 MAC	Distal	45.3 (2.6)	43.6 (2.7)
	1.9 MAC		44.3 (2.7)	43.9 (3.1)
	2.8 MAC		44.8 (3.3)	43.5 (3.5)

experiments were determined and correlated with gas chromatography samples and infrared absorption analyser (Poet II for halothane or Datex for desflurane) measurements. The infrared absorption measurements correlated with gas chromatography samples after these values (mmol $litre^{-1}$) were converted to percentage volume values. The infrared absorption measurements were than used to ensure stable anaesthetic concentrations in the baths throughout the experiments. The infrared absorption analyser intake sampler located in-line with the carrier gas showed that the anaesthetic concentrations in the baths equilibrated in less than 5 min. One dog MAC of halothane is equivalent to 0.88% [13] and 1 dog MAC of desflurane is equivalent to 7.2% [14].

DATA ANALYSIS

The control response for each ring was isometric contraction to the ED_{50} of acetylcholine before administration of the anaesthetic. Airway smooth muscle relaxation was the change in tension caused by the anaesthetic. This change was expressed as a percentage of the control response. Analysis of variance was performed on the control response to the ED_{50} of acetylcholine, expressed as a percentage of maximal contraction, between the proximal and distal airway, for each volatile anaesthetic and anaesthetic dose, to confirm that there was no significant difference between the control responses in both tissue groups. The control response to the ED_{50} of acetylcholine was also compared with the post-control response to the ED_{50} of acetylcholine using the paired *t* test to evaluate potential tissue deterioration or residual anaesthetic effect. To evaluate the differences between proximal and distal airway responses at each anaesthetic dose within an anaesthetic group, paired *t* tests were used.

Analysis of variance with Scheffé's test was used to test for significant differences between halothane and desflurane, the three concentrations of each anaesthetic and the tissue groups. $P < 0.05$ was considered significant. The results are expressed as mean (SD).

Results

To reach optimal length with the use of micromanipulators, the proximal airway required 1.0–3.5 g of applied tension and the distal airway 0.50–2.0 g. The average increase in length (3.8 (0.8) mm) needed to reach optimal length in the proximal airway was almost equal to the od (5.0 (0.4) mm). This finding was consistent with that of Stephens, Meyers and Cherniack [15]. The increase in length (1.6 (0.7) mm) needed to reach optimal length in the distal airway was slightly greater than the od (1.0 (0.4) mm). The resting tension of the proximal airway (0.29 (0.12) g) was twice the resting tension of the distal airway (0.13 (0.04) g) (table 1).

The maximum effective dose (ED_{max}) of acetylcholine, the dose required for a plateau response, was 10 mmol $litre^{-1}$ for the proximal airway and 1 mmol $litre^{-1}$ for the distal airway. The physical characteristics of the proximal and distal airways in each anaesthetic group are presented in table 1. The control responses to the ED_{50} of acetylcholine, expressed as a percentage of maximal contraction, were not significantly different between the proximal and distal airways in each anaesthetic group (table 2). This indicates that each airway group was contracted

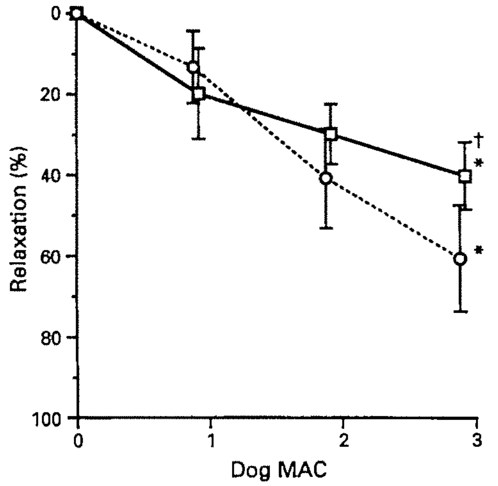

Figure 1 Percentage relaxation of proximal (third-generation) airway smooth muscle pre-contracted with the ED_{50} of acetylcholine at 0.9, 1.9, and 2.8 dog minimum alveolar anaesthetic concentration (MAC) of desflurane (○) and halothane (□). $*P < 0.05$ *vs* 0.9 MAC; $\dagger P < 0.05$ *vs* desflurane.

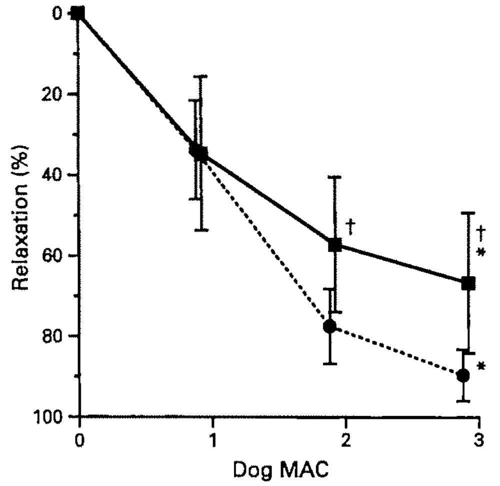

Figure 2 Percentage relaxation of distal (fifth- and sixth-generation) airway smooth muscle pre-contracted with the ED_{50} of acetylcholine at 0.9, 1.9, and 2.8 dog minimum alveolar anaesthetic concentration (MAC) of desflurane (●) and halothane (■). $*P < 0.05$ *vs* 0.9 MAC; $\dagger P < 0.05$ *vs* desflurane.

to the same extent before administration of anaesthetic. The post-experimental responses to the ED_{50} of acetylcholine were not significantly different from their respective control values, indicating that no tissue deterioration occurred and the anaesthetic effect was reversible.

There was a significant difference between the relaxant effects of 0.9, 1.9 and 2.8 MAC for both desflurane and halothane (figs 1, 2) in the proximal and distal airway tissue groups, indicating a dose–response effect for these anaesthetics. Also, there was a significant difference between the relaxant effects of the proximal and distal airways at each anaesthetic dose within each anaesthetic group ($P < 0.003$) the average distal airway relaxed 50 % more than the proximal airway). Desflurane relaxed the proximal airway smooth muscle to a greater extent than halothane at 2.8 MAC ($P = 0.0001$) and the distal airway smooth muscle at 1.9 ($P = 0.0007$) and 2.8 MAC ($P = 0.002$). The proximal airway smooth muscle relaxed 13 %, 41 % and 61 % with desflurane and 20 %, 29 % and 41 % with halothane at 0.9, 1.9 and 2.8 MAC, respectively. The distal airway smooth muscle relaxed 34 %, 78 % and 90 % with desflurane and 35 %, 57 % and 67 % with halothane at 0.9, 19 and 2.8 MAC, respectively (figs 1, 2).

Discussion

This study demonstrated that volatile anaesthetics (desflurane and halothane) had a greater bronchodilator effect on distal airway smooth muscle than on the more proximal airway smooth muscle in a dose-dependent manner, similar to the effects of isoflurane [7]. Furthermore, we found that desflurane had a greater direct bronchodilator effect than halothane at the doses tested (greater than 1 MAC for the distal airway smooth muscle and greater than 2 MAC for the proximal airway smooth muscle). Therefore, desflurane had good direct bronchodilator effects on the intraparenchymal airway despite its association with coughing and laryngospasm on induction [1].

To compare the proximal airway, which has a larger diameter and more muscle mass, to the distal airway, isometric tension was measured, thereby allowing the diameter of the airway ring to remain constant. Under these circumstances, changes in tension would be linearly proportional. In addition, the airway smooth muscle rings were evaluated at optimal length. This enables each airway to be compared at the same point on the length–tension curve. Furthermore, the ED_{50} of acetylcholine for each individual tissue was used as the baseline for comparison. This response maintains each tissue at the same degree of activation and contraction. The ED_{50} response, when expressed as a percentage of the EDmax response, reflects the effects of functional muscle tissue so that it is not necessary to take into account the mass of the tissue.

It is possible that the increased ED_{50} of acetylcholine in the proximal airway was caused by cartilage. However, the ED_{50} of acetylcholine between airways with and without papain-softened cartilage were not found to be different [16]. Also, isometric tension measured in bronchial smooth muscle with cartilage compared with bronchial smooth muscle with the cartilage removed was not significantly different [17]. This suggests that the presence of cartilage does not oppose contraction. Furthermore, cartilage does not oppose relaxation but may actually facilitate it. When airway smooth muscle is contracted, cartilage plates and collagen fibres between these plates frequently reverse their orientation by almost 180° [18]. This orientation and the elastic nature of cartilage results in a tendency to spring outward, as described by Olsen and colleagues [18]. Agents that relax airway smooth muscle such as volatile anaesthetics would then allow the cartilage to spring outward, facilitating the tendency for relaxation. Despite this tendency, the distal airway, which lacks cartilage, relaxed to a greater extent than the proximal airway.

To minimize the difference in gas diffusion time, lung parenchyma and vascular tissues were removed carefully and the airway rings were cut into small segments. In addition, airway smooth muscle was allowed to equilibrate with the anaesthetic for a minimum of 15 min, or until the tissue response stabilized, to ensure that each tissue reached the same anaesthetic saturation point. Therefore, the effects on airway smooth muscle contraction could be normalized and compared.

Previous studies have examined the bronchodilator effect of anaesthetics by conventional techniques, such as measuring lung resistance (RL) *in vivo* [19–21], a value indicative of proximal airway resistance [22], or by *in vitro* techniques, such as measuring isometric force [11, 23, 24]. The results of these studies have shown that the indirect [21, 23, 24] and direct effects [11, 19, 20, 25] of anaesthetics are responsible for bronchodilatation. Warner and colleagues, using aerosolized acetylcholine, examined the direct effects of halothane on changes in pulmonary resistance and found a decrease in pulmonary resistance at 1.2 MAC from a baseline value of 6.32 to 4.85 $\text{cm H}_2\text{O litre}^{-1}\text{ s}^{-1}$ (23% change). Hirshman and colleagues [20], using an aerosolized cholinergic agonist, also found a reduction in pulmonary resistance as a result of halothane in the Basenji–Greyhound dog model of asthma. In a study measuring both airway smooth muscle tension and intracellular Ca^{2+} in canine trachea, Jones and colleagues [25] found that halothane reduced both of these variables. Halothane was also found to suppress tracheal smooth muscle contractions produced by direct muscle stimulation and increase the threshold for muscle activation [26].

In vivo studies have evaluated variations in global lung resistance (RL), which is indicative of changes in the more proximal airway and may be insensitive to changes in the more distal airway [21]. In addition, RL is a function of airway resistance and tissue resistance, with tissue resistance being the principal component of RL [27]. However, it has been shown that RL can be used as an index of changes in airway calibre [27], although it is not known if this index is homogeneous throughout the lung. Studies performed *in vitro* examined the direct effects of anaesthetics on the trachea and in some, only as far distally as the segmental bronchus. The results of these *in vivo* and *in vitro* studies indicated that volatile anaesthetics have a significant bronchodilator effect on proximal airway smooth muscle [11, 19, 20, 21]. Furthermore, the effects of 1 MAC of halothane may depress neural transmission and smooth muscle to an equal extent [19].

The clinical importance of the direct bronchocontraction effects of volatile anaesthetics on airway smooth muscle may be more important than previously thought. Earlier studies focused on the direct effects of anaesthetics on the larger, more proximal, airway rather than the distal airway, which is the main contributor to airway resistance. However, in a more recent study, Brown, Zerhouni and Hirshman [28], using high resolution computer tomography, examined the effects of isoflurane and halothane on proximal and distal airways constricted with histamine. Their data suggested that administration of isoflurane and halothane (> 1.1 MAC) resulted in greater bronchodilatation in airways less than 3 mm compared with airways greater than 7 mm. Mazzeo and colleagues confirmed that the volatile anaesthetic isoflurane had a differential effect on airway smooth muscle and that the distal airway smooth muscle was significantly more sensitive to the bronchodilating effects of isoflurane [7]. In this study, we also demonstrated that desflurane and halothane *in vitro* had a similar heterogeneous effect on airway smooth muscle.

The increased bronchodilator effect in the distal airway could be a result of several possibilities. This differential effect could be caused by structural or physiological differences, or both, in the bronchus compared with the bronchiolus. Further investigations are needed to define the factors involved in the differential effect of anaesthetics on airway smooth muscle and the greater relaxant effect of desflurane on airway smooth muscle in general. Discovering the reason for the differential effect of anaesthetics may help to develop a better understanding of anaesthetic actions on airway smooth muscle in the normal patient and in those with bronchospastic disease. This understanding may also lead to improvement and development of more rational drug therapies for the treatment of patients with reactive airway disease.

Halothane and potassium channels in airway smooth muscle

T. FUKUSHIMA, A. HIRASAKI, K. A. JONES AND D. O. WARNER

Summary

Earlier studies have suggested that halothane may relax smooth muscle in part by opening adenosine triphosphate-sensitive potassium (K_{ATP}) channels. We tested this hypothesis *in vitro* by examining the interaction of halothane with glibenclamide, a K_{ATP} channel blocker, and YM934, a K_{ATP} channel opener, in strips of canine tracheal smooth muscles mounted in an organ bath system. To examine the specificity of any effects of halothane on the K_{ATP} channel, we assessed the interaction of halothane with tetraethylammonium (TEA), an antagonist of the large-conductance, calcium-activated potassium channel. Experiments were conducted with drugs added before exposure to increasing concentrations of acetylcholine (ACh), and with drugs added after stable increases in force produced by ACh were achieved (ACh precontraction). Exposure to halothane 0.62 mmol litre^{-1} (equivalent to approximately 2 MAC) increased significantly the ED_{50} for ACh-induced contractions (by 0.24 (SEM 0.07) µmol litre^{-1}). TEA 1 mmol litre^{-1} but not glibenclamide 10 µmol litre^{-1} significantly augmented this increase in ED_{50} (by an additional 0.17 (0.06) µmol litre^{-1}). In strips precontracted with ACh, TEA, but not glibenclamide, potentiated concentration-dependent relaxation induced by halothane. Incubation with YM934 0.32 µmol litre^{-1} increased significantly the ED_{50} for ACh-induced contractions (from 0.12 (0.02) to 0.55 (0.11) µmol litre^{-1}), an increase not affected by exposure to halothane 0.72 mmol litre^{-1}. When added to strips precontracted with approximately ACh 0.3 µmol litre^{-1}, YM934 produced concentration-dependent relaxation; halothane had little effect on this relaxation. These results do not support the hypothesis that halothane relaxes canine tracheal smooth muscle in part by opening K_{ATP} channels. (*Br. J. Anaesth.* 1996; **76**: 847–853)

Key words

Anaesthetics volatile, halothane. Lung, trachea. Ions, potassium. Ions, ion channels. Airway, muscles.

Halothane is a potent bronchodilator, relaxing airway smooth muscle both by depressing neural pathways innervating the muscle and by a direct effect on the smooth muscle cell [1, 2]. One proposed mechanism for this effect is a decrease in intracellular calcium concentration [3, 4], produced in part by depression of calcium influx via voltage-sensitive calcium channels in the sarcolemma. Under voltage-clamped conditions, halothane depresses the function of these channels in several types of cells [5], including vascular smooth muscle [6, 7]. Changes in membrane potential could also affect calcium channel function. Hyperpolarization of the cell membrane has been suggested as a mechanism for anaesthetic action in several cell types [8], including airway smooth muscle [9]. One mechanism that could produce hyperpolarization would be an increase in conductance of potassium channels [10]. In support of such a mechanism in airway smooth muscle, Mehr and Lindeman [11] found that glibenclamide, an antagonist of adenosine triphosphate (ATP)-sensitive potassium (K_{ATP}) channels, abolished the ability of halothane to decrease airway responsiveness to hypocapnia in a canine model of asthma. Evidence for activation of potassium channels has been reported for several other types of cells, including activation of the K_{ATP} channel in vascular smooth muscle [12]. However, there is also considerable evidence that halothane depresses the function of several types of potassium channels [6, 7, 13–15], although the K_{ATP} channel has not been examined specifically.

The purpose of this study was to test the hypothesis that halothane relaxes airway smooth muscle *in vitro*, in part by activation of K_{ATP} channels. We examined the interaction of halothane with glibenclamide and YM934, a K_{ATP} channel opener [16], during stimulation of isolated strips of canine tracheal smooth muscle with acetylcholine (ACh). To determine the specificity of any effects of halothane on the K_{ATP} channel, we also examined the interaction of halothane with tetraethylammonium (TEA), an antagonist of the large-conductance, calcium-activated potassium (K_{Ca}) channel.

Materials and methods

TISSUE PREPARATION

The trachea was removed from 45 mongrel dogs anaesthetized with pentobarbitone and exsanguinated. The tissue was immersed immediately in a chilled physiological salt solution (PSS) of the following composition (mmol litre^{-1}): $MgSO_4$ 0.8, KH_2PO_4 1.2, KCl 3.4, $CaCl_2$ 2.4, NaCl 110,

$NaHCO_3$ 25.7 and glucose 5.6. After removal of the epithelium and connective tissue, rectangular strips of smooth muscle (10–15 mm long and 2 mm wide) were dissected from the middle of the trachea. Each strip was suspended vertically in a 25-ml water-jacketed tissue bath containing PSS at 37 °C and bubbled with 94% oxygen–6% carbon dioxide, providing a pH of 7.4, Po_2 of 73 kPa and Pco_2 of 4.8 kPa (Instrumentation Laboratories model 1302). The strips were connected to strain gauges (Grass FT03) for isometric force recording (Hewlett-Packard 7418A). Indomethacin 10 μmol litre^{-1} was added to all baths.

The strips were washed in PSS for approximately 2 h while being stimulated supramaximally (0.5-ms pulse duration, 25 Hz, 15 V) by electrical field stimulation at 5-min intervals. Muscle length was increased after each contraction until the force of contraction reached a maximum. Each strip was maintained at this optimal length for the duration of the experiment. The contractile response to ACh 100 μmol litre^{-1}, defined as the maximal response, was then determined.

EXPERIMENTAL DESIGNS

Because different mechanisms are involved in the induction compared with the maintenance of force in airway smooth muscle [17], experiments were conducted both with drugs added before exposure to increasing concentrations of ACh, and with drugs added after stable increases in force produced by ACh were achieved (ACh precontraction).

Interpretation of precontraction experiments is complicated by the fact that the amount of relaxation produced by an antagonist of contraction may depend on both the initial force and the concentration of contractile agonist needed to produce that force (a phenomenon referred to as functional antagonism). In some experiments, prior exposure to a compound with effects on muscle contractility (e.g. halothane) changes the initial force of contraction produced for a given concentration of ACh. In the case of halothane, such an effect is observed even at maximal concentrations of ACh [18]. In these instances, options include maintaining a constant ACh concentration and allowing the initial force to vary, or manipulating ACh concentration to keep the initial force constant between experimental conditions. We chose the latter option, as described below. However, when the ACh concentration needed to produce equal initial forces differed significantly between conditions, we also performed additional experiments, using these different ACh concentrations and allowing initial forces to vary, to determine if functional antagonism was responsible for the observed results.

Four series of experiments were performed, evaluating: (1) the effects of K^+-channel block produced by TEA 1 mmol litre^{-1} or glibenclamide 10^{-5} mol litre^{-1} on the ability of 1.7% halothane to inhibit force developed in response to cumulative increases in ACh concentrations; (2) the effects of K^+-channel block on the ability of halothane to relax strips precontracted with ACh to approximately 50% of maximal force; (3) the effect of 1.7% halothane pretreatment on the ability of YM934, a K_{ATP} channel opener, to inhibit force developed in response to cumulative increases in ACh concentrations; and (4) the effects of halothane on the ability of YM934 to relax strips precontracted with ACh to approximately 50% of maximal force. When appropriate, control experiments were performed with the vehicle used to solubilize glibenclamide (4×10^{-5} vol% dimethylsulphoxide (DMSO)). In all experiments using ACh precontraction, another strip paired for each experimental condition was used to control for any effects of time on the level of precontraction [1].

DATA ANALYSIS

Isometric forces were expressed as a percentage of the maximal force (for ACh concentration–response procedures) or as a percentage of the initial force (for ACh precontraction procedures). In strips precontracted with ACh, the contractile responses were adjusted for the effect of time [1] according to the formula:

$$C_t = (C_1/C_2)\,C_d$$

where C_t = the time-adjusted response, C_1 = response of time-control muscle (initial measurement), C_2 = response of time-control muscle (measured in parallel with the exposed muscle) and C_d = response of the muscle exposed to drug.

Sigmoidal concentration–response curves to ACh or YM934 were analysed using the method of Meddings, Scott and Fick [19]. In this method, force (F) at any concentration of drug (C) is given by the equation:

$$F = F_m\,C/(\mathrm{ED}_{50} + C)$$

where F_m = maximal (or minimal) force and ED_{50} = concentration that produces the half-maximal (or minimal) force for that drug. Non-linear regression analysis was used to fit values of F_m and ED_{50} to data for F and C for each condition studied. This method allows comparison of curves to determine if they are significantly different, and if this overall difference can be attributed to differences in F_m, ED_{50}, or both.

The potency of halothane in relaxing strips precontracted with ACh was quantified by linear regression of the relationship between force and halothane concentration. To test for differences in potency between conditions, slopes were compared by one-way analysis of variance (ANOVA), with *post hoc* comparisons performed using the Student–Newman–Keuls method.

Data are expressed as mean (SEM). $P < 0.05$ was considered significant. In all cases n represents the number of pairs of strips analysed for a given experimental condition. For a given condition, each pair of strips was obtained from a different dog.

DRUGS

Halothane (Ayerst Laboratories) was added to the aerating gas mixture via an on-line vaporizer. The concentration of halothane in the gas mixture was monitored continuously by a mass spectrometer (model MGA-1100, Perkin–Elmer). The concentration of halothane in the PSS was determined by gas chromatography (model 5880A, Hewlett-Packard). The drugs used were ACh hydrochloride, indomethacin (Sigma), tetraethylammonium chloride, glibenclamide (Research Biochemicals) and YM934 (Yamanouchi Pharmaceuticals). Drug concentrations are expressed as final bath concentrations of the salts.

Results

EFFECTS OF HALOTHANE AND K$^+$-CHANNEL ANTAGONISTS ON THE ACH CONCENTRATION–RESPONSE RELATIONSHIP

Exposure to TEA 1 mmol litre^{-1} increased significantly the maximal force developed in response to cumulative increases in ACh concentration (from 94.7 (1.8)% to 108.1 (1.8)% of the initial maximal force; $P < 0.05$ by non-linear regression) without changing significantly the ED_{50} concentration of ACh (from 0.33 (0.04) to 0.29 (0.03) µmol litre^{-1}) (fig. 1), that is TEA increased maximal force developed in response to ACh but did not change the sensitivity of the strips to ACh. Exposure to glibenclamide 10 µmol litre^{-1} did not change significantly the ACh concentration–response relationship (change in maximal force from 96.7 (1.7)% to 101.4 (1.6)% and change in ED_{50} from ACH 0.21 (0.02) to 0.18 (0.03) µmol litre^{-}) (fig. 2.).

Exposure to 1.7% halothane increased significantly the ED_{50} concentration of ACh in strips not incubated with a K$^+$-channel antagonist (control, $P < 0.05$), and in strips incubated with TEA 1 mmol litre^{-1} or glibenclamide 10 µmol litre^{-1} (figs 1, 2; $P < 0.05$). The increase in ED_{50} produced by halothane was significantly greater in strips incubated with TEA compared with control strips (increases of ACh 0.41 (0.09) and 0.24 (0.07) µmol litre^{-1}, respectively; $P = 0.016$ by paired t test), demonstrating that TEA potentiated the effect of halothane on the sensitivity of the strips to ACh. However, the increase in ED_{50} produced by halothane was not significantly different in strips incubated with glibenclamide compared with control strips (increases of ACh 0.19 (0.06) and 0.15 (0.04) µmol litre^{-1}, respectively; ns by paired t test). Halothane did not significantly change the maximal force under any conditions.

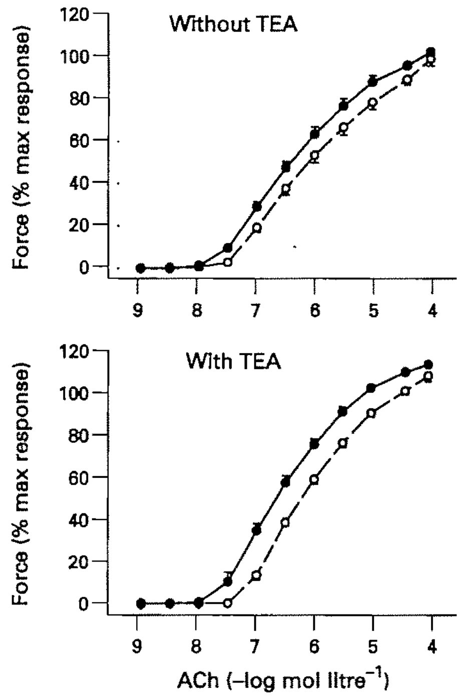

Figure 1 Active isometric force developed in response to increasing concentrations of acetylcholine (ACh) in strips exposed (○) or not exposed (●) to halothane 0.62 (0.02) mmol litre^{-1} (equal to approximately 2 MAC in the gas phase). Strips in the lower panel were incubated with tetraethylammonium chloride (TEA) 1 mmol litre^{-1} for 20 min before exposure to ACh. At this concentration, TEA predominantly affects the K_{Ca} channel, with little if any effect on delayed rectifier potassium channels in airway smooth muscle [20]. Values are mean, SEM, for six experiments.

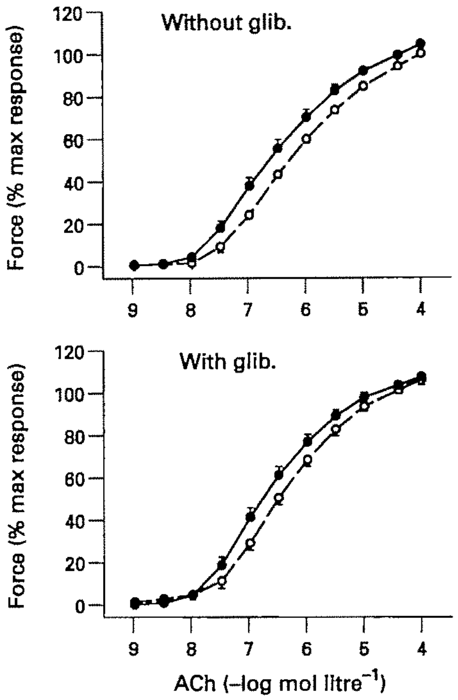

Figure 2 Active isometric force developed in response to increasing concentrations of acetylcholine (ACh) in strips exposed (○) or not exposed (●) to halothane 0.62 (0.02) mmol litre^{-1}. Strips in the lower panel were incubated with glibenclamide 10^{-5} mol litre^{-1} for 20 min before exposure to ACh. Values are mean, SEM, for six experiments.

EFFECTS OF K-CHANNEL ANTAGONISTS ON HALOTHANE-INDUCED RELAXATION

Precontraction of strips to approximately 50% of maximal force required a significantly lower concentration of ACh in strips incubated with TEA 1 mmol litre^{-1} (ACh 0.19 (0.04) µmol litre^{-1}) compared with control strips (ACh 0.33 (0.07) µmol litre^{-1}; $P < 0.02$ by paired t test). ACh concentrations for strips incubated with glibenclamide 10 µmol litre^{-1} (ACh 0.24 (0.06) µmol litre^{-1}) did not differ significantly from those required in control strips. The actual forces achieved were 48.1 (0.5)%, 49.3 (0.8)% and 48.6 (0.5)% of maximal force for control, TEA- and glibenclamide-treated strips, respectively.

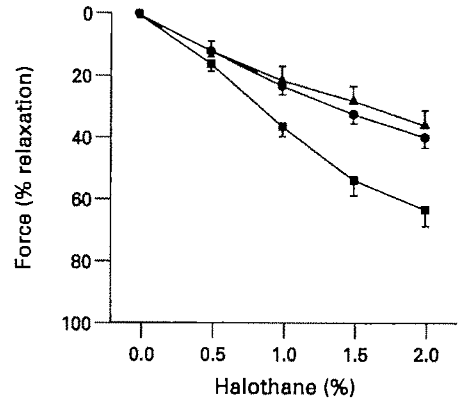

Figure 3 Relationship between force and halothane concentration in gas aerating the tissue bath in strips precontracted with acetylcholine to approximately 50 % of maximal force. Data for strips not exposed to potassium channel antagonists (control, ●), strips incubated with tetraethylammonium chloride (TEA) 1 mmol litre^{-1} (■) and strips incubated with glibenclamide 10^{-5} mol litre^{-1} (▲) are shown. Halothane concentrations achieved in the tissue baths were 0.23 (0.01), 0.41 (0.01), 0.54 (0.02) and 0.70 (0.03) mmol litre^{-1} for 0.5 %, 1.0 %, 1.5 % and 2 % halothane added to the gas aerating the baths, respectively. Values are mean, SEM, for eight experiments.

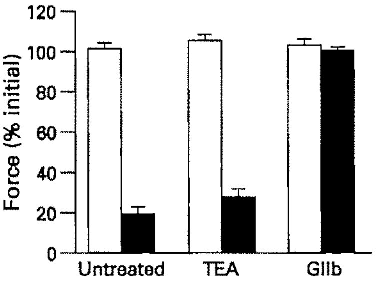

Figure 4 Effect of YM934 0.32 μmol litre^{-1} (■) on force in strips precontracted with acetylcholine to approximately 50 % of maximal force and incubated with tetraethylammonium chloride (TEA) 1 mmol litre^{-1}, glibenclamide 10 μmol litre^{-1} or neither (untreated). Force is expressed as a percentage of the force initially developed in response to ACh. Control strips (□) did not receive YM934 and represent controls for any effects of time. Values are mean, SEM, for eight experiments.

Halothane produced concentration-dependent relaxation of these precontracted strips (fig. 3) that could be quantified as the slope of a linear regression of force *vs* halothane concentration. The absolute value of this slope was significantly greater in strips incubated with TEA 1 mmol litre^{-1} compared with control strips (−33.8 (2.8) and −21.0 (1.7) % initial force × halothane^{-1}, respectively; $P < 0.05$ by ANOVA and Student–Neuman–Keuls test), indicating that TEA potentiated halothane-induced relaxation. Glibenclamide 10 μmol litre^{-1} did not significantly affect the slope of this relationship, indicating that glibenclamide did not affect the ability of halothane to relax the strips.

The K_{ATP} channel agonist YM934 was added to strips precontracted with ACh to 50 % of maximal force to assess the adequacy of K_{ATP} channel antagonism by glibenclamide 10 μmol litre^{-1} and the specificity of TEA. YM934 0.32 μmol litre^{-1} produced significant relaxation in control strips and strips treated with TEA 1 mmol litre^{-1} (fig. 4, $P < 0.05$ by ANOVA and Student–Neuman–Keuls). The amount of relaxation was not significantly different between control strips and strips treated with TEA 1 mmol litre^{-1}. However, glibenclamide 10 μmol litre^{-1} completely blocked this relaxation (fig. 4).

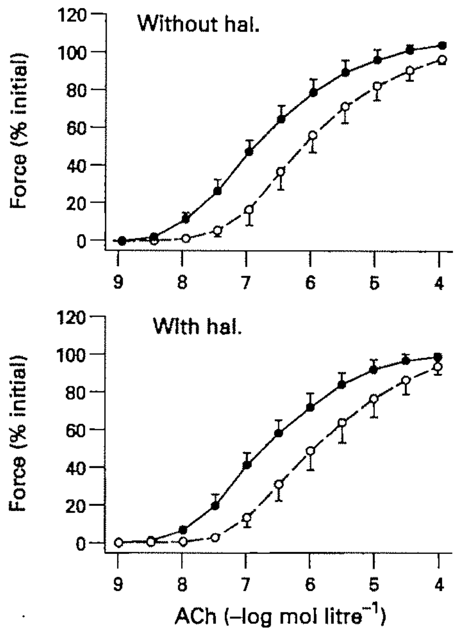

Figure 5 Force developed in response to increasing concentrations of acetylcholine (ACh) in strips exposed to YM934 0.32 μmol litre^{-1} (○) or to the vehicle used to solubilize YM934 (●). Strips in the lower panel were incubated with halothane 0.72 (0.04) mmol litre^{-1}. Values are mean, SEM, for five experiments.

Because TEA decreased significantly the ACh concentration required to produce approximately 50 % of maximal force (from 0.33 (0.07) μmol litre^{-1} to 0.19 (0.04) μmol litre^{-1}; $P < 0.01$), the ability of halothane to relax strips precontracted with these two concentrations of ACh was studied in separate experiments (in the absence of TEA, $n = 6$). The slopes of linear regressions of force *vs* halothane concentration did not differ between the two concentrations of ACh (−22.4 (1.6) and −24.2 (1.2) % initial force × % halothane^{-1}, respectively, $P = 0.09$), demonstrating that the potentiation of halothane-induced relaxation by TEA was not an artefact of functional antagonism. In other words, changes in the response to halothane produced by TEA could not be explained by the different ACh concentrations used to precontract TEA-treated and control strips.

EFFECTS OF HALOTHANE AND A K_{ATP} AGONIST ON THE ACH CONCENTRATION–RESPONSE RELATIONSHIP

Incubation with YM934 0.32 μmol litre^{-1} increased significantly the ED_{50} of ACh (from 0.12 (0.02) to 0.55 (0.11) μmol litre^{-1}; $P < 0.01$), demonstrating that YM934 decreased the sensitivity of the strips to ACh (fig. 5). Exposure to halothane 0.76 (0.04) mmol litre^{-1} did not affect significantly the increase in ED_{50} produced by YM934. YM934 did not change the maximal force developed in response to ACh under any condition. The vehicle used to

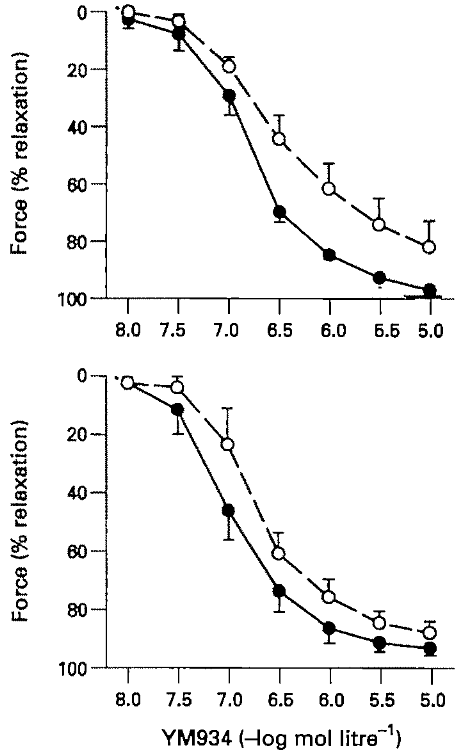

Figure 6 Top: Relationship between force and the concentration of YM934 in strips exposed (halothane, ○) or not exposed (control, ●) to halothane 0.76 (0.03) mmol litre^{-1}. ACh concentration was manipulated to produce an initial force of approximately 50 % maximal force. Values are mean, SEM for eight experiments. Bottom: Relationship between force and the concentration of YM934 in strips contracted with ACh 0.33 μmol litre^{-1} (○) or ACh 0.86 μmol litre^{-1} (●), values equal to the mean ACh concentrations used to precontract the control and halothane-treated strips, respectively, depicted above. Note the similar results to those above, suggesting much of the difference in YM934-induced relaxation depicted above can be accounted for by differences in ACh concentrations used to produce approximately equal initial forces. Values are mean, SEM, for six experiments.

dissolve YM934 did not significantly affect the ACh concentration–response relationship (data not shown).

EFFECT OF HALOTHANE ON RELAXATION PRODUCED BY A K_{ATP} CHANNEL AGONIST

Precontraction of the strips to approximately 50 % of maximal force required a significantly higher concentration of ACh in strips incubated with halothane 0.82 (0.04) mmol litre^{-1} (ACh 0.86 (0.15) μmol litre^{-1}) compared with control strips (ACh 0.33 (0.07) μmol litre^{-1}; $P = 0.0008$ by paired t test). When added to strips precontracted with ACh, YM934 produced a concentration-dependent relaxation (fig. 6 (top)). Halothane exposure significantly attenuated the maximal decrease in force produced by YM934 (from 1001 (3.0) to 83.6 (5.5) % of the initial force; $P < 0.05$ by non-linear regression), without significantly changing the ED_{50} of YM934 (0.19 (0.03) and 0.30 (0.09) μmol litre^{-1} for strips exposed and not exposed to halothane, respectively. The addition of the vehicle used to dissolve YM934 did not significantly affect force (data not shown).

Because halothane exposure increased significantly the ACh concentration required to produce approximately 50 % of maximal force (from 0.33 (0.07) to 0.86 (0.15) μmol litre^{-1}), the ability of YM934 to relax strips precontracted with these two concentrations of ACh was studied in separate experiments (without halothane exposure, $n = 6$). Increasing the ACh concentration used for precontraction significantly attenuated the maximal decrease in force produced by YM934 (from 96.8 (2.0) to 90.3 (2.5) % of the initial force; $P < 0.05$ by non-linear regression) without significantly changing the ED_{50} of YM934 (0.13 (0.01) and 0.21 (0.03) μmol litre^{-1} for strips contracted with ACh 0.33 μmol litre^{-1} and 0.86 μmol litre^{-1}, respectively). The changes in the maximal decrease in force and ED_{50} produced by halothane and by increases in precontraction ACh concentration did not differ significantly. Thus it appears that the difference in YM934-induced relaxation observed in figure 6 can be accounted for by differences in ACh concentrations used to produce approximately equal initial forces.

Discussion

The principal findings of this study were that there was no interaction between halothane and a blocker of the K_{ATP} channel in their effects on force in isolated canine airway smooth muscle during stimulation with ACh, and that halothane had little effect on the ability of a K_{ATP} channel opener to relax airway smooth muscle. These findings do not support the hypothesis that halothane relaxes this tissue by opening K_{ATP} channels.

Potassium channels are important regulators of resting membrane potential in smooth muscle. In general, these channels are inhibited during agonist-induced contractions [21], producing membrane depolarization which may contribute to extracellular calcium influx via voltage-dependent calcium channels. Conversely, compounds that open these channels tend to relax smooth muscle. It appears that β adrenoreceptor agonists relax smooth muscle in part by augmenting potassium channel activity [22, 23], and compounds that act primarily as potassium channel openers are currently being developed for therapeutic applications. At least three classes of potassium channels are present in airway smooth muscle [21]. Large-conductance, calcium-activated (K_{Ca}) channels are abundant in airway smooth muscle cell membranes and are modulated by agents that affect smooth muscle tone. Delayed rectifier potassium channels are open under resting conditions and may serve to stabilize membrane potential [24]. Although the ATP-sensitive potassium (K_{ATP}) channel has not been characterized fully in airway smooth muscle, there is considerable pharmacological evidence for its presence. The K_{ATP} channel openers cromakalim and levcromakalim hyperpolarize and relax airway smooth muscle [25, 26], effects that can be antagonized by glibenclamide, a blocker of the K_{ATP} channel [27, 28].

We found pharmacological evidence for the presence of both K_{Ca} and K_{ATP} channels in our preparation. Based on the lack of interaction between TEA and a K_{ATP} channel opener in our preparation (fig. 4) and previous work finding little evidence of the effect of TEA (at 1 mmol litre^{-1}) on delayed rectifier channels in airway smooth muscle [20], we assume that TEA acted predominantly on the K_{Ca} channel, although effects on other channel types not yet identified in airway smooth muscle are possible. Block of K_{Ca} channels by TEA increased the sensitivity of the muscle to ACh-induced contraction, consistent with previous studies of smooth muscle [29]. Presumably, K_{Ca} channel block allowed a greater degree of membrane depolarization during block, leading to an increase in calcium influx, intracellular calcium concentration and force. Block of K_{ATP} channels by glibenclamide did not affect ACh-induced contractions, suggesting that this channel is not functionally important during this mode of stimulation in this tissue. However, during precontraction with ACh, this preparation was relaxed readily by the K_{ATP} channel opener YM934, a relaxation that was blocked by glibenclamide, indicating that K_{ATP} channels can modulate functional effects in this tissue.

Previous work has suggested that halothane and other anaesthetics modulate the function of several types of ion channels, including potassium channels. Inhibitory effects of halothane on K_{Ca}-channel function have been demonstrated in several different cell types, including vascular smooth muscle [13], with an ED_{50} of approximately 0.5 mmol litre^{-1} in all studies. Halothane depresses 4-aminopyridine-sensitive potassium currents in coronary arterial smooth muscle cells, suggesting antagonism of delayed rectifier potassium channels [7]. Halothane also depresses the function of a wide variety of both invertebrate and mammalian potassium channels with diverse functional characteristics [15]. In contrast, Franks and Lieb [10] have described a K^+ channel in mollusc neurones that is activated by halothane.

Electrophysiological measurements of the effects of halothane specifically on the K_{ATP} channel have not yet been performed. However, some pharmacological studies have suggested that halothane may activate this channel. Larach and Schuler [12] found that glibenclamide inhibited halothane-induced vasodilatation of coronary resistance vessels in perfused rat hearts. However, this effect was not observed in isolated rings of epicardial coronary vessels denuded of endothelium; glibenclamide actually potentiated the effects of halothane in rings with intact endothelium. Mehr and Lindeman [11] measured the response of peripheral airway resistance, using a wedged bronchoscope technique, to hypocapnia produced by increasing flows of gas free of carbon dioxide in a canine model of asthma (the Basenji–Greyhound dog). They found that the response to hypocapnia was suppressed in dogs anaesthetized with 1.2% halothane, compared with dogs anaesthetized with thiopentone and fentanyl. Pretreatment with glibenclamide aerosolized into the airway via the bronchoscope restored responsiveness to hypocapnia in dogs anaesthetized with halothane, and had no effect in dogs anaesthetized with thiopentone and fentanyl. They concluded that halothane suppressed the response of peripheral airways to hypocapnia by opening K_{ATP} channels.

In contrast with these findings, we found no interaction between the effects of halothane and glibenclamide in canine tracheal smooth muscle. The apparent antagonism by halothane of the ability of YM934, a potassium channel opener, to relax strips precontracted with ACh would suggest that halothane blocks K_{ATP} channels under these conditions. However, it appears that the results of this experiment may be explained primarily by functional antagonism; the effects of YM934 observed in halothane-treated muscles (fig. 6) can be ascribed to the higher ACh concentration necessary to produce an initial force similar to that in control muscles (compare fig. 6 (top and bottom)). Furthermore, there was no evidence of an interaction between the effects of halothane and YM934 on the ACh concentration–response relationship. Direct comparison of our results with the study of Mehr and Lindeman is not possible, because of differences in the breed of dog, location of the airway smooth muscle studied, method used to produce muscle contraction and differences in experimental condition (*in vivo vs in vitro*).

We also studied the interaction of halothane and TEA to determine if any effects of halothane that might have been observed in the glibenclamide procedures were specific to effects on the K_{ATP} channel. Halothane potentiated the effects of TEA on the ACh concentration–response relationship, and TEA potentiated the effect of halothane on muscles precontracted with ACh. Marijic and colleagues [29] observed a similar potentiation of halothane effect by TEA in vascular smooth muscle. The authors suggested, and provided supportive evidence in a subsequent study [7], that halothane antagonized ion fluxes through both potassium and calcium channels. Antagonism of potassium channel function would favour membrane depolarization and increases in muscle tone; antagonism of calcium channel function would decrease intracellular calcium concentration and favour decreases in muscle tone. Under most circumstances, effects on calcium channels predominate, and the muscle relaxes when exposed to halothane. When potassium channels are blocked by TEA, halothane can inhibit only calcium channels, so that its relaxing effect is magnified. Our results are consistent with this explanation. Thus interference with the normal function of ion channels produced by anaesthetics may have opposite effects on physiological function, depending on the experimental conditions.

Recovery of respiratory ciliary function after depression by inhalation anaesthetic agents: an *in vitro* study using nasal turbinate explants

J. H. RAPHAEL, J. STRUPISH, D. A. SELWYN, H. C. L. HANN AND J. A. LANGTON

Summary

We have developed a human tissue preparation suitable for measurement of cilia beat frequency derived from nasal turbinates. Cilia beat frequency of turbinate explants from 11 patients did not change significantly over a 10-day observation period while maintained in an incubator, with mean cilia beat frequency of 13.1 (SEM 0.3) Hz to 14.4 (0.2) Hz (ANOVA for repeated measures, $P = 0.168$). We have used this preparation to investigate recovery of ciliary function after depression by inhalation anaesthetic agents. Eight or nine turbinate explants were exposed to three times the minimum alveolar concentration (MAC) of halothane, enflurane or isoflurane for a period of 1 h and thereafter to a period of air washout. After exposure to the inhalation agent there was a significant reduction in cilia beat frequency with all three agents: halothane 14.3 (0.4) Hz to 9.5 (0.3) Hz; enflurane 13.7 (0.6) Hz to 10.5 (0.5) Hz; isoflurane 15.9 (0.6) Hz to 10.6 (0.3) Hz. Cilia beat frequency returned to values after air washout that were not significantly different from baseline after 90 min of washout of halothane and 60 min of washout of enflurane and isoflurane (repeated measures ANOVA, unpaired *t* test; $P = 0.01$ at 60 min and $P = 0.31$ at 90 min washout for halothane; $P = 0.83$ at 60 min washout for enflurane; $P = 0.26$ at 60 min washout for isoflurane). (*Br. J. Anaesth.* 1996; **76**: 854–859)

Key words

Anaesthetics volatile, halothane. Anaesthetics volatile, enflurane. Anaesthetics volatile, isoflurane. Lung, trachea.

Mucociliary clearance is an important defence against respiratory tract infections. The depressant effects of inhalation anaesthetic agents on mucus transport *in vivo* are well established in both animals and humans [1, 2], however, the mechanisms involved have not been elucidated. Mucus transport depends on the volume and physical properties of the mucus and on the function of the beating cilia. Cilia beat frequency is an important determinant of mucus transport rate; there is a logarithmic relation between the two such that modest reductions in cilia beat frequency are associated with substantial reductions in mucus transport rate [3, 4].

In a previous study [5] we have demonstrated depression of human respiratory cilia beat frequency with 3 MAC of the three inhalation anaesthetic agents, halothane, enflurane and isoflurane. In this investigation we have studied the duration of cilia beat frequency depression by measuring the recovery characteristics of cilia beat frequency after a period of air washout.

We have developed an alternative source of human respiratory ciliated epithelium suitable for measurement of cilia beat frequency. This is derived from explants of the inferior nasal turbinates removed from patients at elective surgical turbinectomy for a primary diagnosis of tissue hypertrophy. The preparation of these specimens, measurements of cilia beat frequency and the effects of 3 MAC of the inhalation agents followed by a period of air washout are described.

Methods

TISSUE PREPARATION

We collected the inferior nasal turbinates removed from patients at elective surgery with a primary diagnosis of tissue hypertrophy without any history of allergy. The turbinates were rinsed thoroughly in medium 199 (M199) (containing 2.2 g litre^{-1} of $NaHCO_3$ and L-glutamate, GibcoBRL Life Technologies) to remove as much blood and mucus as possible. Discs of the surface ciliated epithelium were removed using a 4-mm biopsy punch (Stiefel Laboratories, Wooburn Green, Bucks, UK). The specimens were rinsed in a mixture made from 100 ml of M199 and 2 ml of antibiotic–antimycotic solution (containing penicillin 10000 u., streptomycin 10 mg, and amphotericin 23 µg ml^{-1}, diluted 1:100; Sigma Chemical Co.). We placed the specimens in 10 ml of culture medium made from 100 ml of medium 199, 10 ml of fetal calf serum (Gibco Life Technologies), 2 ml of antibiotic–antimycotic solution and 1 ml of mixed additives containing insulin 250 µg ml^{-1}, transferrin 250 µg ml^{-1} and hydrocortisone 36 µg ml^{-1}. The specimens were then

incubated at 37 °C with occasional mixing for 1 h to separate the mucus. We then transferred the specimens into multidishes with 3 ml of culture medium per well and incubated at 37 °C in 5% carbon dioxide–air. The medium was changed after 24 h and every 3–4 days thereafter.

MEASUREMENT OF CILIA BEAT FREQUENCY

Cilia beat frequency was measured using a modification of the transmitted light technique that we have described previously [6]. The 4-mm disc of tissue was placed in a purpose-built perfusion chamber system and images of the ciliated epithelium were produced using a Nikon microscope by viewing the edge of the disc (fig. 1). The chamber consists of an aluminium block with integral channels at two sides and reversibly sealed coverslips at the top and bottom. The chamber has a depth of 0.85 mm and an internal volume of 1.1 ml. The chamber is perfused using connecting tubing passing from a bottle of Hanks buffered salt solution (HBSS) into the entry port of the chamber and out from its exit port through connecting tubing into a collecting beaker.

HBSS flows from a container immersed in a water bath maintained at 37 °C under the effect of gravity at a flow rate of 0.5 ml min^{-1} measured by a calibrated photoelectric drop counter. Air flows into the container at 1000 ml min^{-1}. The perfusion chamber is maintained at 37 ($\pm$0.1) °C using a thermostatically controlled heating element mounted on the underside of the chamber.

Images of the ciliated epithelium were produced using differential interference contrast microscopy (Nikon Diaphot 200, Nikon UK). Using a 60 × objective with a 10 × ocular lens, the image obtained from the microscope was transmitted via a video camera (Panasonic vw-CL 110-AE) to a high resolution video monitor (Sony KX-14CPI). A low pass filtered pinhead photodiode with a cut-off above 25 Hz was attached to the monitor screen and the image of the sample moved so that the cilia interfered with the light reaching the photodiode. The magnification of the optical system and aperture of the photodiode results in 3–5 cilia being captured by the photodiode and as adjacent cilia beat in phase, the frequency of interruption to the light reaching the photodiode by this number of cilia is representative of cilia beat frequency.

The output was transferred to a Gould 20-MHz cathode ray oscilloscope to confirm the detection of ciliary movements. Voltage changes across the photodiode were passed simultaneously via an analogue-to-digital converter to a computer (Dell 386sx) that samples voltage at a frequency of 200 Hz. The voltage signals were collected over a period of 15 s by recording continuously from one edge. These data were then divided into three sequential 5-s intervals for analysis.

The data were transferred to an RM Centra V466 computer and analysed by software in Mathematica 2.2 to provide a power spectrum using fast Fourier transforms. Mean frequencies less than 2 Hz were filtered out to eliminate artefacts of low frequency caused by sudden movements of the light pen or microscope stage. The peak of the power spectrum was taken to represent cilia beat frequency. The whole apparatus is mounted on a concrete block to reduce extraneous vibrations that interfere with photometric techniques of measurement. Acceptable ciliated edges for measurement were deemed to be those devoid of mucus, and at least 60 μm long.

STATISTICAL ANALYSIS

The mean of peak cilia beat frequencies from the power spectrum was computed for each sample at each time point. The data were analysed by analysis of variance for repeated measures. If this was significant the data were analysed by unpaired *t* tests with Bonferroni correction, comparing baseline cilia beat frequency with that measured at subsequent times. Significance was taken as $P < 0.05$.

Turbinate cilia survival characteristics

In order to investigate the survival characteristics of cilia from the turbinate preparations over time, we measured cilia beat frequency of samples obtained from 11 patients. These patients had a mean age of 28.3 (range 21–56) yr, all were non-smokers, receiving no regular medications, who were anaesthetized with propofol for induction of anaesthesia, morphine or fentanyl for analgesia, and isoflurane for maintenance of anaesthesia. All patients received cocaine 200 mg and adrenaline 1 mg applied topically to the nasal cavity before surgical excision.

We measured cilia survival characteristics over a period of 10 days from discs obtained from the 11 patients by measuring cilia beat frequency 1, 3, 6, 8 and 10 days after surgical excision. On each of these days we transferred six discs from any six of the patients into the perfusion chamber and measured cilia beat frequency 1–2 h after removal from the incubator. After measurement, these discs were discarded and on subsequent days this process was repeated with another set of discs from any six of the 11 patients stored in the incubator. Between six and 10 readings of cilia beat frequency were obtained from each disc.

Effect of 3 MAC of the inhalation agents and a period of air washout

Samples of human respiratory ciliated epithelium were obtained in the same manner as above from the inferior nasal turbinates of nine patients undergoing turbinectomy surgery for a primary diagnosis of turbinate hypertrophy. The patients were aged 30.1 (range 18–43) yr, seven were male, and all were healthy, non-smokers.

Discs of 4 mm from the patient's turbinates of variable storage period and up to 6 days old were mounted in the perfusion chamber. The chamber was perfused from a delivery bottle of HBSS under the effect of gravity at 0.5 ml min^{-1}. Air at 1000 ml min^{-1} was passed through a Tec 3 vaporizer before passing into the delivery bottle. The vaporizer was set at a concentration of 3 MAC for unpremedicated young adults at 37 °C; this represented 2.25 % for halothane, 5 % for enflurane and 3.6 % for isoflurane. We have shown previously that this apparatus delivers the volatile anaesthetic agents into the perfusate and equilibrates within 15 min [5]. Samples from eight patients were exposed to halothane and isoflurane and samples from nine patients to enflurane. After exposure to 3 MAC of one of the three inhalation agents for a period of 1 h, we recorded 6–10 readings of ciliary beat frequency. We then exposed the samples to air alone by perfusing them from a separate delivery bottle of HBSS and measured cilia beat frequency after exposure to air at 30-min intervals for 1.5 h.

Results

Cilia beat frequency of the turbinate samples did not change significantly over the 10-day observation period while maintained in the incubator, with mean cilia beat frequency ranging from a minimum of 13.1 (SEM 0.3) Hz to a maximum of 14.4 (0.2) Hz (MANOVA for repeated measures, $P = 0.168$) (table 1).

Turbinate explants from eight patients were exposed to 3 MAC of halothane and subsequently to air. Mean cilia beat frequency after exposure to halothane for 1 h was 9.5 (SEM 0.32) Hz, after 30 min of air washout 8.3 (0.50) Hz, after 1 h of air washout 12.6 (0.5) Hz and after 90 min of washout 13.7 (0.4) Hz. These compared with a pretreatment value of 14.3 (0.4) Hz. After 1 h of air washout, cilia beat frequency remained significantly depressed, but after 90 min of air washout it had returned to a value that was not significantly different from the pretreatment value (repeated measures ANOVA, unpaired, *t* test with Bonferroni correction, $P = 0.01$ at 1 h and $P = 0.31$ at 1.5 h of air washout compared with pretreatment control) (fig. 2).

Table 1 Cilia beat frequency (CBF) of turbinate explants over 10 days (mean (SEM))

Day	CBF (Hz)	Ciliated edges measured
1	14.0 (0.33)	109
3	14.5 (0.24)	99
5	13.8 (0.26)	123
8	13.1 (0.24)	112
10	13.2 (0.28)	97

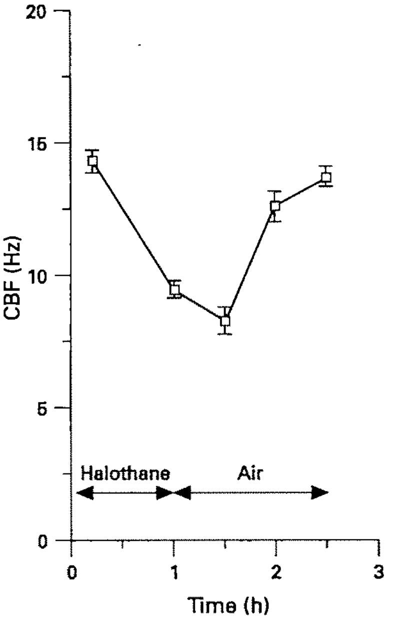

Figure 2 Cilia beat frequency (CBF) after 3 MAC of halothane for 1 h and air washout for 1.5 h (mean, SEM).

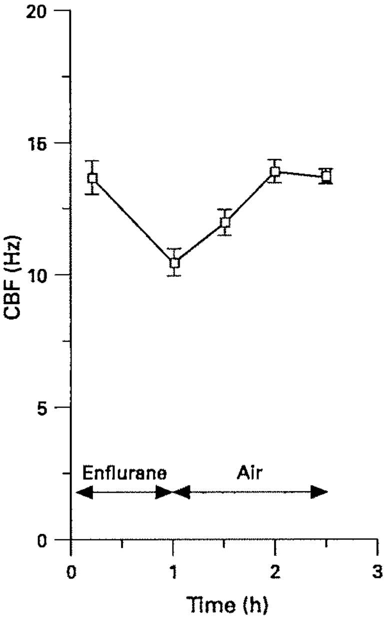

Figure 3 Cilia beat frequency (CBF) after 3 MAC of enflurane for 1 h and air washout for 1.5 h (mean, SEM).

Mean cilia beat frequency after exposure to enflurane for 1 h was 10.5 (0.51) Hz, after 30 min of air washout 12.0 (0.4) Hz and after 1 h of air washout 13.9 (0.4) Hz compared with a treatment value of 13.7 (0.6) Hz. Mean cilia beat frequency had returned to values that were not significantly different from pretreatment values after an air washout period of 1 h (repeated measures ANOVA, unpaired *t* test with Bonferroni correction, $P = 0.83$, at 1 h of air washout compared with pretreatment controls) (fig. 3).

Mean cilia beat frequency after exposure to isoflurane for 1 h was 10.6 (0.30) Hz and after 1 h of

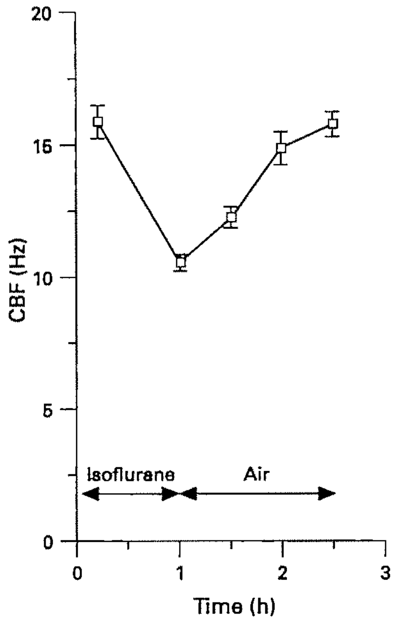

Figure 4 Cilia beat frequency (CBF) after 3 MAC of isoflurane for 1 h and air washout for 1.5 h (mean, SEM).

air washout 14.9 (0.6) Hz compared with a pretreatment value of 15.9 (0.6) Hz. Mean cilia beat frequency had returned to values that were not significantly different from pretreatment values after an air washout period of 1 h (repeated measures ANOVA, unpaired t test with Bonferroni correction, $P = 0.26$ at 1 h of air washout compared with pretreatment controls) (fig. 4).

Discussion

Cilia beat frequency of the nasal turbinate explants was unchanged during storage in a controlled environment for up to 10 days. Using this preparation there was reversible depression of cilia beat frequency *in vitro* after exposure to 3 MAC of the three inhalation agents halothane, enflurane or isoflurane; however the reduction was more prolonged after exposure to halothane compared with the two other agents.

Almost all human *in vitro* studies of respiratory ciliary function have used cytological specimens from brushings of the respiratory tract [7]. Nasal brushings are favoured because this is less invasive and cilia beat frequency is similar to bronchial ciliated specimens [8] implying nasal cilia are representative of cilia further down the respiratory tract. However, such exfoliated tissue samples may present problems as the cells are disrupted from their basement membrane, they are prone to sample movement which interferes with measurement of cilia beat frequency [9] and we have found that the samples are suitable for analysis only on the day of removal, which causes logistical restraints.

We intended originally to culture the ciliated cells from excised nasal turbinates using techniques described by Devalia and colleagues [10]; however, we noticed that the cilia of the turbinate explants remained functional for more than 1 week, despite no evidence of growth, and therefore explored the use of these preparations. We continued to use the growth factors for tissue storage as described in the earlier study [10], although this may not in fact be necessary.

Historically, *in vitro* samples of respiratory ciliated epithelium were provided by biopsy of the inferior nasal turbinates and used to diagnose such conditions as cystic fibrosis; however, such techniques became unpopular because they were performed under local anaesthesia with its attendant ciliotoxic effects and there was a risk of haemorrhage associated with this procedure. We considered that biopsies obtained from the inferior nasal turbinates had advantages over nasal brushings. Such preparations may provide a better model of *in vivo* ciliary behaviour as much of the adjacent tissue is retained and the use of larger samples reduces the likelihood of sample movement which interferes with measurement of cilia beat frequency. Furthermore, we had found that cilia of turbinate explants remained beating for up to 10 days after excision and could provide a tissue source in the laboratory. In addition, the specimens derived from the turbinates were found to have superior edges from which to measure cilia beat frequency. Using explants from excised turbinates overcomes the problems of haemorrhage from turbinate biopsies referred to earlier and the ability to store the tissue for use more than 24 h after excision overcomes the short-lived effects of topical vasoconstrictors and local anaesthetics on ciliary function [11].

Clearly such samples are derived from patients with abnormal turbinates requiring surgical excision and the possibility that their cilia may be abnormal was considered. We therefore only used tissue from turbinates removed from patients with a diagnosis of tissue hypertrophy causing nasal obstruction without any history of allergy. Other workers have demonstrated that the mucus transport rate of such turbinates is normal, implying normal mucociliary function [11].

Cilia beat frequency of explants was within the range reported by previous workers using different ciliated preparations and different measurement techniques of 11–18 Hz [9]. The range of ciliary beat frequencies we computed from the nasal brushings of 11.2–12 Hz [6] was lower than that measured from the turbinate explants of 11.6–15.0 Hz. This difference represents different patterns of interference with the light beam, the rate of which is deemed to represent ciliary beat frequency. The diameter of the light pen images 3–5 cilia in any plane and cilia throughout the depth of the field. Because adjacent cilia are co-ordinated and beat in synchrony, interference in the light path by multiple cilia imaged with each position of the light pen provides a measure of cilia beat frequency. The depth and co-ordination of adjacent cilia may well be different in cytological specimens compared with explants. With turbinate explants there is a greater depth of ciliated tissue interfering with the light path but the greater ciliary continuity may provide better co-ordination. These factors may explain the different cilia beat frequency computed. Nevertheless, for each specimen, whether nasal brushings or turbinate explants, cilia beat frequency was within the range found by other workers, was reproducible and predictably responsive to pharmacological agents.

There are few previous studies of the effects of inhalation anaesthetic agents on cilia beat frequency with which to compare this investigation; however, other studies found similar reductions in cilia beat frequency. Using rabbit trachea, Lee and Park found reductions in cilia beat frequency with 3 MAC of halothane of 22 %. This compares with our reductions at these concentrations of 25 %. In the case of enflurane, these workers found reductions in cilia beat frequency at 3 MAC of 26 % which compares with our finding of 26 % [12]. Depression of cilia beat frequency in our turbinate preparations of 33 %, 25 % and 33 % with halothane, enflurane and isoflurane, respectively, differs from that found at 1 h with nasal brushings in our previous study [5], where we found reductions of 28 %, 10 % and 2 % with these three agents. The difference is because of the use of a different tissue preparation and interestingly the results with the turbinate preparations are closer to those found by Lee and Park using rabbit trachea than our measurements from nasal brushings. The turbinate samples may be a more physiological tissue than exfoliated cells to investigate ciliary function.

Cilia beat frequency is an important determinant of mucus transport rate. Forty years ago, Hill investigated the movement of carborundum particles across frog oesophagus and rat trachea [13]. She described a hyperbolic relationship between mucus transport rate and particle velocity such that there were disproportionately larger decreases in mucus transport rates at lower particle velocities. It was hypothesized that this relationship arose because the transfer of power from the beating cilia to the mucus was most effective within a narrow range of cilia beat frequencies.

Puchelle and Zahm studied the relationship between the transport rate of sputum from bronchitic patients across mucus-depleted frog palate and the rheological properties of sputum [14]. Not surprisingly, the rheological properties of increased viscosity, increased elasticity and reduced spinnability were associated with reduced transport rates; however the most important determinant of mucus transport rate found by step-by-step multiple regression was ciliary beat frequency.

Duchateau and colleagues investigated the relationship between nasal cilia beat frequency measured photometrically from biopsies *in vitro* with nasal mucociliary clearance of dye and saccharin *in vivo* in 31 healthy volunteers [3]. A good correlation was found between the logarithm of mucus clearance rate and cilia beat frequency.

Hee and Guillerm similarly described a non-linear relationship between cilia beat frequency and mucus transport rates in sheep such that modest reductions in cilia beat frequency were associated with large reductions in mucus transport rates [4]. These studies suggest that cilia beat frequency has an important role in determining the transport rate of mucus.

The return to baseline values of cilia beat frequency after exposure to 3 MAC of halothane, enflurane and isoflurane for 1 h took 1 h for enflurane and isoflurane and 1.5 h for halothane. Interestingly, cilia beat frequency measured 30 min after ceasing exposure to the inhalation agent demonstrated some recovery with enflurane and isoflurane but a further reduction with halothane.

Differences in recovery time and effects of early washout with the three agents may be related to their different recovery characteristics from general anaesthesia which is dependent on their physical properties. Halothane has a greater lipid–water solubility coefficient than the two other agents and may take longer to diffuse out from the fat soluble tissues of the preparation. The mechanism of continuing reduction in cilia beat frequency after cessation of halothane is unknown but is an interesting finding that merits further investigation. The only comparable work is by Gyi, O'Callaghan and Langton investigating the effects of halothane alone on cilia beat frequency. Their data failed to show a reversal of effect after air washout for 50 min [15]. This concurs with our findings at 1 h.

There are no data available comparing the duration of reduction in mucus transport or clinical data comparing the incidence of infective respiratory problems with different inhalation agents.

The time for reversal of depression in ciliary function found in this study may appear to be clinically insignificant, especially in the light of the longer duration of depression of mucus transport rates demonstrated with inhalation anaesthetics *in vivo*. Forbes and Gamsu measured tantalum bronchographic clearance in dogs anaesthetized with halothane and found that 1.2 MAC of halothane administered for 2 h delayed the clearance of tantalum for more than 4 h after termination of anaesthesia [1]. This may represent additional effects of the anaesthetics on the mucus itself. Alternatively, even relatively short periods of depression of ciliary beat frequency which produce mucus stasis could alter the physical properties of mucus and therefore impair mucus transport for a longer period.

Effect of halothane on myocardial reoxygenation injury in the isolated rat heart

W. SCHLACK, M. HOLLMANN, J. STUNNECK AND V. THÄMER

Summary

Several studies have reported a protective effect of halothane on myocardial injury in an ischaemia–reperfusion situation. It is unclear if the protection is a result of the haemodynamic effects of halothane or if halothane has a specific action on ischaemia or reperfusion pathomechanisms. To examine this question, we have used an isolated rat heart model where heart rate (300 beat min^{-1}), ventricular volume and coronary flow are constant. Left ventricular developed pressure (LVDP) and release of creatine kinase (CK) were measured as variables of myocardial performance and cellular injury, respectively. Five control hearts were subjected to 35 min of low-flow (2 ml min^{-1}) anoxic and substrate-free perfusion and were then perfused for 1 h with the oxygenated buffer. In the treatment groups, halothane 0.4 mmol $litre^{-1}$ was added during the first 30 min of anoxic perfusion ($n = 5$) or during the first 30 min of reoxygenation ($n = 5$). In five additional hearts, the effect of halothane 0.4 mmol $litre^{-1}$ was tested under normoxic conditions. Mean basal CK release was 0.29 (SEM 0.13) iu g^{-1} min^{-1} and LVDP was 105.5 (4.0) mm Hg. Under normoxic conditions, halothane reduced LVDP to 52.0 (2.6) mm Hg. In control hearts, the major cell injury occurred at the onset of reoxygenation (CK release increased to 149.1 (9.1) iu g^{-1} min^{-1}) and functional recovery after 1 h of reoxygenation was poor (control LVDP, 14.2(2.)% of baseline). Halothane during anoxia attenuated myocardial injury only moderately (CK release 50.2(5.7) iu g^{-1} min^{-1}) and LVDP recovered to 30.8(3.0)% (each $P < 0.05$ *vs* control). When halothane was administered at reoxygenation, CK release was reduced to 10.1(0.9) iu g^{-1} min^{-1} and LVDP recovered to 69.4(4.9)% (each $P < .05$ *vs* control). We conclude that halothane not only attenuated ischaemic injury but had a specific protective action against reoxygenation injury. (*Br. J. Anaesth.* 1996; **76**: 860–867).

Key words

Anaesthetics volatile, halothane. Heart, ischaemia. Heart, myocardial injury. Heart, isolated preparation. Model, heart. Rat.

Reperfusion of temporarily ischaemic myocardium can initiate cellular and biochemical changes which reduce the amount of potentially salvageable myocardium ("reperfusion injury"). The term "lethal reperfusion injury" is used for the irreversible deterioration of myocardium that can be reduced by modifications of the conditions of reperfusion [1]. Some experimental evidence suggests that halothane may have myocardial protective properties in an ischaemia–reperfusion situation. Halothane anaesthesia reduced infarct size in a rabbit model with coronary occlusion and subsequent reperfusion, compared with i.v. anaesthesia with propofol, pentobarbitone or ketamine [2]. The results in non-reperfusion infarct models are contradictory; in a dog model, a reduction in infarct size was reported compared with awake controls [3], while an increase in infarct size was found in rats [4]; both studies explained their findings by the haemodynamic effects of halothane. In a pig model (with collateral circulation after a stenosis operation at a young age), halothane had no effect on infarct size [5].

Administration of halothane during hypoperfusion (low coronary perfusion pressure) to isolated guinea pig hearts, reduced the loss of adenosine and inosine during early reperfusion [6] and improved functional recovery [7]. When supplied to isolated working rat hearts before or during cardioplegic arrest, halothane did not cause preservation of ATP during the ischaemic period, but led to an improved recovery of ATP content and myocardial function during the following reperfusion period [8]. In the same model, lower calcium accumulation during cardioplegic arrest and reperfusion, and better recovery of microscopic signs of ischaemic cell damage were found when halothane was added to the perfusion medium (before and after ischaemia). Similarly, administration of halothane during hypoxic perfusion, and for the first 10 min of reoxygenation, resulted in better recovery of contractile function in isolated guinea pig hearts [9].

While most of the above studies found evidence for the cardioprotective effects of halothane, it is unclear if this protection is caused by the haemodynamic effects of halothane (i.e. a reduction in sympathetic tone, myocardial inotropy and myocardial work) or if halothane has specific protective

effects against ischaemia or reperfusion pathomechanisms. In addition, it is not possible to distinguish from these studies if the protective effects occur before, during or after the ischaemic period.

To examine these questions, we have used an isolated rat heart model so that extrinsic humoral and autonomic nervous system influences could be excluded and ventricular volume, coronary flow and heart rate could be kept constant. In order to differentiate between anti-ischaemic and protective effects against reperfusion injury, halothane was supplied to the myocardium only during a state of oxygen and substrate deprivation (simulated ischaemia) or only during the initial period, when oxygen and substrates were re-supplied (simulated reperfusion).

Materials and methods

The study was performed in accordance with the regulations of the German Animal Protection Law and local institutional regulations.

EXPERIMENTAL PREPARATION

We excised hearts from 200–250-g male Wistar rats, anaesthetized with halothane, and mounted them on a Langendorff perfusion system. Retrograde perfusion was initiated with an oxygenated modified Krebs–Henseleit buffer containing (mmol litre^{-1}): NaCl 116, KCl 4.7, $MgSO_4$ 1.1, KH_2PO_4 1.17, $NaHCO_3$ 24.9, $CaCl_2$ 2.52, glucose 8.3 and pyruvate 2.0, and was gassed with 95% oxygen–5% carbon dioxide. Flow in the system was controlled by two calibrated roller pumps (Model 7518, Cole-Parmer Instruments, IL, USA). After ligating both venae cavae, the right ventricle was vented via the pulmonary artery with a Teflon catheter (1.2-mm outer diameter). Heart rate was maintained at 300 beat mean^{-1} by atrial pacing. The stimulation voltage was maintained at 20% above threshold (control 2–4 V) and was adjusted continuously throughout the experiment (up to 12 V in reperfused hearts, if necessary). After completion of the experimental preparation, the heart was placed in a water-jacketed chamber at 37 °C, filled with humidified, warmed air. During surgical preparation, hearts were perfused at a flow rate of 15 ml min^{-1}. Coronary flow rate was adjusted in order to achieve a coronary perfusion pressure (measured by P23 ID, Statham) of 100 mm Hg and was then kept constant throughout the normoxic perfusion period.

The buffer for anoxic and substrate-free perfusion contained (mmol litre^{-1}): NaCl 126.3, KCl 4.7, $MgSO_4$ 1.1, KH_2PO_4 1.17, $NaHCO_3$ 24.9, $CaCl_2$ 2.52, and was gassed with 95% nitrogen–5% carbon dioxide. During anoxic perfusion, the heart chamber was filled with a humidified, warmed 95% nitrogen–5% carbon dioxide mixture.

A saturated solution of halothane was prepared in anoxic buffer and infused into the perfusion system near the aortic cannula at appropriate fractions of total coronary flow in order to achieve a final concentration of 0.4 mmol litre^{-1} using a calibrated syringe pump (Model 5003, Precidior Infors, Basel, Switzerland). Only glass or Teflon tubing was in contract with the halothane-containing perfusion medium. Halothane concentrations were determined in the saturated solution by gas chromatography.

HAEMODYNAMIC MEASUREMENTS

For measurements of left ventricular pressure, a latex balloon (size No. 5, Hugo Sachs Elektronik, March, Germany) was introduced into the left ventricle via the cut mitral valve. The balloon was fixed at the tip of a stainless steel cannula (length 5.9 cm) which was connected directly to a pressure transducer (Gould P23, Cleveland, OH, USA). Left ventricular pressure and, by electronic differentiation, dP/dt, were monitored continuously on an ink recorder (Gould, Mark 260, Cleveland, OH, USA). At the beginning of each experiment, the latex balloon was filled, air-bubble free, with normal saline to achieve an end-diastolic left ventricular pressure of 5 mm Hg. This volume was then held constant for the remainder of the experiment. Left ventricular pressure and coronary perfusion pressure signals were digitized at a sampling rate of 2000 Hz using an analogue-to-digital converter (Data Translation 2801, Marlboro, MA, USA) and then processed further on a personal computer system. Left ventricular end-diastole was determined as the point when left ventricular dP/dt started its rapid upstroke after crossing the zero line. Left ventricular end-systole was defined as the point of minimum dP/dt [10]. Left ventricular peak systolic pressure (LVSP), end-diastolic pressure (LVEDP), developed pressure (LVDP), and maximum and minimum dP/dt (dP/dtmax and dP/dtmin) were obtained from the digitized signals. Only hearts with an LVSP greater than 95 mm Hg during the initial control period were used for the study.

METABOLIC MEASUREMENTS

Aliquots from the perfusion medium and the coronary venous effluent perfusate were sampled anaerobically at the times indicated. Samples were processed immediately for P_{O_2} measurements (ABL 30, Radiometer, Copenhagen, Denmark). Oxygen consumption ($\dot{V}_{O_2}$) was calculated according to Fick's principle with the use of Bunsen's absorption coefficient ($\alpha' = 0.036$ µl × mm Hg^{-1} × ml^{-1}) at 37 °C as follows:

$$\dot{V}_{O_2}(\mu l\ min^{-1}) = (Pa_{O_2} - Pv_{O_2})\,\alpha'\,CF$$

where Pa_{O_2} = arterial P_{O_2}, Pv_{O_2} = venous P_{O_2} (both in mm Hg) and CF = coronary flow (ml min^{-1}).

For determination of creatine kinase (CK) release, 1-min samples of the effluent were collected at the times indicated (fig. 3). CK activity was measured with an "optimized standard method" according to the recommendations of the Deutsche Gesellschaft für Klinische Chemie (CK test, Boehringer, Mannheim, Germany). After each experiment, the dry weight of the hearts was measured. Myocardial oxygen consumption and creatine kinase release were expressed per gram of dry tissue.

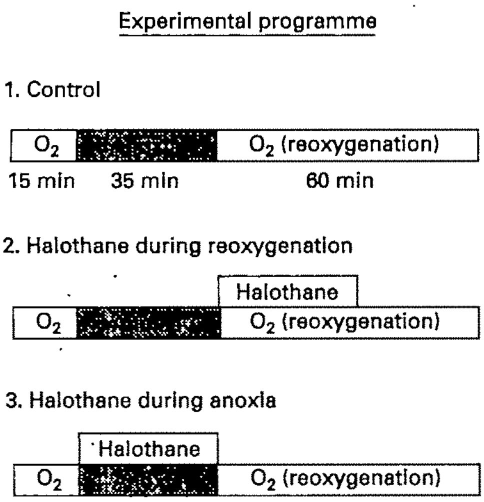

Figure 1 Experimental programme.

EXPERIMENTAL PROGRAMME

After mounting the heart on the Langendorff apparatus, a preparation and stabilization period of 30 min was allowed. The experimental programme consisted of three experimental phases: baseline, anoxia and reoxygenation (fig. 1). After a 15-min baseline period with two control measurements of all experimental variables, the hearts underwent 35 min of anoxic and substrate-free perfusion at a coronary flow of 2 ml min^{-1}. After the anoxic period, the hearts were re-supplied with oxygen, glucose and pyruvate by changing back to the initial normoxic perfusion conditions for 1 h (reoxygenation). Halothane was added to the perfusion medium to achieve a concentration of 0.4 mmol $litre^{-1}$ during the first 30 min of anoxic perfusion (halothane–anoxia, $n = 5$) or during the first 30 min of reoxygenation starting with a 1-min wash-in of the substance (halothane–reoxygenation, $n = 5$). Five hearts served as controls and underwent the anoxia–reoxygenation programme without receiving halothane. Five hearts received halothane 0.4 mmol $litre^{-1}$ for 15 min during normoxic perfusion conditions for assessment of the haemodynamic effects of halothane on normal myocardium in this experimental model.

DATA ANALYSIS

Data are presented as mean (SEM). The effects of halothane on normal myocardium were assessed by Student's *t* test for paired observations. In the anoxia–reoxygenation experiments, statistical analysis was performed by two-way analysis of variance (ANOVA) for time and treatment (experimental group) effects. If an overall significant difference between groups was found, comparison was made for each time using one-way ANOVA followed by the Tukey–Kramer post-test when appropriate.

Results

A total of 28 hearts were used. Eight did not fulfil the predefined quality criteria (LVDP > 95 mm Hg at a coronary perfusion pressure of 100 mm Hg) and were excluded from the study. Mean dry heart weight was 0.168 g (range 0.15–0.18 g).

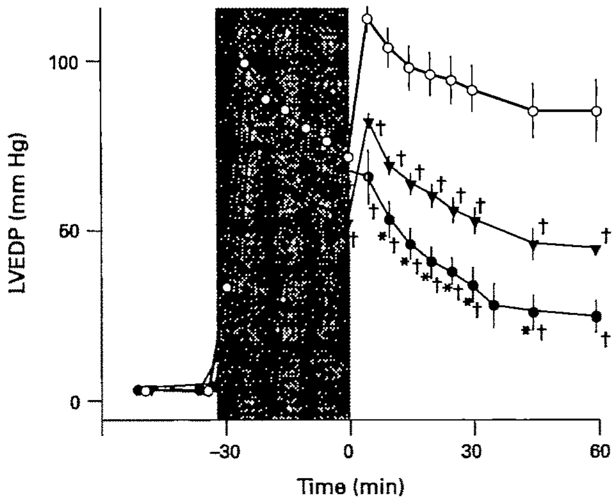

Figure 2 Effect of halothane 0.4 mmol $litre^{-1}$, given during the first 30 min of anoxic perfusion (▼) or during the first 30 min of reoxygenation (●), on left ventricular end-diastolic pressure (LVEDP) as a variable of myocardial contracture (mean, SEM). †$P < 0.05$ *vs* control hearts; *$P < 0.05$ halothane–anoxia *vs* halothane–reoxygenation. Note that in control hearts (○) contracture developed with the onset of reoxygenation. This phenomenon was absent when halothane was given during reoxygenation, but persisted when halothane was given during anoxia.

HAEMODYNAMIC FUNCTION

Basal values and effect of halothane on normal myocardium

In five additional hearts, we investigated the effects of halothane 0.4 mmol $litre^{-1}$ on normal myocardium (measurements were made after 15 min under steady state conditions). Halothane reduced LVDP from 99.2 (1.8) to 52.0 (2.6) mm Hg ($P < 0.001$). LVEDP was 4.0 (0.3) mm Hg before and 2.9 (0.4) mm Hg after administration of halothane ($P < 0.05$). $\dot{V}O_2$ decreased from 869.6 (29.5) to 681.0 (21.0) µl min^{-1} g^{-1} ($P < 0.001$). After discontinuation of halothane, recovery to baseline values occurred within 5 min.

Anoxic contracture development

During anoxic perfusion, a progressive increase in LVEDP was noted in all groups (fig. 2). the time of onset of anoxic contracture was defined as the time at which the end-diastolic pressure had increased by 2 mm Hg; it was similar in all three groups (control 140 (17) s; halothane–anoxia 133 (18) s; halothane–reperfusion 150 (10) s). The maximum level of contracture was reached within 10 min (ns between groups) and LVEDP decreased gradually during the anoxic period. The level of contracture was reduced in the halothane–anoxia group; at the end of the anoxic period, LVEDP was 55.2 (2.0) mm Hg compared with 71.2 (5.1) mm Hg in control hearts ($P < 0.05$) and 69.2 (4.3) mm Hg in hearts treated during reperfusion ($P < 0.05$).

End-diastolic pressure after reoxygenation

The main effect on functional recovery during reoxygenation was a difference in the behaviour of end-diastolic pressure of the experimental groups (fig. 2). In the control group, there was an increase in LVEDP by a mean of 40.0 mm Hg with the onset of reoxygenation (reoxygenation-induced contracture), followed by a slow decrease in LVEDP during the rest of the reoxygenation period to 85.3 mm Hg at 60 min of reoxygenation. The hearts treated with halothane during anoxia had a lower LVEDP before the onset of reoxygenation (51.8 mm Hg) than the two other groups, but then also showed reoxygenation-induced contracture (by 30.0 mm Hg). LVEDP was, however, lower compared with untreated hearts and showed a faster recovery to 43.9 mm Hg at 60 min of reoxygenation. In the group treated with halothane at reoxygenation, reoxygenation-induced contracture was absent and LVEDP decreased rapidly, reaching 24.2 mm Hg at 60 min of reoxygenation.

Recovery of contractile function during reoxygenation

LVDP was similar in all groups (about 105 mm Hg) during baseline measurements before anoxia and then declined rapidly to 0 mm Hg during anoxic perfusion (fig. 3, top). In control hearts, recovery of LVDP started at 30–40 min of reoxygenation and reached 15.4 % of baseline values after 60 min. In hearts treated with halothane during anoxia, recovery was better, starting at 20–30 min of reoxygenation and reaching 32.4 % of baseline values. The best functional recovery was seen in hearts treated with halothane only during reoxygenation; recovery started within the first 5 min and reached 70.4 % of baseline at 60 min of reoxygenation. After discontinuation of halothane at 30 min of reoxygenation, LVDP showed a steep increase by a mean of 32 mm Hg within the next 5 min.

LVSP (table 1) in this experimental model can be regarded as the sum of LVEDP and LVDP. Consequently, it showed a different behaviour between the three groups. In control hearts, LVSP remained almost unchanged during the course of the experiment. In hearts treated with halothane during anoxia, LVSP was reduced compared with baseline values at the onset of reoxygenation (to 81.8 (2.6) mm Hg) and remained at a lower level throughout the reoxygenation period. In hearts that received halothane during the first 30 min of reoxygenation, LVSP was reduced during the first 30 min and then increased after discontinuation of halothane to values not different from baseline.

METABOLIC MEASUREMENTS

Creatine kinase

In untreated control hearts, CK release, as an indicator of cell damage, did not increase significantly during anoxic perfusion but increased markedly during the early reoxygenation phase with a peak value (149.1 iu min^{-1} g^{-1}) at 1 min of reoxygenation (fig. 3, bottom). CK release was increased in control hearts during the first 40 min of reoxygenation. In hearts treated with halothane during anoxia, maximum CK release was reduced to 33.7 % compared with control hearts and in hearts treated with halothane only during early reoxygenation to 6.7 %. As a consequence, total cumulative CK release (fig. 4) was reduced significantly when halothane was given during reoxygenation (60 (12) iu g^{-1}) compared with untreated controls (712 (52) iu g^{-1}) or hearts treated with halothane during anoxia (188 (8) iu g^{-1}).

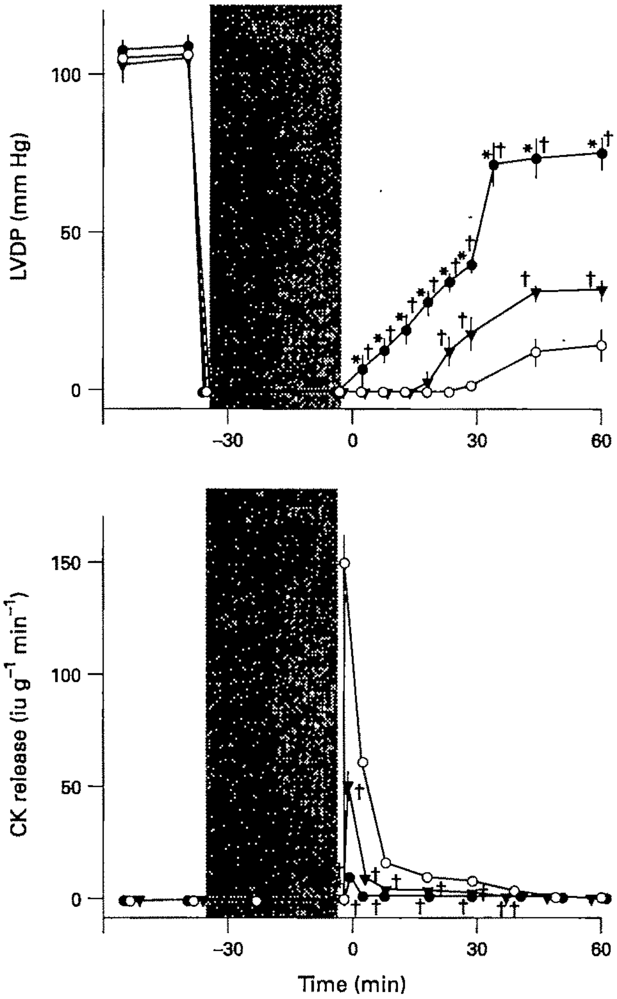

Figure 3 Effect of halothane 0.4 mmol litre^{-1} given during the first 30 min of anoxic perfusion (▼) or during the first 30 min of reoxygenation (●), on left ventricular developed pressure (LVDP) as a variable of myocardial function, and release of creatine kinase (CK) into the coronary venous effluent as a variable of cellular damage (mean, SEM). †$P < 0.05$ *vs* control hearts (○); *$P < 0.05$ halothane–anoxia *vs* halothane–reoxygenation. Top: Functional recovery was best when halothane was given during reoxygenation. Bottom: Major cellular injury, as evident from the release of an intracellular marker enzyme, occurred at the onset of reoxygenation and was reduced most markedly when halothane was present at reoxygenation.

Oxygen consumption

$\dot{V}O_2$ was approximately 1000 µl min^{-1} g^{-1} dry tissue under baseline conditions in all three groups (table 1). In control hearts, $\dot{V}O_2$ increased to 100 % of baseline with the onset of reoxygenation and then decreased to 57.3 % at the end of reoxygenation. In hearts treated with halothane during the anoxic period, $\dot{V}O_2$ was 108 % of baseline at the onset of

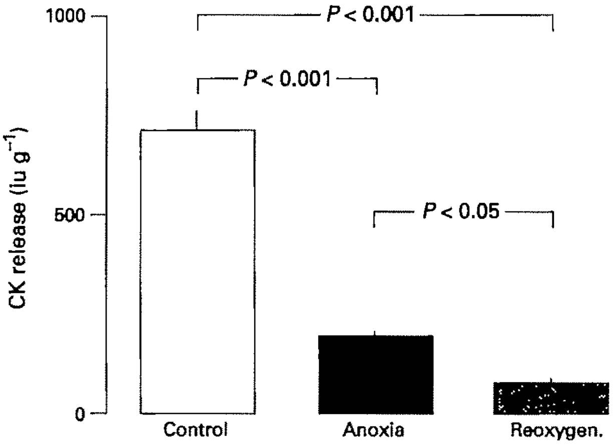

Figure 4 Effect of halothane 0.4 mmol litre^{-1} given during the first 30 min of anoxic perfusion (Anoxia) or during the first 30 min of reoxygenation (Reoxygen.) on the total amount of creatine kinase (CK) released during anoxia and reoxygenation (mean, SEM).

reoxygenation and then decreased to 70.8%. In hearts treated with halothane during the first 30 min of reoxygenation, $\dot{V}o_2$ was lower during the initial reoxygenation period compared with the two other groups; it was 83% of baseline at 5 min reoxygenation and then decreased to 75% at 15 min of reoxygenation. After discontinuation of halothane, $\dot{V}o_2$ increased again in this group, reaching 84% of baseline at the end of the reoxygenation period.

Discussion

We have found, in an isolated rat heart model, that halothane only moderately attenuated myocardial injury during a state of oxygen and substrate deprivation, but had a pronounced protective action on myocardial injury at reoxygenation after an anoxic period.

CRITIQUE OF METHODS

In this study, we used a period of anoxic and substrate-free perfusion to simulate myocardial ischaemia, and subsequent reoxygenation and resupply of metabolic substrates to simulate myocardial reperfusion. Although the terms "reperfusion" and "reoxygenation" and the terms "anoxic perfusion" and "ischaemia" are often used synonymously, some important differences should be taken into account in the interpretation of our results. First, anoxic perfusion was used to allow the possibility of halothane administration during simulated ischaemia. Anoxic perfusion may have attenuated the development of intracellular acidosis and accumulation of intracellular adenosine; *in vivo*, both mechanisms may have some endogenous myocardial protective effects. Second, during buffer perfusion there are no neutrophils and thrombocytes; both may interact with the development of *in vivo* ischaemia–reperfusion injury (for review see [11]). Thus this experimental model excludes some of the (patho)mechanisms that play a role in an *in vivo* ischaemia–reperfusion situation.

In most previous *in vitro* and *in vivo* studies that have found a reduction in myocardial injury in an ischaemia–reperfusion situation in the presence of volatile anaesthetics, the beneficial effects were explained primarily by the action of anaesthesia on sympathoadrenal activity and on myocardial oxygen demand [6, 7, 9], rather than by any intrinsic property of the volatile anaesthetics. Some studies also discussed a protective effect on myocardial reperfusion injury [8, 12], but the interpretation of these data is difficult because halothane was given also before reperfusion (during a period of ischaemia [13], hypoxia [6, 7, 9] or cardioplegic arrest [8]) and often also before the onset of oxygen deprivation (hypoxia [6, 7, 9], ichaemia [13] or cardioplegic arrest [8, 12]). However, it is known that other negative inotropic drugs (e.g. calcium antagonists or β blockers) exert potent anti-ischaemic effects when given before or during ischaemia. As the extent of reperfusion-induced injury is proportional to the severity of the preceding ischaemia, it is impossible from these studies to ascertain if a protective effect is caused by a reduction in reperfusion injury or if it is secondary to an anti-ischaemic action.

In order to reduce haemodynamic side effects in the experimental model used in this study, we controlled heart rate, ventricular volume and coronary flow. Nevertheless, loading conditions between the experimental groups were not identical during reoxygenation; halothane-treated hearts had a higher LVDP and consequently a greater wall stress during reoxygenation compared with untreated controls. However, in the treatment group, myocardial injury was reduced markedly and increased loading conditions should have had the opposite effect. Therefore, differences in loading conditions can be regarded as a "conservative" effect that cannot explain the observed protection.

To differentiate between anti-ischaemic effects and protection against reperfusion injury, halothane was administered only during the first 30 min of anoxia or for the first 30 min of reoxygenation. Because the danger of impending contracture in the reoxygenated myocardial cell is evoked by the reactivation of mitochondrial energy production [14], administration of halothane was started with a 1-min anoxic wash-in of the substance into the perfusion system before reoxygenation in the halothane–reoxygenation group. In the hearts treated with halothane during the anoxic perfusion, halothane was discontinued 5 min before the onset of reoxygenation. Although we found in preliminary experiments in normoxic hearts that a 5-min washout of halothane was sufficient for complete reversal of the haemodynamic effects of halothane, it should be taken into consideration that an unknown amount of halothane may have been present at the onset of reoxygenation in this group. Therefore, some protection against reoxygenation-induced injury may have been present in addition to the anti-ischaemic effect in this experimental group.

INTERPRETATION OF RESULTS

In the ischaemia–reperfusion model used in this study, the manifestation of lethal cell injury occurs at the onset of reoxygenation, as evident from the massive release of creatine kinase, an intracellular marker enzyme. Because the extent of this injury can be reduced through an intervention at the time when oxygen is re-supplied, cell injury represents not only the manifestation of ischaemic injury, but in part true "reperfusion injury" in the sense defined by Rosenkranz and Buckberg [1] as "metabolic, functional and structural consequences of restoring coronary arterial flow...that can be avoided or reversed by modifications of the conditions of reperfusion". The mechanisms underlying the type of "reperfusion injury" that occurs in the present model have been studied in the past years; one important mechanism is cellular contracture that occurs at reoxygenation and most likely results from the combination of a high cytosolic calcium concentration, accumulated during the anoxic period, and the re-supply of metabolic energy with the onset of reoxygenation (for review, see [15]). Contracture may result in mechanical disruption of the cells [15] that have an increased mechanical fragility after the period of energy depletion [16]. Consequently, in the isolated heart model used in this study, reoxygenation induced a sudden increase in LVEDP (contracture) and a high myocardial oxygen consumption. Simultaneously, there was a massive release of creatine kinase. Oxygen consumption decreased to approximately 57% of baseline values, probably an effect of the reduced amount of viable myocardium. These findings were identical to others in similar models [17–19].

When present at the critical moment of reoxygenation, halothane had a pronounced protective effect against this type of "reperfusion injury"; it completely prevented the development of contracture and reduced the peak release of creatine kinase to 6.7% of that seen in untreated hearts. In addition, myocardial oxygen consumption was reduced compared with untreated controls despite an increased mechanical work index (LVDP). From these results it seems likely that the protective effect of halothane against "reperfusion injury" consists of attenuation of cellular contracture.

It was clearly beyond the scope of the study to identify the cellular mechanisms of the protective effect of halothane against reperfusion-induced contracture. However, in parallel with the recent understanding of the underlying pathophysiology, some protective mechanisms have been identified, and from the mechanisms of action that have been described for halothane in normal myocardium, several protective mechanisms against contracture development are possible. First, contractile inhibition at the level of the myofibrils. It has been shown previously that temporary block of the contractile apparatus (using the substance BDM) can prevent or reduce "reperfusion injury" in isolated cardiomyocytes [20], isolated hearts [17] and intact hearts [21]. Even partial contractile inhibition (by SIN-1C) had a protective effect in isolated hearts [18] and *in vivo* [22], probably by reducing developed force in the re-energized cardiomyocyte below a critical threshold [22]. A reduction in the calcium sensitivity of myofibrils by halothane has been described [23, 24] and the resulting contractile inhibition may have contributed to the observed protective effect.

Second, effects on intracellular calcium. The high intracellular calcium concentration accumulated during the ischaemic period represents the trigger for cellular contracture during reperfusion. With the onset of reperfusion, intracellular calcium may increase even further by calcium influx via the Na^+–Ca^{2+} exchanger [25], and phasic oscillations of intracellular calcium occur as a result of pathological calcium cycling by the sarcoplasmic reticulum [26]; both mechanisms can increase further contractile activation. In normal myocardium, inhibition of the Na^+–Ca^{2+} exchanger by halothane has been shown [27]. In addition, halothane interferes with the calcium handling of the sarcoplasmic reticulum (of normal myocardium) by direct inhibition of sarcoplasmic function [28] and an action on the calcium-dependent calcium-release channel [29]. At low intracellular pH and ATP concentrations (conditions similar to early reperfusion), halothane may have an opposite effect on sarcoplasmic reticulum calcium handling, enhancing calcium uptake [30]. Halothane may also interact with the Na^+–H^+ exchange mechanism, as has been shown in the erythrocyte model [31]. Inhibition of the Na^+–H^+ exchanger at reperfusion preserves intracellular acidosis, prevents pathological calcium cycling [32] and protects myocardial structure and function [19]. Halothane also inhibits calcium influx via the voltage-dependent calcium channel and this may be an important mechanism for the reduction of myocardial contractility by halothane in normal myocardium [33]; but for the development of reperfusion injury the voltage-dependent calcium channel may play only a minor role [15]. It should be taken into account that the cellular mechanisms of action mentioned above have been shown for halothane in normal myocardium or cellular organelles isolated from normal myocardium and that the possible protective effects mentioned on the pathomechanisms of reperfusion injury remain speculative. However, this study provides evidence that the main protective mechanism must be involved in the prevention of reoxygenation-induced cellular contracture. The mechanisms of action of halothane on ischaemic-reoxygenated myocardium are now under investigation.

Besides the markedly reduced cellular injury at the onset of reoxygenation, the hearts showed a faster and better functional recovery when halothane was given during reoxygenation in a concentration that reduced LVDP as a variable of contractility in normal hearts by about 50%. The improved functional recovery may be simply the result of a greater amount of viable myocardium in these hearts because of the reduction of lethal reperfusion injury. In addition, a direct influence on non-lethal cell injury that results in post-ischaemic myocardial dysfunction (myocardial stunning) must also be discussed; *in vivo*, such attenuation of myocardial stunning has been found in different experimental models [13, 34, 35].

Halothane was also protective when given during anoxic perfusion (reduced creative kinase release and improved functional recovery), but the protective effect was smaller. A beneficial role of volatile anaesthetics during myocardial ischaemia was observed in 1969 by Spieckermann and colleges [36], who found a prolonged tolerance to global ischaemia and enhanced preservation of high energy compounds in dog hearts. It was shown recently that halothane slows calcium accumulation during "ischaemia" [12]. Consequently, the level of diastolic tension was reduced in the present model. However, reoxygenation-induced contracture still occurred in these hearts and initial $\dot{V}O_2$ during reoxygenation was high despite a reduced myocardial work index. Thus the hearts showed typical signs of reperfusion injury, although the extent of reperfusion injury was reduced. As the latter depends mainly on the severity of the preceding ischaemia, the presence of halothane during an ischaemic period seems to attenuate ischaemic injury. This is also in accordance with the findings of Lochner and co-workers [12], who found reduced cellular damage when halothane was given during cardioplegic arrest to isolated rat hearts.

Acknowledgement

We thank Mr Husmann from the Max Planck Institute for Carbon Research, Mühlheim, Germany, for his help with the design of the method of halothane administration and for measurements of halothane concentrations. The help of Professor Novotny, Institut für Anatomie, Heinrich-Heine Universität Düsseldorf, Germany is also gratefully acknowledged.

SHORT COMMUNICATIONS

Occupational x-ray exposure of anaesthetists

C. McGowan, B. Heaton and R. N. Stephenson

Summary

Lithium fluoride thermoluminescent dosimeter chips were used to measure the radiation dose received by anaesthetists caused by the use of image intensification during a typical 4-week period in an orthopaedic theatre. These were used to estimate an annual dose, for comparison with dose limits, to ascertain if anaesthetists should be included in personnel monitoring services. Doses proved to be below detectable limits; hence anaesthetists are at minimal risk from occupational exposure to radiation. The orthopaedic theatre is believed to use more x-rays than other theatres, so exposure elsewhere should also be undetectable. *(Br. J. Anaesth.* 1996; 868–869)

Key words

Anaesthetist, risks. Operating rooms, contamination.

Although anaesthetists can frequently be exposed to ionizing radiation, in the form of scatter from diagnostic x-rays used during some theatre procedures, little work has been done to determine the level of exposure and whether or not they might be at risk. It is generally assumed that the doses are very low, and consequently anaesthetists are often not included in radiation protection personnel monitoring services. In this study we tested this assumption of negligible exposure.

Previous studies [1–3] relating to dose measurements in anaesthetists have tended to address the issue as incidental to measurements on the patient and other theatre staff, often examining exposures incurred during specific procedures only, rather than obtaining an assessment of total annual exposures caused by all work. Such an assessment could then be used as a basis for the decision as to whether or not anaesthetists should be included in personnel monitoring services.

Methods and results

Careful consideration was given to the best way in which to obtain a reasonable estimate of the annual dose. To this end, advice was sought from anaesthetists, radiographers and theatre staff as to the operating theatres in which most x-rays were used. The conclusion reached was that orthopaedic theatres used the most x-rays, and it was decided to measure the doses received in the orthopaedic trauma theatre. If these doses proved to be low, it was felt that it could be concluded that doses in other theatres would also be low, and hence no anaesthetist would be at risk.

A period of 4 weeks was devoted to the initial measurements in the trauma theatre. The total number of operations performed during this time and the number using x-rays were noted, and compared with the same values (obtained from theatre records) for the 4 months before the start of the study. It was possible to show that the period of study was typical as regards the use of x-rays, and thus the doses meaured could be extrapolated to provide a reasonable estimate of the annual dose received by anaesthetists in theatre.

All dose measurements were made using lithium fluoride thermoluminescent dosimeter (TLD) chips (TLD 100, Harshaw Chemical Company). These were selected for their low dose threshold, reasonable tissue equivalence, and small size, so that the wearers would not be unduly inconvenienced. These chips had a minimum detectable dose of 0.1 mSv.

It was suspected that the dose received by the anaesthetist during a single operation or even during a single working session would be too low to measure, and hence it was decided to conduct the measurement continuously over 4 individual weeks and also for the 4 weeks together, in the event that the weekly dose was below the detection limit. This was achieved by transferring the dosimeters between anaesthetists, to obtain cumulative weekly and monthly dose meaurements. Doses were monitored only during the day, from Monday to Friday; the weekend and evening operations were excluded. In reality, an individual anaesthetist would only work a maximum of about two sessions per week in the trauma theatre at Aberdeen Royal Infirmary (excluding emergency hours) and therefore an estimate of the annual dose from the above would be a "worst case scenario" value for the hypothetical situation of a single anaesthetist working in theatre all of the time.

Six positions were selected at which the doses would be measured. These were the forehead, to obtain an estimate of the eye dose as the lens of the eye is vulnerable to ionizing radiation; thyroid;

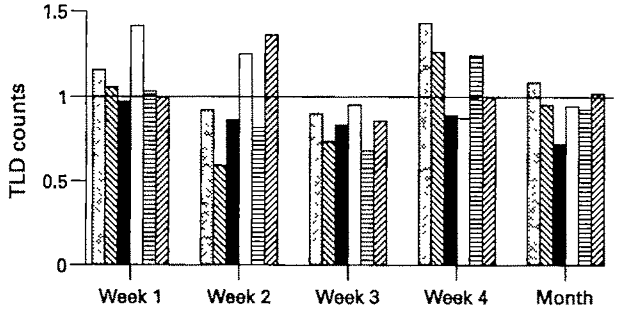

Figure 1 Total number of counts, including background, recorded on the lithium fluoride thermoluminescent dosimeter (TLD) chips worn by the anaesthetists, compared with the average background counts. ◫ = Over apron, ▧ = under apron, ■ = right side, □ = left side, ▤ = eye, ▨ = thyroid.

torso, to provide a measure of the whole body dose, both under and outside the protective lead rubber aprons worn when x-rays are used in theatre; and on the left and right sides of the body, where the lead apron does not always fasten securely. Thus at any one time the anaesthetist wore 12 TLD; six to measure the weekly dose and six to measure the monthly dose.

All TLD used for the experiment were initially read out at the same time and all started accumulating a background dose from that time. After completion of the individual exposure periods, the TLD were read after an interval of 24 h rather than waiting until the end of the experiment and reading all at the same time. (In the latter case background TLD are normally kept for the full duration of the experiment and on reading out a constant background dose rate is assumed.) This readout method was adopted, partly because time constraints implied that any procedural changes had to be implemented rapidly but also to reduce variations in signal fading which may have occurred if low doses were received. In order to measure the background, a group of 21 TLD was selected, kept initially for 7 days, and every 3 days, three were read out and the average value calculated. Thus it was possible to determine approximately by the way in which the background signal built up with time, and hence calculate the expected number of background counts on a TLD that had been used for a measurement. The calculated value is only an estimate as the total background level consists of counts produced by background radiation, and a signal inherent in the TLD which varies slightly between chips, so real background count values fluctuate around the estimated level.

Figure 1 shows the counts detected by each of the TLD during each week and for the whole month. These values are inclusive of the background counts, and each is shown normalized to the estimated background count value for that particular group of TLD. The background value is represented by the horizontal line.

As can be seen from the histogram, the recorded counts fluctuated approximately equally above and below the background level, as would occur if no doses were recorded, because of the variation in the inherent signals on the chips. Thus the dose received by the anaesthetists, even over the course of a month, was below or approximately equal to the limit of detection of the TLD.

Comment

As it was shown that the 4 weeks of the study had a typical distribution of operations involving x-rays, the doses recorded in those 4 weeks could be used to estimate an annual dose. However, as the measured dose was below the detection limit, it was effectively zero, and therefore this estimate cannot be made accurately. But even though the monthly dose was undetectable, the annual dose may reach detectable levels, and a more extended study would be needed to determine if this is the case. However, such a study would not be necessary as if the monthly dose is undetectable, the annual dose must be extremely small, and negligible compared with the recommended dose limit of the Ionizing Radiations Regulations of 15 mSv year^{-1} for a non-classified radiation worker [4], and also to future recommendations of the International Commission on Radiological Protection [5]. Moreover, because it is generally agreed that trauma theatres use more x-rays than any other operating theatre, the dose received in other theatres should be even smaller. Over the course of a year an anaesthetist moving between theatres should receive a negligible dose of ionizing radiation and thus is not at risk. Hence it is not necessary to include anaesthetists in personnel monitoring services.

Total i.v. anaesthesia for transcranial magnetic evoked potential spinal cord monitoring

J. W. H. Watt, M. H. Fraser, B. M. Soni, P. K. Sett and R. Clay

Summary

Continuous intraoperative monitoring of transcranial magnetic motor evoked potentials (TcMMEP) can warn the surgeon of motor tract damage more effectively than somatosensory evoked potentials. As a non-invasive technique it is especially useful during post-traumatic internal fixation and is applicable whatever the level of the spinal cord at risk. Inhalation and many i.v. anaesthetics block the single pulse TcMMEP but a total i.v. anaesthetic regimen based on methohexitone, alfentanil and ketamine was effective in seven patients undergoing post-traumatic internal fixation. Consistent TcMMEP of 100–1000 mcV were obtained in all patients, with a latency change of only 2 ms above preoperative values. Good cardiovascular stability was maintained during operation. (*Br. J. Anaesth.* 1996; **76**: 870–871).

Key words

Anaesthetics, i.v. monitoring, evoked potentials. Spinal cord, evoked potentials.

Spinal column surgery is associated with a risk of permanent neurological damage and it is imperative to monitor reliably and repetitively the integrity of the long motor tracts throughout surgery and before operation. Dependence on the use of somatosensory evoked potentials may give a false sense of security [1]. Currently, difficulties in obtaining responses in anaesthetized patients [2, 3], even in the absence of neuromuscular block, are impeding wider adoption of transcranial magnetic motor evoked potential (TcMMEP) monitoring. Previous unpublished work at this centre established that a combination of ketamine, alfentanil and etomidate permitted TcMMEP monitoring. A recent publication of experimental work in dogs demonstrated that methohexitone also had a permissive effect in this situation [4], despite contrary effects with thiobarbiturates.

The aim of this study, therefore, was to use a reliable total anaesthesia (TIVA) regimen for spinal surgery with intraoperative TcMMEP monitoring.

Method and results

In seven adult patients undergoing internal fixation of the spinal cord after spinal column trauma, we recorded continuous intraoperative TcMMEP from a suitable muscle. Selection of the latter depended on the level of neurological injury and was either below the fracture in patients in whom the muscle was neurologically intact or incomplete ($n = 3$), or on the last intact myotome of neurologically complete lesions ($n = 4$). Two patients had cervical injuries and the remainder thoracolumbar. The stimulus was provided by a Magstim model 200 single pulse machine using a double 70-m cone coil which produces a peak magnetic field strength of 2.0 Ta. Recordings were made using a Medelec MS 91a machine. Peak-to-peak voltage and latencies were assessed continuously and compared with preoperative values. As voltage responses are always less during anaesthesia, the Magstim output of 100% was usually used in the intraoperative period.

Patients were premedicated with either promethazine or morphine, deliberately avoiding benzodiazepines [3]. The anaesthesia regimen comprised a bolus dose of methohexitone 2 mg kg^{-1} for hypnosis, followed by 100 µg kg^{-1} for 30 min and then 75–50 µg kg^{-1} min^{-1}. Analgesia was provided by a bolus dose of alfentanil 50 µg kg^{-1} followed by 5 µg kg^{-1} min^{-1} for 15 min and 1 µg kg^{-1} min^{-1} thereafter. Ketamine was used in a low dose of 20 µg kg^{-1} min^{-1} decreasing to 14 µg kg^{-1} min^{-1} after 1 h, to augment anaesthesia and improve TcMMEP amplitude responses [5]. One bolus of a neuromuscular blocking agent was used in most instances at induction of anaesthesia for initial airway control, but before recording TcMMEP, subsequent recovery of neuromuscular function was confirmed using a conveniently located peripheral motor nerve. The adequacy of the TIVA-based anaesthesia was assessed with familiarity according to cardiovascular stability with the aid of invasive arterial pressure monitoring, and by the absence of reflex body movements in response to surgical stimuli. All patients were awakened within 30 min of discontinuation of the TIVA, albeit with the aid of doxapram or naloxone, and none had psychomimetic side effects from ketamine.

Reliable TcMMEP were obtained in all patients using this TIVA regimen, latencies being within 2 ms of preoperative values. When anaesthesia in an individual patient was optimized, if necessary even by elimination of 25% nitrous oxide from the air and

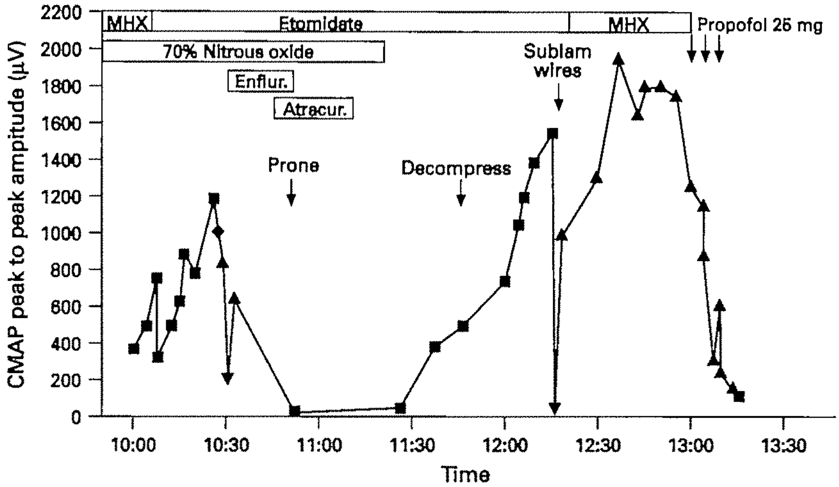

Figure 1 Compound muscle action potential from the tibialis anterior in patient No. 1 produced by transcranial magnetic motor stimulation during total i.v. anaesthesia with methohexitone (MHX), etomidate or propofol. ■ = 100% Magstim output, ◆ = 90% output, ▲ = 80% output, ▼ = 70% output.

oxygen mixture, voltage was at least 100 mcV in all patients. It was noticeable in many cases that TcMMEP increased permanently after surgical decompression of the compromised spinal cord (Fig. 1). There was a temporary loss of TcMMEP in two patients after passage of sublaminar wires but no patient sustained neurological deterioration after operation. Two factors affecting TcMMEP amplitude during surgery were variation in the intensity of the surgical stimulus and changes in the position of the hand-held stimulation coil. However, rogue weak TcMMEPs were discounted by repeating stimuli every 2–5 min and examining the stability of the latency.

Comment

Before this series in which methohexitone proved successful, etomidate was the principal hypnotic, used after consultation with the Medicines Control Agency and after local Ethics Research Committee approval. A direct comparison was made between etomidate and methohexitone in patient No. 1 in this series and as there were comparable TcMMEP with both agents (fig. 1), etomidate was abandoned thereafter, although 24-h tetracosactrin responses had recovered in seven patients with an etomidate-based regimen.

Propofol and inhalation agents are powerful suppressants of both magnetic and electrical transcranial evoked potentials, as confirmed in patient No. 1 (fig. 1). The evidence suggests that this effect takes place at the spinal motoneurone or interneurone [2]. While the next generation of magnetic stimulators use the summation effect from double or quadruple pulsing and are better able to overcome anaesthetic-induced TcMMEP depression [6], our experience indicates that the methohexitone-based TIVA regimen provides the greatest potential for non-invasive monitoring of spinal motor tract integrity and would cause less hypotension than propofol. The exact role of ketamine has yet to be clarified.

Spinal clonidine produces less urinary retention than spinal morphine

M. GENTILI AND F. BONNET

Summary

We have conducted a double-blind, randomized study in two groups of 20 patients each, undergoing hip surgery during spinal anaesthesia, to compare the incidence of urinary retention after spinal morphine or clonidine. Patients received 0.5% spinal bupivacaine 15 mg combined with either clonidine 75 µg or morphine 0.2 mg. After operation, patients were examined for micturition, bladder distension, or both; when they failed to void, they received naloxone 0.2 mg, and if bladder distension persisted, a catheter was inserted. At 12 h, all patients in the morphine group but only five in the clonidine group had bladder distension, and at 24 h this was present in seven and one patient in the morphine and clonidine groups, respectively ($P < 0.001$). Naloxone was given in 16 and one, and a catheter was placed in one and six patients in the morphine and clonidine groups, respectively ($P < 0.001$). We conclude that spinal clonidine impaired bladder function to a lesser extent than morphine. (*Br. J. Anaesth.* 1996; **76**: 872–873)

Key words

Anaesthetic techniques, subarachnoid. Analgesics opioid, morphine. Complications, urinary retention. Sympathetic nervous system, clonidine.

Urinary retention is common after spinal administration of opioids [1, 2]; it may be distressing and is a serious limitation to the use of spinal opioids in daily practice, especially in orthopaedic surgery where patients do not routinely have a bladder catheter.

Spinal clonidine strengthens local anaesthetic block and produces postoperative analgesia, with side effects such as hypotension, bradycardia and sedation, but there are no reports of urinary retention [3]. If spinal clonidine is unlikely to promote urinary retention in postoperative patients, it could be an alternative to spinal morphine when bladder catheterization is considered harmful. In this study we tested the hypothesis that spinal bupivacaine with clonidine resulted in a lower frequency of urinary retention than spinal bupivacaine with morphine.

Methods and results

After obtaining informed consent and Ethics Committee approval, we studied 40 ASA II–III patients undergoing hip surgery. Patients were excluded if they were receiving drugs which may interfere with clonidine or morphine, or if they had pathology of the urinary tract.

Patients were premedicated with flunitrazepam 1 mg orally, and allocated randomly to one of two groups. All received spinal 0.5% isobaric bupivacaine 15 mg (3 ml); in addition, patients were given spinal morphine 0.2 mg (group M) or clonidine 75 µg (group C). Maximal extension of the anaesthetic block was evaluated by pinprick.

Ringer's lactate solution was infused at a rate of 15 ml kg^{-1} h^{-1} during surgery and at 3 ml kg^{-1} h^{-1} after operation for 24 h. Blood loss was replaced during surgery with colloids and autologous blood. When hypotension (decrease in systolic arterial pressure $>30\%$ of control value). or bradycardia (heart rate < 50 beat min^{-1}) occurred, doses of ephedrine 6–12 mg i.v. were administered. Atropine was not used. Postoperative pain treatment included propacetamol i.v.

After operation, patients were examined at 6, 12 and 24 h by a blinded observer. At each time, micturition within the preceding hours was noted, and the bladder was examined for distension. When bladder distension was noted, patients were asked to void. If they failed, or if a second examination revealed persistent bladder distension after incomplete micturition, they received naloxone 0.2 mg. If naloxone did not result in complete voiding, the bladder was catheterized transiently.

Results are expressed as mean (SD). Data were analysed using one-way ANOVA and a Student's t test, and chi-square test and Yates' correction and Fisher's exact test where appropriate.

There were 20 patients in each group. The two groups were comparable in age (group C, 64.8 (range 41–77) yr and group M, 61.2 (44–70) yr), weight (77.6 (SD 13.3) kg and 72.9 (11.4) kg) and height (169 (5) cm and 166 (6) cm) (ns). Group C included 16 men and four women and group M, 13 men and seven women. Maximum extension of block was comparable in the two groups. Duration of surgery was 95.8 (8.7) min and 100.9 (15.7) min in groups C and M, respectively (ns). Mean amounts of i.v. infusions were comparable in the peroperative period

Table 1 Incidence of urinary retention (number of patients). *$P < 0.05$ between groups

	Time after operation (h)		
	6	12	24
Bladder distension			
Group C	0	5*	1*
Group M	2	20	7
Bladder catheterization			
Group C	0	1*	0
Group M	0	4	2

(2684 (730) ml and 2875 (428) ml in groups C and M, respectively), and after operation (6055 (1392) ml and 6500 (875) ml in groups C and M). Ephedrine was given to five patients in group C and to three in group M.

At 6 h no patient had experienced spontaneous micturition. At 12 h, 17 patients in group C but none in group M had experienced spontaneous micturition. At 24 h, 20 patients in group C and 12 in group M reported micturition within the preceding 12 h ($P < 0.001$).

Bladder distension was noticed in two patients in group M and in none in group C at 6 h (table 1). At 12 h, all patients in group M had bladder distension compared with only five patients in group C; at 24 h, seven patients in group M and one in group C had bladder distension ($P < 0.001$) (table 1). All patients were able to void when they had bladder distension but micturition was incomplete in one patient in group C and in 14 in group M at 12 h ($P < 0.05$), and in two patients in group M at 24 h. Consequently, naloxone was given to 16 and one patient in groups M and C, respectively ($P < 0.001$).

Bladder catheterization was performed after naloxone in only one patient who failed to empty his bladder at 12 h (group C), while four and two patients were catheterized at 12 h and 24 h, respectively, in group M ($P < 0.001$) (table 1).

Comment

We have found that the incidence of bladder dysfunction was less when spinal clonidine, instead of morphine, was given with spinal bupivacaine.

A difference in urinary output between the two groups might have explained the difference in urinary retention. We did not measure urinary volumes but previous studies indicated that spinal morphine may decrease urinary output by release of arginine vasopressin [4] and conversely that clonidine has a diuretic effect [5]. Such effects would have favoured bladder distension in group C whereas we observed the opposite effect.

Spinal and extradural opioids are considered risk factors for urinary retention [2]. Extradural morphine induces difficulties in micturition in healthy volunteers [6]. Urinary retention ranges from 42% to 62% in patients who have received spinal or extradural opioids [1, 2].

Activation of the parasympathetic pathways to the detrusor and relief of the somatic input to the external bladder sphincter induce micturition. Activation of the sympathetic outflow to the urinary tract promotes an increase in urethral resistances and depresses detrusor contraction, favouring urinary retention. Spinal opioids acting on spinal or supra spinal mu receptors may depress efferent parasympathetic outflow to the bladder, inhibiting detrusor contractions and micturition reflex for several hours after spinal administration.

Spinal administration of clonidine results in less difficulties in micturition. Alpha$_2$ adrenergic agonists have complex and potentially opposite effects on bladder emptying. Peripheral α_2 adrenergic receptors are documented in the bladder wall, especially at the level of the trigone [2]. Their stimulation induces contraction of the smooth muscle fibres of the internal sphincter tone and therefore increases urethral resistances and impairs voiding. As a small dose was given intrathecally, a peripheral effect of clonidine is unlikely. Spinal clonidine decreases sympathetic tone through a supraspinal and spinal effect (on preganglionic sympathetic neurones) which could facilitate micturition. Indeed, administration of clonidine stimulates bladder motility in cats by depressing sympathetic outflow to the bladder [7].

Removal of the laryngeal mask airway in children: anaesthetized compared with awake

A. J. KITCHING, A. R. WALPOLE AND C. E. BLOGG

Summary

We studied 60 children, aged 12 months to 8 yr, undergoing plastic surgery under general anaesthesia supplemented by regional anaesthesia. Patients were allocated randomly to have the laryngeal mask airway removed either on awakening or while anaesthetized. Subsequent observation of respiratory factors and oxygen saturation showed a significant difference between the groups for coughing ($P < 0.001$), with a greater incidence (17 of 33) in the awake group compared with those from whom the laryngeal mask airway was removed while anaesthetized (two of 27). There were no differences in the incidences of laryngospasm, desaturation ($< 95\%$) and excess salivation between the groups. Removed of the laryngeal mask airway during deep anaesthesia reduced coughing in the immediate postoperative period. (*Br. J. Anaesth.* 1996; **76**: 874–876)

Key words
Anaesthesia, paediatric. Equipment, masks anaesthesia. Children.

The laryngeal mask airway (LMA) has been used for more than 4 yr in children [1] and appears to be associated with fewer respiratory effects compared with tracheal tubes. The designer of the LMA suggested originally [2] that it should be left in place until the patient regained protective airway reflexes; however, the LMA was not used in children at that time. We found that many of our colleagues did not follow the example of Mason and Bingham [1], who left the device *in situ* "until the return of laryngeal reflexes" (particularly in children), for fear of provoking coughing or laryngospasm and desaturation.

There is no objective evidence to suggest that removing the LMA in the conventional manner [2] is better than removing it at a deep plane of anaesthesia. However, two studies in children showed that extubation of conventional tracheal tubes [3, 4] at a deep plane of anaesthesia, rather than with the subject awake, may result in fewer episodes of coughing and arterial oxygen desaturation.

In this study we compared the incidence and severity of adverse respiratory events during the immediate postoperative period in children after removal of the LMA, either under surgical anaesthesia, or on awakening.

Methods and results

A letter was sent to the parents before admission, inviting their child's participation in a randomized, prospective, single-blind study of patients aged 12 months to 8 yr undergoing elective urogenital or lower limb plastic surgery for which general anaesthesia combined with regional block was appropriate. Local Ethics Committee approval was obtained. On admission, written informed consent was obtained from the parents after personal interview. Exclusion criteria were: anaesthesia within 3 months, current or chronic upper airway disease, asthma and congenital heart disease.

Premedication was with oral diazepam 0.3 mg kg^{-1} and oral atropine 30 μg kg^{-1} [5], 1–2 h before operation. Anaesthesia was induced with halothane, oxygen and nitrous oxide (with the parents invited to be present), followed by fentanyl 1 μg kg^{-1} i.v. and insertion of the LMA. Any difficulties in insertion were noted. A rolled-up gauze swab served as a bite block until the LMA was removed. Caudal 0.25% plain bupivacaine was then given in a volume of 0.5 ml kg^{-1} in the majority of cases. Anaesthesia was maintained with appropriate concentrations of oxygen, nitrous oxide and halothane. Oxygen saturation was maintained at or above 95% during operation. Morphine 0.1 mg kg^{-1} i.m. was given when spontaneous ventilation was judged to be satisfactory.

Five minutes before the anticipated end of surgery, anaesthesia was deepened by giving twice the minimum alveolar concentration (MAC) of halothane (adjusted for age) [6] with nitrous oxide. The child was then allocated randomly, by tossing a coin, to have the LMA removed (and replaced with a Guedel airway) (deep group) or left *in situ* (awake group). Each child was then turned onto the left side and transferred to the recovery room, breathing air supplemented by oxygen 4 litre min^{-1} by Hudson's face mask. Diclofenac 12.5 mg (or 25 mg if the child weighed more than 20 kg) was inserted *per rectum* on

arrival in the recovery room. A pulse oximeter probe (Ohmeda 3700) was applied to a finger of the uppermost hand and haemoglobin oxygen saturation and heart rate were displayed. Continuous close observation by one of the investigators and routine observations by trained nursing staff were made of coughing, laryngospasm, airway obstruction, changes in oxygen saturation and heart rate, for 60 min from the end of anaesthesia or until the child was awake (whichever was sooner). Observations and management were recorded (table 1). The LMA or Guedel airway was removed in the recovery room when the child awoke sufficiently to swallow.

Heart rate and oxygen saturation (Sp_{O_2}) from the pulse oximetry were stored on computer for further analysis (Polysomnography program, K. R. Casey).

We studied 60 children; 59 were boys undergoing plastic surgery on the urogenital system; there was one girl undergoing removal of a thigh haemangioma who was allocated randomly to the deep group. In 27 patients the LMA was inserted at a deep plane of anaesthesia (group D) and in 33 when they awoke (group A).

The mean weight of patients in the deep group (D) was 14.7 kg compared with 13.4 kg in the light group (A). The mean age of patients in group D was 30.93 months and 25.3 months in group A.

The number of patients with airway complications in each group is shown in table 2. Neither patient in the deep group who coughed had oxygen saturation values less than 95%. However, four of 17 patients who coughed in the awake group had saturation values of 95% or less during the coughing episodes. Four of those in the awake group who coughed did so within the 5 min before its removal and nine coughed at the time of removal. None in this group required a Guedel airway. Values of oxygen saturation were regarded as reliable if the pulse waveform was regular and corresponded to that displayed on the electrocardiogram.

Patient data were compared using Student's *t* test, while categorical data were compared using the chi-square test with Yates' correction, $n \times 2$ contingency test or Fisher's exact test. $P < 0.05$ was considered significant.

There were no significant differences between the groups in age, weight, salivation, stridor or incidence and severity of desaturation. The only complication that was significant was an increase in the incidence of coughing in the awake group in the recovery period. In four of 17 patients who coughed, saturation decreased to 95% or less.

Comment

We conducted a randomized, prospective study to compare the incidence of airway complications in young children (aged 1–8 yr) after removal of the LMA at either a deep plane of anaesthesia or when the child was awake.

We used a standard anaesthetic regimen so that the groups were as comparable as possible. I.v. induction agents were not used because we knew that in some of these children it would be difficult to obtain venous access and inhalation induction would be more appropriate. We therefore decided from the outset to use halothane and nitrous oxide for induction of anaesthesia in all patients. Further, thiopentone and propofol, our i.v. induction agents of choice, are known to have different effects on airway excitability.

When the child was anaesthetized we used a small dose of i.v. fentanyl to suppress airway reflexes in all patients before insertion of the LMA. A caudal extradural block or alternative block provided analgesia for the operative site, and all patients received a small dose of morphine 0.1 mg kg^{-1} i.m. during operation. Thus we eliminated airway irritability caused by pain of the operation site, and therefore airway complications were likely to be secondary to the local effect of the LMA.

Failure to prevent coughing in the recovery period can be a problem after plastic surgery operations: the induced increase in venous pressure can lead to oozing from the wound edge, and even haematoma formation, which could impair the viability of tissue flaps and grafts.

Therefore, for older infants and young children we now advocate removal of the LMA at a deep plane of anaesthesia to remove the stimulating effect on the airway. This supports the results of other studies [3, 4] comparing deep *vs* awake extubation of tracheal tubes which demonstrated a difference in saturation between the two groups, with better outcome in the deep group.

CASE REPORTS

Fracture of the cricoid cartilage after Sellick's manoeuvre

K. J. HEATH, M. PALMER AND S. J. FLETCHER

Summary

We report a case of fracture of the cricoid cartilage associated with cricoid pressure during rapid sequence tracheal intubation in a patient with status asthmaticus. This patient had a history of laryngeal trauma 48 yr previously. Fracture of the cricoid cartilage has not been reported previously after cricoid pressure. (*Br. J. Anaesth.* 1996; **76**: 877–878)

Key words

Larynx, cricoid pressure. Complications, fractured cricoid cartilage.

Case report

A 67-yr-old man was admitted to hospital suffering from acute exacerbation of bronchial asthma. He had a long-standing history of asthma and chronic obstructive airways disease and had been treated with bronchodilators and inhaled steroids for many years.

He had been in hospital for 48 h when his condition worsened and he became progressively hypoxic and hypercapnic, despite nebulized salbutamol therapy; he developed a "silent" chest with arterial blood–gas tensions of Pa_{CO_2} 15 kPa and Pa_{O_2} 8.5 kPa on an inspired oxygen fraction of 0.6. The decision was made to perform tracheal intubation and intermittent positive pressure ventilation. He was transferred to the intensive therapy unit and tracheal intubation was carried out by an anaesthetic senior registrar using ketamine 1 mg kg^{-1} and suxamethonium 1 mg kg^{-1}, with an experienced operating department assistant (ODA) performing cricoid pressure. Intubation was easy, with a grade 1 [1] view of the larynx, and a size 9 cuffed oral tracheal tube was passed. The patient underwent intermittent positive pressure ventilation requiring inflation pressures of up to 35 cm H_2O, and was treated with bronchodilators and hydrocortisone. A chest radiograph performed shortly after tracheal intubation revealed slightly hyperinflated lungs and the tracheal tube in a satisfactory position; there were no other abnormalities on the chest radiograph.

The patient made a rapid recovery and 24 h later was assessed as being ready for extubation. Almost immediately after extubation the patient developed marked inspiratory stridor, severe hypoxia and suffered a brief cardiorespiratory arrest. His trachea was re-intubated rapidly by an anaesthetic senior house officer and cricoid pressure was applied by an experienced intensive care nurse. On this occasion the larynx was difficult to see initially; however, a good view of the vocal cords was obtained by repositioning the patient's head. The laryngeal structures were noted to be swollen but not markedly, a size 9 cuffed oral tracheal tube was reinserted and the lungs ventilated again, requiring inflation pressures of 30–36 cm H_2O. Another chest radiograph was obtained shortly after re-intubation; this showed a possible mediastinal mass that could have accounted for the marked stridor after extubation. The tracheal tube was noted to be in a satisfactory position, level with the fifth thoracic vertebra, and there were no signs of barotrauma or surgical emphysema to account for the patient's difficulty in breathing.

The patient was investigated further for a mediastinal mass because he was noted to have generalized swelling of his neck and dilatation of the veins of his chest and upper extremities, consistent with a possible diagnosis of superior vena cava obstruction. It was suggested that a mediastinal mass could have accounted for the marked inspiratory stridor immediately after extubation and the clinical signs. A limited CT scan of the patient's upper mediastinum, however, showed no abnormalities and when the chest radiograph was reviewed by a consultant radiologist it was reported to show some increased shadowing at the left lung base, but no other abnormal findings. Fibreoptic bronchoscopy was also performed which showed a normal tracheobronchial tree, the larynx was not examined fibreoptically as the tracheal tube was positioned below the larynx and it was not felt necessary to withdraw the tube to examine the larynx.

It was difficult to wean the patient from the ventilator and he underwent a formal tracheotomy performed by an ENT senior registrar on day 8 after admission to the intensive care unit. At operation the surgeon reported that the cricoid cartilage was partially calcified and that there was an undisplaced fracture to the left of the midline of the cricoid arch. The surgeon suggested that the fracture may have been caused by cricoid pressure.

The patient made a slow recovery from his asthma attack and was eventually discharged to the ward breathing spontaneously through his tracheostomy. When the patient had recovered sufficiently to provide a full history, he denied any recent trauma;

K. J. HEATH, MS, BS, BSC, DMCC, FRCA, M. PALMER, MB, BS, S. J. FLETCHER, MB, BS, FRCA, Anaesthetic Department, Norfolk and Norwich Hospital, Brunswick Road, Norwich, Norfolk NR1 3SR. Accepted for publication: January 22, 1996.

however, on further questioning he admitted that he had been in hospital when aged 19 yr after an accident where he had managed to partially hang himself. He had also sustained direct blunt trauma to his larynx 20 yr previously during a caravaning accident but had not been hospitalized on that occasion.

We suggest that the fracture of this patient's cricoid cartilage may have been caused by Sellick's manoeuvre in the presence of a weakened cricoid cartilage associated with the hanging accident when the patient was 19 yr of age and possibly with later more minor laryngeal trauma. This patient's long-term steroid therapy may also have caused some weakening of the cricoid cartilage. Inspiratory stridor after extubation could have been caused by either oedema associated with fracture of the cricoid cartilage or collapse of the fractured cricoid cartilage inwards on inspiration. The other possible causes for stridor after extubation were excluded, such as a mediastinal mass or surgical emphysema associated either with the fractured cricoid cartilage or barotrauma from high airway pressures.

Discussion

Cricoid pressure was first described by Sellick in 1961 [2]. It is often difficult to judge exactly how much pressure to exert during Sellick's manoeuvre. Sellick referred to "firm" pressure in his original article [2] and "the pressure which would cause pain if applied to the bridge of the nose" has also been suggested [3]. A force of 44 N [4] applied to the cricoid ring pressing back against the bodies of the cervical vertebrae has been shown to be effective in protecting the majority of adult patients from regurgitation of gastric contents.

There are several potential complications associated with cricoid pressure, such as rupture of the oesophagus should vomiting occur during the manoeuvre or aggravation of cervical spine injury. Incorrectly applied cricoid pressure can distort the view of the larynx making tracheal intubation difficult. Complete airway obstruction has been caused by Sellick's manoeuvre [5] in a patient undergoing rapid sequence induction of anaesthesia with an undiagnosed lingual thyroid that resulted in supraglottic obstruction when cricoid pressure was applied. There has also been a case of airway obstruction after cricoid pressure in a patient with undiagnosed traumatic injury [6]. In this case the laryngeal injury was acute and the resulting airway obstruction required urgent surgery.

Our case is unique in that the patient underwent tracheal intubation for medical reasons and there was no acute trauma to the larynx. Intubation was carried out by a senior anaesthetist with an experienced assistant in order to minimize any complications, with what was essentially an emergency procedure in a patient *in extremis*; it would have been unlikely in these circumstances that cricoid pressure would have been applied incorrectly. It has been demonstrated, however, that there is a wide variation in force applied to the cricoid ring during cricoid pressure, even by experienced staff. Pressures applied have ranged from 10.8 to 120.6 N [7]. Laryngotracheal injury is rare, requiring considerable force. It would be highly unlikely, even if cricoid pressure was applied too forcibly, that a fracture could occur in a normal cricoid cartilage. Eighty percent of laryngeal injuries and 90 % of fractures, dislocations and separation of the laryngotracheal skeleton are caused by significant, high velocity blunt trauma sustained during road traffic accidents [8]. These high velocity injuries are often associated with multisystem trauma and cervical spine injury. Fracture of the thyroid cartilage is the most frequently encountered injury to the larynx, while fracture of the cricoid alone is unusual; in most cases fractures of the cricoid cartilage also involve the trachea or the thyroid cartilage. Underlying weakness of the cricoid ring was therefore highly likely in our patient.

Hanging is the other main recognized cause of laryngeal trauma [9], and we suggest that our patient had a weakened cricoid cartilage or even an ununited fracture as a result of his hanging injury at 19 yr of age. In a series of 80 consecutive cases of death caused by hanging, 45 % were associated with laryngeal trauma. In this series, however [9], the cricoid cartilage was never fractured and there were no fractures of the larynx in subjects less than 25 yr of age. The second injury to this patient's neck occurred 20 yr ago, but did not result in hospital admission; as significant force is required to fracture the cricoid cartilage it is unlikely that the cricoid ring was fractured at that time. We postulate, therefore, that the old injuries to this patient's larynx together with long-term steroid therapy caused weakening that resulted in fracture of the cricoid cartilage when routine cricoid pressure was applied during rapid sequence tracheal intubation for status asthmaticus.

Balloon mitral valve dilatation as an aid to weaning from ventilatory support in patients with intractable pulmonary oedema caused by severe mitral stenosis

G. DAVIS, R. M. KHAN, N. RANDALL, J. S. WRIGHT AND D. H. ROBERTS

Summary

Intractable pulmonary oedema in patients undergoing mechanical ventilation must be investigated as older patients with severe mitral stenosis can be rescued by balloon dilatation of the mitral valve, thus enabling elective cardiac surgery at reduced risk. We describe two such cases and discuss the role of transoesophageal echocardiography in the intensive care unit in the diagnosis and management of these patients. (*Br. J. Anaesth.* 1996; **76**: 879–880)

Key words

Complications, pulmonary oedema. Complications, stenosis. Monitoring, echocardiography.

Mechanical ventilation is often used to rescue patients who have respiratory arrest caused by severe pulmonary oedema. We report two patients in whom repeated attempts at weaning from ventilatory and haemodynamic support were unsuccessful because of severe mitral stenosis. The success of emergency balloon dilatation of the mitral valve in the management of this problem is discussed.

Case reports

PATIENT NO. 1

A 61-yr-old male in atrial fibrillation underwent elective cardiac catheterization for severe mitral stenosis (estimated valve area on echocardiography of 0.9 cm^2). He was found to have severe pulmonary hypertension and significant two-vessel coronary artery disease with moderate left ventricular function. He developed severe pulmonary oedema leading to respiratory arrest 4 h later and required mechanical ventilation. He became severely hypotensive (systolic arterial pressure 75 mm Hg) requiring treatment with i.v. dobutamine, dopamine and noradrenaline. He continued to suffer from pulmonary oedema.

Transoesophageal echocardiography (fig. 1) showed severe mitral stenosis with calcification of the anterior mitral valve leaflet, mild mitral regurgitation and absence of thrombus in the left atrium and atrial appendage. He therefore underwent emergency Inoue balloon percutaneous transvenous mitral commissurotomy (PTMC) up to a maximum dilatation of 26 mm. There was an immediate decrease in mitral valve end-diastolic gradient from 12 to 5 mm Hg and echocardiographically derived mitral valve area increased to 1.7 cm^2. Echo-Doppler however, showed increased mitral regurgitation. Despite this he was weaned successfully from ventilatory and inotrope support within 3 days and was discharged home 4 days later. He underwent successful elective mitral valve replacement and coronary artery bypass surgery 2 months after PTMC.

PATIENT NO. 2

A 59-yr-old female with known mitral stenosis and cerebrovascular disease presented as an emergency in an unresponsive state with severe pulmonary oedema requiring ventilation. She was profoundly hypotensive with a systolic arterial pressure of 60 mm Hg which required maximum inotropic support. Multiple attempts at ventilatory weaning were however, unsuccessful because of persistent pulmonary oedema. Transoesophageal echocardiography (fig. 1) showed the mitral valve to be tightly stenosed with a mobile anterior leaflet but an immobile calcified posterior leaflet with thickening and calcification of the subvalvar apparatus. There was mild mitral regurgitation. The left atrium was dilated with spontaneous contrast but no thrombus. She underwent emergency Inoue balloon PTMC and was weaned successfully from ventilatory support within 24 h. An increase in echocardiographically derived mitral valve area (0.7 to 1.9 cm^2) was achieved but there was now moderate mitral regurgitation. Her symptoms remained improved at outpatient follow-up 3 months later, but elective mitral valve replacement is being considered.

Discussion

The presence of severe pulmonary oedema does not necessarily imply a diagnosis of "left ventricular failure" and echocardiography should be performed

Correspondence to G.D.

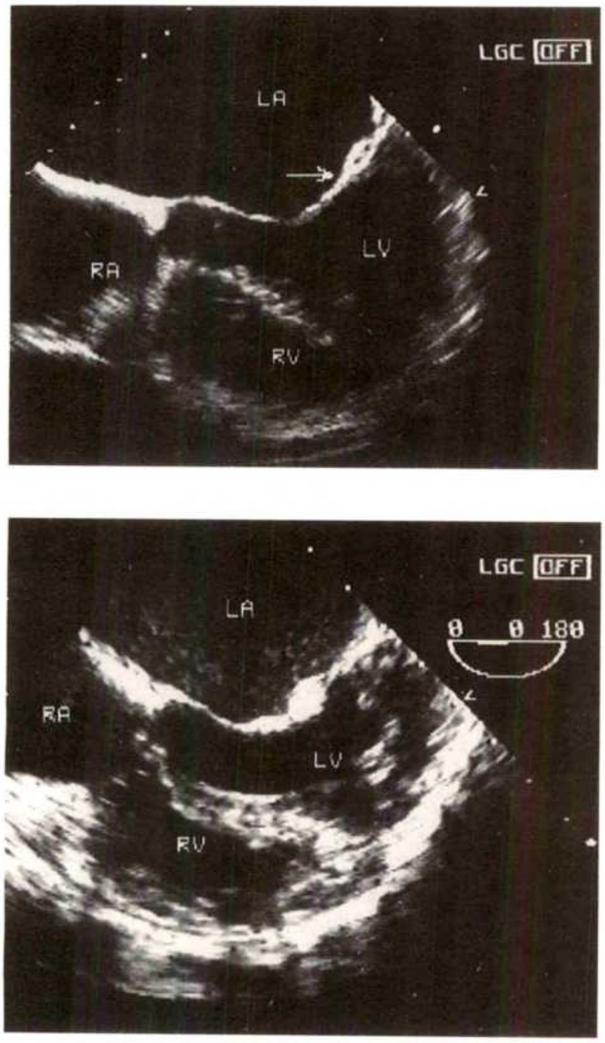

Figure 1 Four-chamber transoesophageal echocardiographic images in patient No. 1 (top) and patient No. 2 (bottom). On both images there is dilatation and a hazy appearance (spontaneous contrast with increased risk of clot formation) of the left atrium. The mitral valve leaflets (arrow, top) are thickened and calcified with restricted opening on both images. RA = Right atrium, RV = right ventricle, LV = left ventricle, LA = left atrium.

to exclude mitral stenosis as a cause of intractable pulmonary oedema in patients undergoing ventilation. Mitral valve replacement in such patients carries prohibitive risks which are increased further in the presence of significant coronary artery disease [1].

Although closed mitral valvotomy and PTMC are equally effective in providing haemodynamic improvement in selected patients with severe mitral stenosis, PTMC may do so more cost effectively and without increased complications [2]. Wilkins and colleagues [3] have suggested an echocardiographic scoring system to predict the result of balloon dilatation and have shown that short-term outcome is related directly to the degree of valve leaflet thickening and involvement of the subvalvar apparatus (thickening and calcification). Transoesophageal echocardiographic examination is also important before PTMC to detect the presence of left atrial thrombus [4] which is a relative contraindication to balloon intervention. This is more likely to be present in older patients with left atrial dilatation and atrial fibrillation.

Inoue balloon PTMC has been shown previously to be particularly useful in treating intractable heart failure caused by severe mitral stenosis in pregnant patients [5] and in critically ill young patients [6]. We suggest that this procedure is also useful in older critically ill patients, even with mitral valves with less than ideal characteristics, as a means of achieving a better cardiac haemodynamic state, thus enabling weaning from ventilatory support and allowing elective mitral valve replacement if indicated on symptomatic grounds.

CORRESPONDENCE

Suxamethonium and auditory evoked potentials

Sir,—I read with interest the article by Brunner and colleagues on the relationship between suxamethonium and cortical auditory evoked potentials [1]. The focus of the article was the hypothesis that suxamethonium may cause arousal of anaesthetized patients, but no plausible explanations were offered by the authors as to the possible mechanism. I suspect that the authors overlooked the effects of neuromuscular blockers on the muscles of the tympanum (tensor tympani and stapedius) which are the most sensitive muscles in the body to the action of blocking drugs. For example, there is considerable literature on the early diagnosis of myasthenia gravis by testing the reflex tensioning of the middle ear ossicles with impedance techniques.

Thus the effect of suxamethonium on the auditory evoked response may not be concerned with arousal. Instead it may merely be the result of abolishing the tensioning reflex mediated by the stapedius, allowing a much larger mechanical signal through to the inner ear and therefore causing a larger stimulus up the auditory nerve. The authors even cited a reference reporting the absence of the "arousal" effect of suxamethonium in the presence of previous non-depolarizing paralysis (ref. [10]) which is what one would expect: when the stapedius has been blocked totally, it cannot be blocked further. The results of this article are nevertheless interesting. The discussion section, however, might perhaps have been reduced to a single 10-line paragraph had the authors taken into account the physiology of the stapedius reflex.

J. Ponte

London

1. Brunner MD, Nathwani D, Rich PA, Thornton C, Doré CJ. Effect of suxamethonium on the auditory evoked response in humans. *British Journal of Anaesthesia* 1996; **76**: 34–37.

Sir,–Our study showed that suxamethonium had an arousal effect according to the auditory evoked response (AER). In the discussion section of our article, we outlined the possible causes of this effect and, according to the literature, felt that cortical stimulation secondary to increased muscle spindle activity after muscle fasciculation or direct spindle stimulation by suxamethonium itself, may be responsible for the arousal pattern which we observed.

Theoretically, as Dr Ponte points out, paralysis of the stapedius by suxamethonium could increase the input up the auditory nerve resulting in an AER response similar to that seen with arousal. However, if this were so, all neuromuscular blocking drugs would have an arousal effect on the AER. There is currently no evidence in the literature to support this theory. In fact, in an article published recently in this journal [1], Richmond and colleagues showed that vecuronium had no effect on the AER.

Regarding the article by Mori, Iwabuchi and Fujita [2], Dr Ponte is correct in saying that these authors found that suxamethonium failed to cause arousal in the presence of previous non-depolarizing paralysis. However, the authors also found that non-depolarizing drugs failed to cause arousal, which they should have if the stapedius reflex were a factor. On the other hand, their findings support our assertion that arousal after suxamethonium may result from muscle spindle stimulation, because its effect on the EEG can be blocked by non-depolarizing blockers which prevent fasciculation. Also, Mori and colleagues did not measure the AER in their subjects. They examined instead EEG responses where auditory reflexes are less important.

Extradural clonidine for postoperative pain relief

Sir,—With regard to a recent letter by Nishikawa [1] criticizing pain assessment by Lee and Rubin [2], we feel that, as our recent article [3] used similar methodology to theirs, we should reply to the points raised.

First, Nishikawa questions that objective assessment of pain is possible in small children. This is an area of obvious difficulty and is the reason why a previously validated [4] objective pain scoring system was used in both studies [2, 3]. This was used by staff [2] or parents [3] to decide when analgesia was necessary. Quite how this makes bias "likely" when observations of randomized groups are being made double-blind is unclear to us.

Nishikawa also states that he "cannot exclude…that intense sedation induced by extradural clonidine (with local anaesthetics) would make estimation of pain intensity impossible". He cites his own study [5] in support of this. However, this article makes no attempt to assess pain in its methodology. In addition, all patients were adults who were premedicated and sedated during operation. Despite this, and one group receiving a larger mean dose of clonidine (3.3 μg kg^{-1}) than in the paediatric studies (2 μg kg^{-1}), none was "sedated to the degree that she could not respond to verbal commands". This suggests that ability to communicate was retained.

Lee and Rubin [2] found it difficult to separate analgesia and sedation in their patients receiving extradural clonidine. They also used sedative premedication. In our study [3] no premedication was used and we confirmed that clonidine 2 μg kg^{-1} provided a longer duration of analgesia than adrenaline 1:200000 when added to caudal 0.25% bupivacaine 1 ml kg^{-1} (medians: clonidine 5.8 h, adrenaline 3.2 h; $P < 0.05$). There was no difference in time to spontaneous eye opening after cessation of anaesthesia (medians: clonidine 21 min, adrenaline 20 min) or sedation scores at 4 h (medians: clonidine 0, adrenaline 0). Only three patients in the clonidine group (total 20) required analgesia at 4 h when median sedation score was 0 (eyes open spontaneously). Therefore, it is our contention that sedation does not preclude estimation of pain in children given extradural clonidine 2 μg kg^{-1} in combination with local anaesthetic, but that the use of other sedative drugs may introduce this difficulty.

5. Nishikawa T, Dohi S. Clinical evaluation of clonidine added to lidocaine solution for epidural anesthesia. *Anesthesiology* 1990; **73**: 853–859.

Sir,—I read with interest the article by Cook and colleagues [1] insisting that sedation does not preclude postoperative pain assessment in small children receiving extradural clonidine and local anaesthetic. I cannot wholly agree with their contention. First, I think that the pain scoring system [2] used in their study did not necessarily provide real assessment of postoperative pain intensity, because estimation of pain with this method is likely to be affected by other discomforts (for example, sleep, hunger or thirst, etc.). Second, paediatric patients received analgesics only when the parent judged its requirements in their study. Therefore, some bias caused by individual variability in the parent's care may be introduced in the quantitative assessment of analgesia.

I still believe that the most objective assessment of postoperative pain can be judged only by the same attending staff, blinded to the treatment, irrespective of patient age, and that it is difficult to separate analgesia from sedation in paediatric patients, as Lee and Rubin [3] found. More importantly, it appears curious to me that Cook and colleagues did not observe significant sedation in patients receiving caudal extradural clonidine 2 $\mu g\ kg^{-1}$ with 0.25% bupivacaine 1 ml kg^{-1} compared with those receiving caudal adrenaline 5 $\mu g\ kg^{-1}$ with 0.25% bupivacaine 1 ml kg^{-1}, as the smaller dose of extradural clonidine of less than 2 $\mu g\ kg^{-1}$ also produced intense sedation in adults in our study [4].

Aprotinin during liver transplantation

Sir,—We were interested to read the double-blind, randomized study by Milroy and colleagues [1] on haemodynamic stability after administration of aprotinin during orthotopic liver transplantation (OLT). We wish to make the following observations.

Aprotinin reduces transfusion requirements and blood loss in patients undergoing heart surgery [2]. However, this beneficial effect has never been assessed in patients undergoing OLT. In the reference mentioned by the authors [3], as in all articles published previously, comparisons were made with historical controls. Moreover, aprotinin did not significantly reduce oozing during OLT in the only randomized study [4].

In the introduction to the article, the authors wrote "the aim of the present study was to determine if aprotinin influenced blood loss, blood product requirements...". We were disappointed not to find the answer in the results as they studied 55 patients, a large sample, in a controlled, randomized study, but failed to answer the question: does aprotinin reduce blood loss in OLT?

C. LENTSCHENER
D. BENHAMOU

2. Bidstrup BP, Royston D, Sapsford RN, Tauylor KM. Reduction in blood loss and blood use after cardiopulmonary bypass with high dose aprotinin (Trasylol). *Journal of Thoracic and Cardiovascular Surgery* 1989; **97**: 364–372.
3. Grosse H, Lobbes W, Frambach M, Ringe B, Barthels M. Influence of high dose aprotinin on hemostasis and blood requirement in orthotopic liver transplantation. *Seminars in Thrombosis and Hemostasis* 1993; **19**: 302–305.
4. Groh J, Welte M, Azad SC, Forst H, Pratschke E, Kratzer MAA. Does aprotinin affect blood loss in liver transplantation? *Lancet* 1992; **340**: 173.

Sir,—We appreciate the chance to reply to the comments of Drs Lentschener and Benhamou. Blood loss values were omitted from this article. Intraoperative blood loss was higher in the placebo group (median 4676.5 ml (interquartile range 3060–6230 ml)) compared with the aprotinin-treated group (3467.5 (1770–5245) ml). These data were subjected to statistical analysis using non-parametric tests. The differences in intraoperative blood loss between the two groups did not reach statistical significance.

There was also a trend towards reduced blood transfusion requirements during and after operation in the aprotinin-treated group, but again this was not statistically significant.

Even though Lentschener and Benhamou consider that our study was conducted on a large group of patients, in retrospect we are of the opinion that this study did not have sufficient statistical power to either support or refute the question it was designed to answer, namely does aprotinin reduce blood loss during orthotopic liver transplantation (OLT)? We have realized that patient selection may not have been ideal in helping to answer this important question.

Our original approach for this study was to include all suitable patients undergoing OLT for chronic or acute hepatic failure. This led to the inclusion of a high proportion of "low risk" patients (48% in the placebo group and 29% in the aprotinin group) with a preoperative diagnosis of primary biliary cirrhosis and primary sclerosing cholangitis. We now consider these patients to be at low risk of intraoperative fibrinolysis, and no longer administer prophylactic antifibrinolytic therapy.

It was our intention to publish this article merely to highlight the interesting and previously (to our knowledge) unreported finding that administration of aprotinin during OLT can confer statistically significant improvements in haemodynamic stability during the post-reperfusion phase.

We are currently conducting a more powerful randomized, double-blind study in patients we consider to be at high risk of intraoperative fibrinolysis and bleeding during OLT to definitively answer Lentschener and Benhamou's question.

Aortic stent surgery

Sir,—We were interested to read the case report by Greiff, Thompson and Langham [1].

To our knowledge there are four centres in the UK, including Leicester, that are involved in endoluminal repair of abdominal aortic aneurysm. At the 1995 annual scientific meeting of the Vascular Surgical Society, the results of several of the centres were presented, and also recently in Sydney [2]. It is interesting to note that the procedure is not always as straightforward as suggested in the case report by Greiff, Thompson and Langham. Failure to deploy the stent is not uncommon [3]. The need to convert to an open operation may occur in up to 35% of patients. Although there is a definite learning curve with mortality being reduced the more experienced the team, perioperative mortality is approximately 10% [4]. Late failure of the graft has also been described.

There are several reasons for these problems. The technique is relatively new and during the early stages of development there is a tendency to use the technique in those patients where open surgery is very likely to result in the death of the patient. For example, the patient may have significant cardiovascular disease and death is a significant risk whatever the operation.

As indicated in the article of Greiff, Thompson and Langham, the main advantage for patients is that when the procedure succeeds smoothly, the postoperative course is usually less complicated than after open surgery. The patient's trachea can usually be extubated early and the patient may be mobilized early. This improved postoperative course may not, however, outweigh the risk of hypotension that occurs while the balloons are inflated to deploy the stent during the procedure. Studies examining the advantages of this technique compared with open surgery in different groups of patients are necessary and also studies evaluating the anaesthetic techniques used.

Sir,—We are grateful for the comments of Dr Baranowski and Mr Adiseshiah, and appreciate the opportunity to clarify several points.

Numerous centres within the UK have preliminary experience of this technique, although it is probably true to say that only Leicester and Nottingham have a representative experience. It is certainly true that there is a definite learning curve to this procedure, but we are unaware of any data to support the assertion that mortality is reduced with increasing experience of the team. It is misleading to describe average mortality for this procedure as many of the patients in the larger series are elderly and unfit for routine conventional surgery [1–3].

It is suggested by Dr Baranowski and Mr Adiseshiah that endovascular aneurysm repair be used in those patients where open surgery is likely to result in patient mortality. It is our view that this is precisely the case in which endovascular surgery should be avoided until the learning curve of the procedure has been overcome and conversion to open operation occurs in a low percentage of patients. It is well documented in the literature that conversion during endovascular aneurysm repair results in a high mortality rate. If a failure to deploy the endograft appropriately is occurring in up to 35 % of cases, it may be appropriate to re-think the indications for endovascular repair in this group of patients. At present we feel that a randomized, controlled trial is required to examine procedural morbidity and mortality in patients suitable for both conventional and endovascular aneurysm repair. It must be determined if endovascular aneurysm repair is a safe procedure in "healthy" patients before its use can be advocated routinely in patients unsuitable for conventional transperitoneal surgery.

We were interested to learn that the group at UCL uses significant procedural hypotension during deployment of the aortic stent. During deployment of a balloon expandable stent in our centre, we regard a mean arterial pressure of 70 mm Hg to be adequate.

Suxamethonium in children

Sir,—The importance of recognizing subclinical myopathies in patients undergoing general anaesthesia was demonstrated clearly many years ago [1] and has been stressed recently in the editorial by Hopkins [2].

When the problem of anaesthesia-induced rhabdomyolysis (AIR) is examined retrospectively, a surprising finding is that many clinical reports (including the most recent ones) lack preoperative evaluation of serum creatine kinase (CK) activity. This indicates that our attention to the problem is either poor or frustrated by the knowledge that serum CK activity is not invariably correlated with the presence or absence of myopathic conditions.

The long preclinical phase of many dystrophinopathies, which are frequently involved in AIR [3], may be easily recognized or suspected on the basis of CK activity.

In our experience, a definite *decrease* in postoperative serum CK activity may be expected in the majority of these patients if they receive general anaesthesia without the use of suxamethonium [4]. In rare circumstances, however, a life-threatening AIR may be observed even though suxamethonium has been avoided [5]. Whether or not these accidents define a particular subpopulation of dystrophinopathic patients or a particular pharmaco-metabolic condition caused by general anaesthesia is unknown.

In our opinion, a poorly investigated problem is the metabolic derangement which might occur when the normal activity of the enzyme carnitine-palmitoyl-transferase is simultaneously stressed by increased lipolysis and by anaesthetic agents [6]. Preoperative fasting, anxiety and restlessness could be important in this regard.

Sir,—Hopkins' editorial [1] correctly asserts the advantages of suxamethonium but has not detailed the contraindications. There is evidence that it is the dystrophinopathies that account for the unexpected cardiac arrests that occur with suxamethonium [2]. The difficulty in clinical practice is to distinguish the mild, often subclinical, forms of dystrophinopathy, such as Becker's, from normal patients. There may be no family history, and a specific history of muscle cramps with normal exercise, especially in males, may be the only clue to the underlying disorder. Hopkins' observation that cardiac arrest occurred after inhalation induction and suxamethonium is very important, particularly as cardiac arrest has occurred after halothane and isoflurane, without suxamethonium, in patients with dystrophinopathies [3, 4]. On the basis of this evidence I believe the following recommendations can be made: (1) suxamethonium and the volatile anaesthetics are contraindicated in patients with known or suspected dystrophinopathies; (2) the use of suxamethonium should be limited to specific indications, especially in children; and (3) suxamethonium should be avoided after inhalation induction.

Mortality from anaesthesia is very low. A further reduction requires attention to the less frequent but known causes. Adhering to the above guidelines may help.

P. T. Farrell

4. Chalkiadis GA, Branch KG. Cardiac arrest after isoflurane anaesthesia in a patient with Duchenne's muscular dystrophy. *Anaesthesia* 1990; 45: 22–25.

Sir,—Fiacchino and colleagues appear to be advocating routine preoperative screening of creatine kinase (CK) activity and yet they observe that the sensitivity and specificity of this investigation for detecting subclinical myopathies is low. Given that the prevalence of myopathies in the population is low, the predictive value of estimating CK activity renders this an unhelpful screening test. If there are clinical features suggestive of myopathy, or there is a family history of such a condition, CK estimation may form part of the investigative process of the underlying condition, but a normal CK result does not exclude a myopathy and will not, therefore, influence short-term anaesthetic management.

I am sympathetic towards Farrell's views, but before concurring with such rigid and generalized recommendations, it is important to be sure that the necessary alternative techniques are likely to be safer in *all* situations. I believe that first, we should distinguish between those cases where the diagnosis of a myopathy has been made, or seems likely on the basis of clinical information, and those cases where the likelihood of a myopathy is low (no family history or clinical features).

In the former group, it is generally accepted that the incidence and severity of complications attributable to suxamethonium (myotonia, postoperative ventilatory failure [1] and rhabdomyolysis) is so high as to outweigh the potential advantages of suxamethonium. When we consider the choice of maintenance drugs for general anaesthesia in these patients, the situation is not as clear. Hypermetabolic reactions and sudden massive rhabdomyolysis have been reported in dystrophic patients anaesthetized with volatile drugs without suxamethonium, but similar responses can occur in myopathic patients receiving total i.v. anaesthesia [2]. However, I believe that volatile anaesthetics do contribute directly to rhabdomyolysis [3, 4]. These disadvantages of volatile drugs need to be weighed against the detrimental cardiovascular effects of i.v. agents in patients who may have a severe cardiomyopathy. Symptoms of heart failure in patients with Duchenne dystrophy are deceivingly uncommon because of the enforced sedentary existence but myocardial dysfunction is common, as is evident from echocardiographic studies [5], which themselves can fail to detect patients with significant ventricular dysfunction [6]. One should also not ignore that there is, albeit anecdotal, great experience of the safe use of halothane in Duchenne patients.

As I hoped was clear from my editorial [7], the overall incidence of cardiac arrest after suxamethonium is low, but by being meticulous in our preoperative assessment of children it is likely that we can further reduce this incidence. What we cannot quantify are the potential advantages of techniques using suxamethonium. There are no published studies that have adequately compared outcome with these and alternative techniques. Again, as argued in the editorial, such studies would need to be extremely large to achieve sufficient power to detect small, but clinically important differences. Neither are there likely to be published case reports of morbidity or mortality associated with failure to rapidly establish a secure airway when suxamethonium was not used.

There will always be a risk with anaesthesia. For some individuals the risk varies according to the technique/drugs used, but there are many factors that can influence relative risk. It is my view, therefore, that rather than rely on rigid dictates, the anaesthetist must tailor the approach to clinical management to the needs of the individual patient if anaesthetic mortality is to be minimized. This requires anaesthetists to be able physicians, trained to a high level of competence in a range of anaesthetic techniques. It also requires anaesthesia to be a strong academic discipline with practitioners motivated to establish the many strands of evidence required for objective clinical decision making, and with the ability to evaluate these in conjunction with other, often conflicting, priorities. In the absence of firm evidence, clinicians can only guess which approach, in their hands, is most likely to provide the best outcome for the patient: this is what we term "clinical judgement". One aim of my editorial was to highlight that, until we can quantify the complete risk/benefit profile for suxamethonium, its use in children must remain a matter of clinical judgement.

Isolated forearm technique

Sir,—In reply to our original letter [1], Healy and Pomfrett [2] chastise us on several counts: that nitrous oxide–oxygen anaesthesia "represents a very specific anaesthetic scenario", that we did not "allay public fears in a public forum" and that the isolated forearm technique (IFT) does not work.

The first implies that nitrous oxide and opioid "anaesthesia" is a little-used, obscure technique, and thus attempts to undermine the significance of the finding that 44% of patients are sufficiently aware to respond to command. Older readers will not need reminding that up until the late 1980s, nitrous oxide–opioid techniques were used commonly in the UK and an MDU anaesthetic adviser was prompted to discourage their use [3]. However, such techniques are still popular in continental Europe [4] and furthermore, studies using these methods continue to appear in reputable anaesthetic journals [5, 6]. Had the IFT been used more widely in the 1980s, British anaesthetists would have been aware much sooner as to how lightly "anaesthetized" their patients were.

With regard to allaying public fears, the authors were interviewed, both individually and together, for various local, national and international radio and regional television networks. During these interviews it was made clear that in the UK today these anaesthetic techniques are used much less commonly than in the past.

The single case of IFT failure [7] which Healy and Pomfrett make so much of occurred during Russell's first study of the IFT when some of the technicalities were still being evaluated, and is only one of many hundreds of successful uses of the procedure. This compares well with technical failure rates of common electronic monitoring devices as a result of poor electrode contact–positioning or diathermy interference.

Healy and Pomfrett suggest that because decerebrate rats show responses to surgical stimuli this invalidates the IFT. Nothing could be further from the truth. The possibility of such subcortical responses in humans is the *sine qua non* behind the necessity of ascertaining correctly the type of response occurring with the IFT, for example asking the patient to make conditional responses.

Merely recording that the hand appeared to move is insufficient. Unfortunately, such unverified responses were used in the principal article quoted by Healy and Pomfrett to suggest that the IFT does not work [8]. Bogod and colleagues [8] used the IFT for the first 30 min of surgery and scored their responses as "nothing, non-specific or firm clenching/flexing". They made no attempt to communicate with the patient. They used a command which asked the patient to open and close her hand if she could hear the message and would rather be more deeply asleep. Bogod and colleagues also classified their patients on the basis of dreams into light and deep groups and assumed that the IFT responses should bear some relationship to this split.

Neither of the two patients reported as being aware [8] showed type-two responses (clenching-flexing responses) but there are major problems in interpreting these data as evidence of intraoperative awareness and failure of the IFT. Patients may not have wished to be more deeply asleep or, as the tape was not personalized with a name, the patients may not have realized the message was intended for them. More importantly, the IFT was used for only 30 min so both experiences (one described discomfort similar to a previous Caesarean section, the other a suffocating feeling) could easily have occurred after this period, particularly during the waking up and extubation period.

It is true that ketamine is believed to disrupt cognitive function, but unlike thiopentone it also provides analgesia. Although the suggestion of Healy and Pomfrett that patients receiving ketamine do not respond to commands because they are conscious with impaired cognition is a possible explanation, it is much more likely that compared with thiopentone, patients who received ketamine were adequately anaesthetized [9].

Sometimes patients respond to a simple command, but do not respond appropriately to more complex commands. While such simple movements in respond to commands might not be a taxing test of cognitive function in the true psychological sense, we do not believe many anaesthetists would be likely to continue surgery without changes to their anaesthetic regimen when they observe a patient squeezing their fingers to a simple command or opening their eyes to command.

In view of the data presented [10, 11], we accept that provided a volatile agent is used appropriately the majority of patients are unconscious during general anaesthesia, but such proof can only be provided by use of the IFT. There is no electronic monitor available which can give real-time quantification of depth of anaesthesia and in its absence we remain firmly of the view that the IFT is the only currently available, real-time, practical method of determining levels of consciousness during general anaesthesia involving neuromuscular block.

Sir,—Thank you again for allowing us to answer yet another of Dr Wang and Dr Russell's letters. Our original letter [1] to *The Times* sought not to chastise these researchers, but rather to temper the conclusions drawn from the original article by a correspondent for *The Times* during April, 1995 [2], which contained the sensational statement that "half of the patients on every operating list show evidence of wakefulness". It is unfortunate that, despite their reported attempts to allay public anxiety in the media, Drs Wang and Russell did not also choose to write to *The Times*. We would then have seen their clarification of the facts, and would not have written any further letters on this subject.

Our statement [3] that opioid anaesthesia "represents a very specific anaesthetic scenario" was not meant to infer that it is a little-used, obscure technique. It was mentioned only because the original article [2] in *The Times* did not mention the anaesthetic technique used, and its title inferred that half of all patients are awake during all anaesthetic procedures. We are glad to note that Drs Wang and Russell agree with us that this is not the case with appropriate levels of other anaesthetics. It is sad that they chose not to reassure readers of *The Times* about the outstanding efficacy of anaesthesia.

It is interesting to note that the failures of the IFT reported in the literature, on which we based our statement "the IFT has been proved to be ineffective," were all, according to Drs Wang and Russell, caused by methodological flaws. Our previous letter [3] discussed the findings of the groups who described the IFT to be ineffective in some detail, and we shall not repeat that discussion here.

If we attempt to attribute something useful to this series of letters, at least they may serve to place the IFT into its proper context. The IFT is, at present, an adjunct to other anaesthetic research. One example of such research [4] used a carefully constructed procedure to define recovery of consciousness in 20 patients after a single dose of thiopentone. The patients were monitored using the IFT and a commercially available EEG monitor (Aspect A-1000). An initial orientating command ("squeeze my fingers") was repeated every 30 s and followed, after a positive response, with a more complex test of cognition ("squeeze my fingers twice"). Only a response to the second condition was taken as proof of recovery of consciousness. This research suggested that the EEG monitor indicated consciousness at least as effectively as the IFT, but with the addition of a continuous, automatic and objective scale (bispectral index). However, neither the IFT nor the bispectral index answer what the anaesthetist really needs to know, that is what is the absolute depth of anaesthesia and is this sufficient to prevent various stimuli during surgery from causing the patient to awaken? As such a monitor, the IFT is ineffective. After all, it is too late if the patient is already awake. That is failure.

CSF progesterone concentrations in pregnancy

Sir,—I read with interest the article by Hirabayashi and colleagues [1] in which the authors showed that there was an increase in CSF progesterone concentrations in pregnancy and a greater cephalad spread of anaesthesia as pregnancy progressed. They were unable to demonstrate any correlation between CSF progesterone concentration and maximum cephalad spread of anaesthesia in any of the groups. However, they claimed that the data suggested that "not only a minimum level of progesterone in CSF but also a certain duration of exposure to elevated CSF progesterone concentrations may be necessary for enhancement of spread of spinal anaesthesia...". Even though they were unable to show a relationship, they seem to want the reader to conclude that progesterone may be related in some way to the higher spread of spinal anaesthesia. They are suggesting causality without any evidence to support it.

All patients had subarachnoid injection of hyperbaric solution which would tend to spread cephalad because of the natural curvature of the spine. One way to avoid the effect of "mechanical factors" on cephalad spread would have been to use an isobaric solution for injection. Spread of isobaric solution is not affected by the position of the patient and other mechanical factors to the same extent as a hyperbaric solution.

The authors have cited several references which support the increased susceptibility of nerve tissue to block by local anaesthetic agents in pregnancy. Mechanisms which have been implicated are the direct effect of progesterone on membrane excitability, indirect actions of neurotransmitters, increased permeability of the neural sheath and potentiation of the analgesic effect of endogenous opioids. These studies can be used to explain an increase in the intensity of subarachnoid block with lignocaine but the references cited cannot explain an increase in cephalad spread of the block.

N. BALIGA
Department of Anesthesiology
University of Michigan Medical Center
Ann Arbor, MI, USA

1. Hirabayashi Y, Shimizu R, Saitoh K, Fukuda H. Cerebrospinal fluid progesterone in pregnant women. *British Journal of Anaesthesia* 1995; 75: 683–687.

Sir,—In our article we demonstrated a time lag between an increase in CSF progesterone concentration and development of enhanced spread of spinal anaesthesia. In addition, enhanced cephalad spread of spinal anaesthesia was found to take place during the middle stage of pregnancy, in spite of its low CSF progesterone concentration. Hence, we concluded that not only a minimum level of progesterone in CSF but also a certain duration of exposure to elevated CSF progesterone concentrations may be necessary for enhanced spread of spinal anaesthesia. Because mechanical factors are insufficient to explain enhanced spread of spinal anaesthesia beginning at the middle stage of pregnancy, an increase in progesterone, as a non-mechanical factor, is expected to play an important role in the enhancement. In addition, our results showed that there was no significant correlation between CSF progesterone concentration and cephalad spread of spinal anaesthesia at any stage of pregnancy, and that cephalad spread did not differ between singleton and twin pregnancies in spite of significantly higher concentrations in CSF progesterone in parturients with twin pregnancies compared with those with singletons. From these data we concluded that the value of CSF progesterone concentration does not correlate directly with the degree of enhancement. This conclusion, however, does not deny involvement of progesterone with pregnancy-induced enhancement of spinal anaesthesia. We presume that a certain duration of exposure to elevated CSF progesterone concentrations causes enhancement of spinal anaesthesia beginning at the middle stage of pregnancy, regardless of the values of CSF progesterone concentration.

We agree with Dr Baliga's suggestion that to avoid the effect of "mechanical factors" on cephalad spread, isobaric anaesthetic solutions are preferable to hyperbaric. Unfortunately, we do not have our own data on cephalad spread with isobaric solution, particularly with respect to pregnant women [1]. On the other hand, Russell and Holmqvist [2] compared the effects of isobaric with those of hyperbaric bupivacaine in parturients undergoing Caesarean section, and suggested that pregnancy enhances the spread of isobaric more than the spread of hyperbaric bupivacaine. Nonetheless, it remains unclear if pregnancy during the early and middle stages enhances the spread of isobaric anaesthetics.

A hyperbaric solution injected into the mid-lumbar subarachnoid space spreads in both cephalad and caudal directions under the influence of gravity. In a cephalad direction, it pools in the lowest part of the thoracic hollow and then diffuses towards cephalad. The concentration of the anaesthetic agent in CSF at the cephalad part of the hollow should be lower than that at the bottom of the hollow. In this condition, a certain concentration that is devoid of local anaesthetic activity in non-pregnant women may cause conduction block in pregnant women who have an increased susceptibility of nerve tissue, resulting in an increase in cephalad spread of block. Thus increased susceptibility of nerve tissue during pregnancy may explain not only the increase in intensity of subarachnoid block but also the increase in cephalad spread of the block. The references cited in our article support the increased susceptibility of nerve tissue to block by local anaesthetics during pregnancy. The cellular mechanism of this effect, however, is not yet clear.

2. Russell IF, Holmqvist LEO. Subarachnoid analgesia for Caesarean section. A double-blind comparison of plain and hyperbaric 0.5% bupivacaine. *British Journal of Anaesthesia* 1989; 59: 347–353.

Extradural analgesia in the first stage of labour

Sir,—We read with interest the article by Buggy and MacDowell [1] comparing an extradural mixture of clonidine and fentanyl with 0.25% bupivacaine for the first stage of labour and wish to raise the following points.

(1) While claiming that the power of the study was too low to detect a true difference in sedation scores (30% power) and the incidence of hypotension (45% power) between the groups, the authors conveniently omitted details of the study's power to detect a difference in analgesic efficacy between the two groups, one of the stated aims of their study. The degree of analgesia, as assessed by visual analogue scores, was said to be similar in both groups, but considering there were only 14 patients in each group, we suspect that the study lacked sufficient power to reveal any difference.

(2) Although the design of the study was said to be double-blind, we believe that the anaesthetist performing the assessments in both groups could not have been truly blinded as to which drug regimen was being used. As the data revealed that eight patients in the 0.25% bupivacaine group, not unexpectedly, developed significant leg weakness, presumably the anaesthetist could not have asked patients in this group to perform a Romberg's test!

(3) The authors found a median sensory level of T10 in both groups, but stated that all patients in the clonidine–fentanyl group had "preserved pinprick and temperature sensation". Are both findings compatible? Perhaps other, unspecified, sensory tests were performed.

(4) The authors stated that overall satisfaction with extradural analgesia after delivery was high in both groups: 79% and 86% in the clonidine–fentanyl and bupivacaine groups, respectively. The implication is that the clonidine–fentanyl mixture provided

good analgesia overall. However, the single dose of clonidine–fentanyl used in group 1 provided analgesia only for a mean of 80 min during a much longer labour (median duration 6.4 h). Both groups subsequently received extradural infusions of 0.1 % bupivacaine in addition to further top-ups of 0.25 % bupivacaine if analgesia was inadequate. There is also no mention of the additional amounts of 0.25 % bupivacaine used in both groups. The implied overall satisfaction with the clonidine–fentanyl mixture must therefore be regarded with scepticism.

(5) The authors stated in conclusion that it may be safer for patients receiving clonidine–fentanyl mixtures to walk during labour compared with a group receiving an ambulatory regimen of 0.1 % bupivacaine with fentanyl 2 $\mu g\ ml^{-1}$ because of reduced dorsal column impairment. However, it is unclear how many individual patients had abnormal dorsal column signs in the clonidine–fentanyl group. For example, did the four patients with impaired proprioception also have impaired vibration sense ($n = 2$) and a positive Romberg's sign ($n = 2$)? Otherwise eight different patients (55 %) could have exhibited abnormal dorsal column signs, precluding ambulation.

(6) Finally, neonatal assessment in the study was inadequate. Umbilical cord blood-gas values and possibly neurobehavioural scoring would have provided additional information on neonatal condition.

R. Fernando
M. G. Parry
Department of Anaesthesia
Royal Free Hospital
London

1. Buggy DJ, MacDowell C. Extradural analgesia with clonidine and fentanyl compared with 0.25 % bupivacaine in the first stage of labour. *British Journal of Anaesthesia* 1996; **76**: 319–321.

Sir,—We thank Drs Fernando and Parry for their interest in our article and respond to their comments sequentially.

(1) Assuming that a reduction of 4 cm on the visual analogue scale (VAS) is a clinically significant reduction in pain intensity, and given a median interquartile range of 2.5 cm on the VAS from all our pain data, the power of our study to detect true differences in VAS scores was 82 %, for an alpha error of 0.05 and $n = 14$ in each group. The reason for our study's apparent greater power to detect differences in pain scores compared with its relatively low power to detect differences in the incidences of side effects lies in the nature of the data: much greater power is required to detect differences in *proportions* between groups than for differences in data on an ordinal scale, especially when, as pointed out in our study, the incidence of these side effects was low

(2) Our hospital pharmacist ensured that our study was double-blind, using coded, labelled syringes. The table in our article indicated MRC < 3, which may have been misleading. Motor weakness was taken as an MRC grade *less than or equal to* 3, and seven of the eight patients in this category were in fact MRC grade 3. All eight patients were able to stand and undertake Romberg's test, although it was deemed abnormal in six.

(3) Sensory level was obtained using a cold ethyl chloride spray, whereas dermatomal sensation was tested with the base of the tuning fork, in addition to pinprick.

(4) All patients received an infusion of 0.1 % bupivacaine after a mean duration of 80 min on the test solutions alone, and although there were no statistically significant differences between the median amounts of bupivacaine infused, there is no doubt that overall patient satisfaction would have been influenced by the analgesia provided by this infusion.

(5) The presence of posterior column signs does not preclude ambulation, as the experience of the Queen Charlotte's group has demonstrated. We suggest a potential for greater safety in the reduction of these transient abnormalities, if the regimen can be shown in future studies to be effective and safe over a longer duration of labour. One patient in our clonidine–fentanyl group had impaired vibration sense alone, otherwise our patients with impaired proprioception also had other posterior column signs.

(6) We accept that umbilical cord gases and neurobehavioural scores would indeed have provided additional information on neonatal condition.

Extradurals and infection

Sir,—We read with interest the article by Jakobsen, Christensen and Carlsson [1] on extradural anaesthesia in the presence of infection. Following a case at St Helier Hospital, where there was microbiological evidence of infection in a patient receiving a continuous extradural infusion for postoperative pain relief, we undertook a survey to culture the tips from all non-obstetric catheters used for postoperative pain relief. During the first 6 months, all catheters were inserted with an aseptic non-standardized technique, and during the second 6 months the catheters were inserted with a standardized technique.

The total number of catheters inserted was 136. The overall incidence of contaminated catheters was 19.8 %. There was no significant difference in the incidence of contamination between the two techniques. There was no significant difference in the duration of the period *in situ* between those with a positive culture (mean 72 h) and those with a negative culture (mean 81.7 h). Specific organisms cultured included *Staphylococcus epidermidis* (most common), *Coliform*, *Bacillus*, *Enterococcus* and *Diphtheroid*. Except for the septicaemia seen in the patient described, we saw no other infective complications. Infected extradural catheters carry a serious risk of morbidity and mortality in terms of septicaemia, meningitis and abscess formation. In a review of the literature, we found 34 reported cases of extradural abscess [2–7] and six cases of meningitis [6, 8–14]. There were no reported cases of septicaemia.

Intuitively we would expect the longer an extradural catheter is *in situ* the more likely the patient is to suffer infective complications, in a manner similar to indwelling i.v. catheters. However, this does not seem to be the case from our results or from a study by DuPenn and colleagues [15]. We were, however, surprised by the duration the authors left their catheters *in situ*, as Bromage [16] recommends that catheters should be changed every 72 h to prevent the occurrence of local tissue reactions.

In view of our results, we feel that the use of indwelling extradural catheters in the management of patients who require repeated surgical procedures in the presence of infection cannot be justified as the benefits have not been shown to exceed the risks.

Cervical haematoma and airway obstruction

Sir,—We are grateful to Munro, Makin and Reid [1] for their report on cases of airway obstruction after carotid surgery. We have encountered similar problems after anterior cervical spine surgery. We agree with the authors that early intervention is to be encouraged and that deterioration of airway patency is unpredictable and can be rapid; fatalities have occurred in our hospital. The problem is that staff are reluctant to establish a tracheal airway until it is clearly necessary, because they know that the intervention may be difficult and they risk criticism of their management. Professor Eichorn has called anaesthesia a specialty with "zero tolerance for complications" [2].

Munro, Makin and Reid apologize for the use of i.v. induction and neuromuscular block in one of their cases, even though the patient's trachea was intubated successfully. We have not found evidence in theirs or other reports [3] that i.v. induction and paralysis are less likely to be successful than inhalation induction. Airway patency nearly always deteriorates when anaesthesia is induced, for two reasons: (1) the glottic opening obstructs against the posterior pharyngeal wall as pharyngeal tone decreases [4, 5]; and (2) reflex glottic activity (coughing, breath-holding and laryngospasm). Obstruction may occur at light levels of anaesthesia in patients with upper airway pathology whatever method is used, including topical anaesthesia of the glottis [Calder, unpublished observations]. Deep general anaesthesia is required to obtund glottic reflex activity sufficiently to allow intubation. This can be difficult to obtain with an inhalation technique and may be impossible if the airway is obstructed. Our experience with halothane and spontaneous ventilation for fibreoptic tracheal intubation led us to abandon the technique. At least one patient in our series survived only because muscle paralysis and positive pressure ventilation were commenced [6]. In our experience a period of positive pressure ventilation is required to obtain sufficient glottic relaxation when halothane is used. The benefits of positive pressure, or at least CPAP, in the relief of severely obstructed airways have been mentioned by several authors [7–9], and positive pressure is the mainstay of treatment in obstructive sleep apnoea [10]. We do not seek to dissuade our colleagues from using an inhalation technique, but we suggest that it is no more likely to succeed than any other when severe airway obstruction is present. It is unhelpful to give the impression that the use of airway-friendly i.v. agents such as propofol or neuromuscular blockers may expose practitioners confronted with a desperate emergency to criticism.

Our advice to practitioners treating patients with anterior cervical haematomas is: (1) be aware that complete airway obstruction can occur suddenly; (2) inhalation of nebulized adrenaline can improve the airway, but is not a substitute for securing the airway – we have had a fatality in a patient whose airway improved dramatically with adrenaline but obstructed completely some hours later; (3) have a surgeon standing by ready to perform a tracheotomy; (4) awake fibreoptic intubation in the sitting position is a good technique, but be aware that the airway can deteriorate during the procedure because of (1) above, and because lignocaine can provoke laryngospasm when applied to the glottis [11]; (5) insufflate oxygen via a nasal catheter; (6) have a laryngeal mask airway (LMA), a gum elastic bougie and also a 6.0-mm diameter tube to allow through LMA intubation [12]; (7) use whatever method of induction with which you are comfortable and give neuromuscular blockers if the patient may benefit; and (8) use a small tube (7.0-mm diameter maximum) and do not remove it for at least 24 h.

Our aim should be to encourage early intervention by emphasizing that in the early stages any method is likely to be successful, and refraining from criticism if difficulty is encountered, because it is probable that pathology, not technique, is to blame.

Sir,—We thank Dr Calder and Dr Koh for their interest in our report.

We appreciate that the safest and most appropriate management of a difficult airway is usually that method with which the anaesthetist feels most confident. However, regarding i.v. induction and paralysis we feel that this may not be as successful, as one or our original references indicates [1]. In a series of six cases, in the four who were paralysed, the lungs could not be ventilated by hand. Two of these patients became asystolic and two suffered bradycardia of which one was less than 10 beat min^{-1}. Of these one had an emergency tracheotomy and in the other three, the trachea was intubated blindly. The two other cases underwent inhalation induction, one after ensuring the ability to hand ventilate was paralysed, and in both the trachea was intubated with comparative ease.

We agree that early intervention is to be encouraged, however, in such cases the degree of airway distortion should never be underestimated, and that a surgical airway may be a safe alternative.

Management of pre-eclampsia

Sir,—We read with interest the recent review article by Mushambi, Halligan and Williamson [1] on recent developments in the pathophysiology of eclampsia, and wish to draw attention to a recent case who responded dramatically to Centoxin. It raises several interesting questions and possibilities for future research and management of these patients, particularly in respect of liver damage and possible gastrointestinal failure, some aspects of which were not included in this review article.

The case was a 31-yr-old primigravida who was delivered of a live infant under extradural anaesthesia by Ventouse extraction. She had had an uneventful antenatal course with no sign of pregnancy-induced hypertension, although 2+′ protein were recorded in the urine throughout labour. Three hours after delivery she started to complain of headaches and epigastric pains, at this time she was found to be mildly hypertensive (165/95 mm Hg). Simple analgesia and baseline investigations were ordered. Six hours after delivery she convulsed. Further episodes occurred 1 and 2 h later. While observed on the delivery ward she was given phenytoin and diazepam, but additional treatment with Heminevrin and thiopentone (at low doses) were required to control the convulsions. Unfortunately, there were no intensive care beds available at the time and so management was continued in the delivery suite. Central venous pressure was monitored and urine output (with heavy proteinuria) maintained with careful boluses of human albumin solution. The patient continued to deteriorate, becoming febrile with tachycardia, and a labile arterial pressure, and she showed signs of pulmonary oedema. Serum blood glucose concentration became unstable (reaching as low as 1.2 mmol litre^{-1} at one time) and required supplementary glucose. Biochemical and haematological evidence of worsening multi-organ failure became evident, as her LFT became elevated and haemoglobin decreased to 8.8 g litre^{-1} with a platelet count of 58×10^9 litre^{-1}. It was thought that an ensuing systemic inflammatory reaction syndrome (SIRS) was developing. It was thought unlikely that any products of conception were retained, her urine was clear of organisms and therefore perhaps significant translocation of gut bacteria and endotoxins was occurring. With deranged liver function, especially the reticulo-endothelial aspect, it was possible that this was causing significant endotoxaemia. After much discussion with the intensivists it was decided to administer Centoxin (HA-1A) to this patient (she was already receiving cefuroxime and metronidazole).

Within 4 h she became demonstrably more stable and less agitated. Sedation was stopped and arterial pressure became normal; blood glucose concentration became less erratic. Over the next 8 h the clinical signs of pulmonary oedema stabilized (she had demonstrable cardiomegaly on the chest x-ray) and her temperature returned to normal. All cultures failed to grow organisms. Despite persisting albuminuria, peripheral oedema stabilized over the next 24 h and blood glucose concentrations became normal.

Although it could be argued that this eclamptic patient would have stabilized as rapidly without Centoxin, as she had delivered the fetal–placental unit, it does suggest that significant endotoxaemia was occurring (although we have no proof). Perhaps the phrase "toxaemia of pregnancy" should be retained? It may well be that a form of systemic inflammatory reaction is occurring in this disease as a result of the immunological insult outlined in the review article. There is limited evidence in animal models that gut translocation can contribute to the pathophysiology of eclampsia [2, 3], although little human evidence has yet been published [4].

Clearly, liver impairment contributes to endotoxaemia (and other forms of sepsis from gut organisms), and often this liver damage is neglected in pre-eclamptic and eclamptic patients until severe failure has occurred. Perhaps the "fatty liver of pregnancy" is one form of end-organ failure caused by the same pre-eclamptic process, another being the more easily recognized HELLP syndrome? In this unit we observe carefully for liver impairment and monitor blood glucose concentrations regularly. Other forms of liver support can then be given as needed for acute liver failure [5]. This aspect of end-organ damage was overlooked in the review article and we commend regular blood glucose estimation as the minimum for monitoring liver dysfunction; regular clotting screen and protein–albumin concentrations should also be undertaken. Perhaps the gastrointestinal tract itself should be encompassed in the list of end-organs to fail?

Another form of end-organ damage which may also be part of the pre-eclamptic disease process is that of the heart failure seen in severe eclamptics; perhaps this is part of "cardiomyopathy of pregnancy" and instituted by a similar immunological stimulus.

Clearly more studies are required into the specific immunological problems and complex processes that occur in pre-eclampsia, but perhaps the role of endotoxins could be defined further.

5. Stanley AJ, Lee A, Haynes PC. Management of acute liver failure; aetiology, complications and management. *British Journal of Intensive Care* 1995; 5: 8–15.

Sir,—We thank Drs Ward, Caunt and Alderson for their interest in our review article and are grateful for their comments. We are unable to comment on their theory of endotoxaemia or the role of Centoxin, but we wish to make some points.

First, Centoxin was withdrawn from use in 1993. This raises the question of why it was used, unless of course the case described occurred before 1993.

We also wish to question their management of eclampsia using phenytoin, diazepam, chlormethiazole (Heminevrin) and "low-dose" thiopentone. The use of magnesium sulphate in this patient would have been a preferable choice of drug. Compared with diazepam and phenytoin, magnesium sulphate has been shown to control convulsions, reduce recurrent convulsions and cause fewer side effects [1]. The use of chlormethiazole in the treatment of eclampsia is unacceptable because of the problem of fluid overload and oversedation. Magnesium sulphate is now the drug of choice in patients with eclampsia.

From the clinical signs described and laboratory findings stated, it is most likely that the above patient had HELLP syndrome, and hypoglycaemia is a known complication of this syndrome, as stated in our article [2, 3].

Pulmonary oedema in patients with pre-eclampsia results commonly from fluid overload and less frequently from left ventricular dysfunction. Unfortunately the letter does not indicate the type or amount of fluid their patient received, her urine output or central venous or pulmonary wedge pressures; these data would have been helpful in determining the cause of her pulmonary oedema.

Unfortunately, pre-eclampsia is still a disease for which many theoretical and improved aetiologies abound and because it is a multisystem disorder, it has many ways of presenting.

BOOK REVIEWS

Anesthesiology, House Officer Series. A. J. Berry and G. B. Knos (editors). Published by Waverly Europe Ltd, London. Pp. 677; indexed; illustrated. Price £9.95.

The publishers describe this series of books as being appropriate to keep in the pocket, but the binding of the book is not strong enough and its size will prohibit it from being easily carried in the pocket.

This book consists of 23 chapters and six appendices, it has 33 contributors, and consequently the chapters lack a consistent approach. Most unfortunately, the first page of chapter 1 has a major printing error, whereby the majority of the first paragraph is repeated; this inevitably colours one's judgement when setting out to review the text.

The chapters cover the whole of anaesthesia, there is frequent use of tables which provides clarity and the appendices on monitoring standards, ACLS and drugs used in anaesthesia are extremely useful. The index is comprehensive and its compilers should be commended.

There are well known differences in practice between North America and the UK and this book is testimony to that fact, for example there are only seven lines of text allocated to the laryngeal mask airway, blood-gas values are quoted in "torr" and the use of an amnesic agent is recommended for insertion of unpleasant monitoring cannulae. As a result of these and many other differences, I do not believe that this book can be recommended for use by the new anaesthetic junior in the UK, as the differences will only serve to confuse and complicate their early formative time in theatre.

G. W. Jones

Ophthalmic Anaesthesia—A Practical Handbook, 2nd Edn. G. Barry Smith, R. C. Hamilton and C. A. Carr. Published by Arnold, London. Pp. 284; indexed; illustrated.

The role of the anaesthetist in the management of patients undergoing ophthalmic surgery has changed markedly in the past decade. There is now much greater emphasis on involvement in procedures during local anaesthesia and there have also been significant changes in surgical practice, an understanding of which is essential for any anaesthetist who wishes to take a full part in patient management. The authors rightly believe that a firm grounding in relevant basic science is an essential prerequisite and the chapter on the anatomy of the eye and orbit is an excellent résumé of current knowledge. Although the illustrations are not in colour they are of very high quality and are adequate for their purpose. Chapters on the physiology of the eye and the effect of drugs on the eye are short but relevant. The section on medical conditions is less appropriate and I doubt the need to consider management of cardiac ischaemia or hypertension even briefly. The discussion of regional compared with general techniques is an area of particular concern to the clinician and is well covered and referenced. There is a full description of techniques of orbital regional anaesthesia and their complications, and many individuals will be interested to note the authors' recommendation that those who wish to practise these should undertake cadaver dissection of the orbital region as part of a training programme. Chapters on general anaesthesia and monitoring, paediatric anaesthesia, strabismus, adnexal surgery, ocular trauma, day-case surgery, vitreo–retinal surgery and audit follow.

The overall impression of this text is that it is written by individuals with considerable personal experience in the field. It is very readable and some of the comments, such as the one on cadaver dissection, are thought provoking. Others are perhaps inappropriate for those in the UK, for example although many ophthalmologists sub-specialize, I doubt that many ophthalmic anaesthetists specialize in anaesthesia for particular surgical procedures. It is an excellent book for those working in the field and many consultants will want a personal copy. Not all trainees are required to know all that is contained in it, but it should find a place in departmental libraries for reference.

W. A. Chambers

Difficult Hypertension: Practical Management and Decision Making. M. J. Kendall, N. M. Kaplan and R. C. Horton (editors). Published by Martin Dunitz, London. Pp. 296; indexed; illustrated. Price £49.95.

Several major text books of hypertension have appeared recently, raising the question "Is there room for one more?" In the case of this book, my answer is yes, because it fills a gap, providing practical approaches to the difficult clinical problems in hypertension. This is a multi-author book, comprising 16 chapters, divided into four sections, dealing with different ages and ethnic backgrounds of patients, types of hypertension, the setting, that is renal disease and diabetes, and decision making in hypertension. Section one concerns hypertension in childhood, pregnancy, the elderly and different ethnic groups. In general the chapters were well balanced but there were several odd recommendations such as the use of i.v. diazoxide for severe hypertension in children. Diazoxide is a powerful and the least controllable form of therapy for acute reduction in arterial pressure with the danger of prolonged severe hypotension. Also, only short-acting ACE inhibitors were recommended, requiring multiple doses throughout the day when surely a single daily dose of a long-acting agent would be preferable. The chapter dealing with hypertension in pregnancy emphasized the clear differences between patients with essential hypertension in pregnancy and those who develop hypertension which is associated with pregnancy; this chapter contained good general advice about management and emphasized important differences in management philosophy. The last chapter in this section on ethnic differences examined the greater severity of hypertension in Blacks and their different responses to antihypertensive therapy, in particular that ACE inhibitors and beta-blockers lower arterial pressure in the White population whereas calcium antagonists and thiazide diuretics are much more effective in the Black population.

The second section entitled "The setting" dealt with secondary hypertension, the problem of "J" shaped curve of cardiovascular risk and reductions in arterial pressure in patients resistant to treatment and the importance and practical difficulties in treating isolated systolic hypertension. These are most important areas in hypertension. I particularly enjoyed the chapter on resistant hypertension which outlined thoroughly sensible and practical approaches for managing these patients. The chapter on the "J" shaped curve marshalled a great deal of evidence to suggest that lowering arterial pressure to less than 85 mm Hg provided no additional benefit and may even be associated with an increase in cardiovascular mortality. Although controversial, this topic is perhaps not one of the most challenging aspects of treatment because large numbers of patients remain untreated or poorly controlled. In my opinion, the problem of reducing a patient's arterial pressure to less than 85 mm Hg diastolic is not a major concern.

The third section covered particular patient settings, including diabetes, cerebrovascular disease, renal failure and a chapter on practical advice on the management of hypertensive patients undergoing anaesthesia. The chapter on cerebrovascular disease dealt with the difficult problem of reducing arterial pressure in stroke patients. Advice about cautious reduction in severe hypertension in acute stroke patients was balanced with the strong message that in the long term, good arterial pressure control is a significant factor in preventing recurrence and improving the long-term outcome of these patients. Only one chapter (12) was aimed at the anaesthetist and gave excellent advice on how to deal with hypertensive patients who require general or spinal anaesthesia. The importance of information on the presence of end-organ damage, in particular the presence of left ventricular hypertrophy which may predispose patients to arrhythmias during induction, was emphasized. The dangers of excessive reductions in arterial pressure during general anaesthesia were discussed, attention being drawn to the role of vascular structural changes leading to thickening of the wall and narrowing of the lumen of blood vessels which limits the ability to increase blood flow in crisis situations.

The fourth and final section of the book concerned decisions relating to the processes involved in introducing a new antihypertensive agent into clinical practice, the impact of antihypertensive therapy on the quality of life of treated patients and how to assess clinical trial data. Quality of life has become an important issue as hypertension is an asymptomatic condition requiring long-term treatment, and treatment should not adversely affect the patient's lifestyle. The final chapter of the book is worth reading by anyone in clinical practice. It outlines a logical approach for evaluation of studies and provides useful rules to test the validity of any clinical study. Limitations of meta-analysis are discussed and provide some understanding of why experts may make different recommendations based on the same clinical data. I very much enjoyed this chapter and commend it to all clinical students and doctors.

H. Thurston

Acute Pain Management: A Practical Guide. P. E. MACINTYRE AND L. B. READY. Published by WB Saunders Co. Ltd, London. Pp. 198; indexed; illustrated. Price £14.95.

There has been an enormous expansion in the provision of acute pain services world-wide over the past decade and there is a need for a small book which can be accessed readily by all involved in this activity. Such a book should be useful for anaesthetists, surgeons, nurses, physiotherapists, pharmacists and other paramedical staff. *Acute Pain Management: A Practical Guide*, by Pamela Macintyre and Brian Ready, more than fulfils this niche. It is an excellent publication and I recommend it highly.

The relatively small volume (198 pages) covers the theoretical and practical aspects of acute pain management in a clear and concise manner. There are nine chapters, many figures, tables and specimen charts, and a short but useful index. In my view, the authors have omitted nothing of importance in this book and its style and depth have been pitched perfectly.

The pharmacology of analgesics and local anaesthetics is described with emphasis on those points which are important in the practical management of patients. The pros and cons of traditional opioid administration are described and there is, of course, a chapter describing patient-controlled analgesia. This latter chapter is particularly good and the theoretical knowledge and practical experience of the two authors shine out from the pages. Extradural and intrathecal analgesia are given the same excellent treatment. The final chapter describes the importance and practical aspects of education of medics, nursing staff and patients.

The style of this book is most impressive; there is hardly a wasted or redundant sentence. Consequently, an enormous amount of factual detail and practical advice is included in this small volume.

I cannot recommend this book too highly. It represents essential reading for those involved in acute pain management and is also extremely good value for money.

D. Rowbotham

Anaesthesia for Surgery of the Spine. S. S. PORTER (editor). Published by Blackwell Science, Oxford. Pp. 390; indexed; illustrated. Price £47.50.

Anaesthesia for spinal surgery is one of those areas in anaesthetic practice which, although it demands special expertise, has not yet acquired the cachet of a subspecialty. In the UK, spinal surgery lies uneasily between neurosurgery, orthopaedics and paediatrics, the emphasis often being dictated by local enthusiasm and custom. Spinal operations may, therefore, be performed in several different units in a region even though there would seem to be substantial clinical and training advantages in concentrating most of these in a spinal surgery unit. Anaesthesia for this type of surgery embraces elements of that used in neurosurgery, orthopaedic and paediatric surgery. There is a particular risk of iatrogenic damage to nervous structures (including the spinal cord) both by the surgeon at operation and by the anaesthetist during manipulation of the neck during laryngoscopy and tracheal intubation.

This is a multi-author book with 20 contributors from a variety of medical institutions in the USA. Although the emphasis is on anaesthesia, there is a substantial surgical contribution which occasionally threatens to dominate. The book is broad in scope, with chapters on the anatomy and physiology of the spinal cord, acute and chronic spinal cord injury, and consideration of surgical procedures involving the cervical and thoracic spine. There are chapters on anaesthesia for spinal surgery in different arthritic conditions, including rheumatoid arthritis and ankylosing spondylitis, thoracolumbar spine correction, radiculopathy and discectomy, and paediatric spine procedures. Electrophysiological monitoring, intensive care management of cervical cord injury and chronic pain after spinal cord injury are considered in depth. Very usefully, the text carries a large number of references, each chapter, therefore, serving as a review of its topic.

Perhaps inevitably there is some repetition. For example, the approach to tracheal intubation in a patient with a proven or suspected cervical spine injury is considered by different authors in chapters 3 and 4; recognition and treatment of venous air embolism is covered equally comprehensively in chapters 4 and 5. The tone throughout, however, is discursive rather than didactic and there are no serious contradictions. There is much that is good, including a review of the anatomy of the adult spinal column (but not that of the child or adolescent), drug-based therapies for acute spinal cord injury, electrophysiological monitoring of the spinal cord and some challenging ideas on living with quadriplegia.

Those sections dealing with anaesthetic techniques describe standard methods for the operations concerned. Topics such as patient positioning, monitoring, hypersensitivity reactions (latex allergy) and assessment and management of the unstable or immobile neck are covered fully. Laryngeal masks, EMLA cream and parental presence at induction are not mentioned and the following topics are addressed very superficially: postoperative monitoring of patient-controlled analgesia (PCA) and extradural analgesia; management of postoperative nausea and vomiting, even in the context of extradural opioids or PCA. The suggestion (p. 190) that the total dose of i.v. infused opioids after thoracolumbar spine surgery can be reduced by giving intrathecal morphine is deplorable.

Notwithstanding these criticisms, this is a readable book containing a fund of useful information not found readily in other single volumes. There are many diagrams, radiographs and scans, although figure 10.10 has an error—the headings "Before" and "After" placed above the columns should refer to rows. The book cannot be recommended unreservedly but would form useful supplementary reading for trainees or those engaged in anaesthesia for spinal operations who wish to refresh their knowledge. It is hardbound, well presented and carries a detailed index.

J. P. H. Fee

Understanding Anaesthesia, 3rd Edn. L. E. S. CARRIE, P. J. SIMPSON AND M. T. POPAT. Published by Butterworth–Heinemann, Oxford. Pp. 431; indexed; illustrated. Price £25.00.

A book which reaches its third edition is clearly established, even more so when a previous edition has been reprinted on several occasions. *Understanding Anaesthesia* is such a book. Its stated aim is the education of the non-anaesthetist who is required to work closely in the anaesthetic environment, for example, operating department personnel, recovery room nurses, anaesthetic assistants, etc. To be successful at this level the book must strike the correct balance between over-simplification and excess complexity. It must also remember the intended audience at all times. In all of these matters it succeeds, hence its established position.

Understanding Anaesthesia contains 431 pages of text which are divided into 47 chapters. One-third of the chapters are of six pages or less and two-thirds are 10 pages or less; only two are more than 14 pages in length. The text is thus concise and confined to the important points only. The information is not too tightly packed however. Good use is made of headings and subheadings and the style is easy to read. The chapters range from fundamental basics, for example applied anatomy and physiology, and interpretation of the ECG, to the more specialized, for example anaesthesia for open heart surgery and neurosurgery. All of the major topics are covered and it is inappropriate to single out any one chapter or section because all are of an equally high standard.

It is difficult in a book such as this to know where to stop and how much detail to include. It is comforting to see that many of the newer drugs and techniques are included. Sevoflurane and desflurane are described and the cardiopulmonary resuscitation guidelines are the latest versions, although some other new agents, for example rocuronium and tramadol are missing. There are, as expected, no fundamental omissions, although the theory and use of the Swan Ganz catheter receives only brief coverage. Any desire for further information is amply catered for by the inclusion of a suggested list of books for further reading.

This is a book which deserves a place in every hospital library. It should also be on the reading list for all relevant nursing and further educational courses. In addition, copies should be available in strategic areas in operating theatre suites to serve as a general bench-book and as a source of information for students and learners. I am certain that this book will, is common with its previous editions, prove to be a bestseller.

B. J. Pollard

Neuromuscular Block. S. FELDMAN. Published by Butterworth–Heinemann, Oxford, Pp. 180; indexed; illustrated. Price £30.00.

You may ask "Do we need yet another book on neuromuscular block, there have been so many in recent times?" However, this monograph is different. The author has studied neuromuscular function for 40 yr; he has had the good fortune to be guided in his formative period by such great men as Organe, Scurr, Wyman and Lucien Morris. These famous contributors to anaesthetic research were able to teach the next generation to think and inquire; if only we had the same stimuli today! Professor Feldman has written his own soliloquy, raising in print those difficult questions he has always loved, in his most gentlemanly fashion, to ask the aspiring research worker (cognizant that none of us really knows the answer). All who are obsessed by the physiology and pharmacology of neuromuscular transmission will want to read this little book at leisure, and to have ready access to the occasionally idiosyncratic thoughts of (chairman) Feldman on his favourite subjects. It will not be read for its factual content, but to obtain a different perspective; for this book is not mundane, it aims to stimulate and provoke, and to a large extent it achieves these aims. The book presumes some prior knowledge of its subject: it is not intended to detail every latest advance, but to highlight the interesting developments and question the explanations, especially in relation to Professor Feldman's own research work.

The opening chapter on historical perspectives will attract interest, as will those on neuromuscular physiology. Indeed, throughout the text there are informative historical facts which I found noteworthy. None of the chapters is long, some are perhaps too short; they are simply tasters, which contain the pertinent points. The chapter on acetylcholine formation and metabolism is particularly interesting; how long will it be before we know the full answers on the putative presynaptic acetylcholine receptor? Is there more than one subtype for the examination candidate to remember. Do anticholinesterases really have any effect at these presynaptic receptors? The chapters are not referenced in detail, but the relevant literature is given. They are bountifully illustrated, making the book easy to read. My only real disappointment was chapter 8 on pharmacokinetics and pharmacokinetic models; it was so short and opinionated as to be barely worth publishing. I would also have hoped that Professor Feldman might be less nihilistic about obtaining a rapid onset nondepolarizing agent, the ultimate goal of neuromuscular pharmacologists. But in this matter, he has the same view as many of his illustrious contemporaries.

Unlike the great composers, perhaps Professor Feldman's greatest works were his earliest. He will always be remembered for his autoradiographic studies (1969), and his publications on the altered effects of neuromuscular blocking drugs in the presence of acidaemia, alkalaemia (1963) or hypothermia (1973). Similarly, his isolated arm technique (1970) is a novel method of studying drug affinity for the postsynaptic nicotinic receptors and recovery from neuromuscular block. It has been used repeatedly to contrast the action of every new neuromuscular blocking agent, as each has become available. Much attention is paid in the text to these areas of the author's particular interest.

This book is not a reference book; as is so characteristic of the author, it is to be read for enjoyment. It is the heritage which Professor Feldman passes on to his successors; those who inherit it have a formidable challenge in maintaining such standards. I am proud to have known him, and shall ask Professor Feldman to autograph my copy at the earliest possibly opportunity!

J. M. Hunter

A Physicians's Guide to the Internet. L. HANCOCK. Published by Lippincott–Raven, New York. Pp. 232; indexed. Price £23.00.

Having recently acquired access to email and the Internet, I was delighted to be given the task of reviewing *A Physician's Guide to the Internet* by Lee Hancock. I had a superficial knowledge of these things but after reading and using this book I now consider myself as something of any authority!

Lee Hancock is an educational technologist who "by night...explores the Internet looking for anything to do with resources in health and medicine." *A Physician's Guide to the Internet* is the result of this activity.

In the introductory section there is a very useful chapter indeed; a glossary of common Internet terms. I now know my Gopher from my elbow and the difference between Archie and Veronica. I have realized also that many of my "Internet-aware" colleagues are not quite as knowledgeable in this area as they would have me believe. For example, having read this book one can look a colleague straight in the eye and ask with confidence "What exactly do you mean by NCSA Mosaic?" The effect is awesome.

The author describes the Internet very well, for example how to access it and the tools available for finding what you want. Clear descriptions over relatively few pages indicate that it is really very simple and easy to understand.

The second section is the guide to the Internet. It is a list of Internet addresses with short summaries of the information available at each site. There are numerous entries listed under headings such as specific diseases or specialties. Naturally, I homed in on the "anesthesiology" section. Five addresses are listed, all in the USA. With eager anticipation I logged in, or tried to. However, what the first section of the book did not highlight is the eternal wait one often has before getting a response from a web site. This is particularly so when accessing from Europe to the USA. I was therefore unable to access the information "available" at these sites in any great detail. However, I was able to confirm that they really were out there. (The reviewer freely admits that he did not try at 03:00 on a Sunday when apparently the Internet is less busy.)

Access is, of course, quicker if the site is in Europe or elsewhere and therein lies my complaint about this book—the vast majority of listed sites are in the USA. It may be that there are no medical sites in the rest of the world, but I doubt it. The implied criticism of US colloquialism applies also to the appendix, listing Internet Access Providers and Medical School Gophers, all in the USA. In my view, this is a serious deficiency of the book—it seems to me that the whole point of the Internet is that it is world-wide.

I found the first section of this book very good and would recommend it. However, from a world-wide perspective, there is no doubt that the impression given by the author, that there are no medical sites on the Internet outside the USA, is very disappointing. A more appropriate title would be "A Physician's Guide to the Web Sites in the USA".

SUBJECT INDEX

A Physicians's Guide to the Internet, Hancock, L., (*R*) 893

A Practical Approach to Cardiac Anesthesia, Hensley, F. A. jr, *et al.*, (editors), (*R*) 174

ACE inhibitor, Hypotension following the administration of fentanyl-diazepam combination in chronic ACE inhibitor users, Özyurt, A., *et al.*, (*EACTA*) A.25

Acid–base equilibrium, pH, Gastric tonometry, Boyd, O., *et al.*, (*C*) 750

Acute Pain Management: A Practical Guide, Macintyre, P. E., *et al.*, (*R*) 892

Adolescents, Anatomical configuration of the spinal column in the supine position. III. Comparison of adolescent and adult volunteers, Hirabayashi, Y., *et al.* 508–510

Age factors, Anatomical configuration of the spinal column in the supine position. III. Comparison of adolescent and adult volunteers, Hirabayashi, Y., *et al.* 508–510

——, Effect of age on MAC in humans: a meta-analysis, Mapleson, W. W. 179–185

Air ambulance, Haemodynamic effects of air travel, Malagon, I., (*ARS*) 590P

Airway, Evaluation of an oesophageal intubation detector device using electrical resistance, Deakin, C. D., (*ARS*) 590P

Airway, calibre, A novel fibreoptic pressure transducer system for the upper airway, Secker, C., *et al.*, (*ARS*) 581–582P

Airway, complications, A novel fibreoptic pressure transducer system for the upper airway, Secker, C., *et al.*, (*ARS*) 581–582P

Airway, muscles, Comparison of sedation with midazolam and ketamine: effects on airway muscle activity, Drummond, G. B. 663–667

——, Differential effects of desflurane and halothane on peripheral airway smooth muscle, Mazzeo, A. J., *et al.* 841–846

——, Halothane and potassium channels in airway smooth muscle, Fukushima, T., *et al.* 847–853

——, Relaxant effect of ketamine and its isomers on histamine-induced contraction of tracheal smooth muscle, Hirota, K., *et al.* 266–270

Airway, obstruction, Airway problems after carotid endarterectomy, Munro, F. J., *et al.* 156–159

——, Cervical haematoma and airway obstruction, Calder, I., *et al.*, (*C*) 888

——, Cervical haematoma and airway obstruction, Munro, F. J., *et al.*, (*C*) 888–889

Airway, pressure, Airway pressure signals during high frequency jet ventilation, Lin, E. S., (*ARS*) 576–577P

——, Magnetic resonance imaging of the superior vena cava during spontaneous respiration with continuous positive airway pressure via a facemask in normal subjects, Mayor, A. H., *et al.*, (*ARS*) 578–579P

Anaesthesia, Effect of anaesthetic agents on pulmonary shunt during coronary artery surgery, Sindjelic, R., *et al.*, (*EACTA*) A.19

——, Hypotension following the administration of fentanyl-diazepam combination in chronic ACE inhibitor users, Özyurt, A., *et al.*, (*EACTA*) A.25

Anaesthesia and Critical Care Manual, 2nd Edn, Cunningham, A. J., (editor), (*R*) 338

Anaesthesia, audit, A pitfall in the use of the Altman nomogram for power estimation, Evans, M. J., *et al.*, (*C*) 334

——, Cost of volatile agents, Barker, I., (*C*) 749

——, Economy during induction of anaesthesia: a comparison of desflurane with isoflurane via a circle system, Pal, S. K., *et al.*, (*ARS*) 582P

——, Measurement of competence, Goodman, N. W., (*C*) 750

——, Omitting nitrous oxide in general anaesthesia: meta-analysis of intraoperative awareness and postoperative emesis in randomized controlled trials, Tramèr, M., *et al.* 186–193

——, Prehospital monitoring of trauma patients: experience of a helicopter emergency medical service, Morley, A. P. 726–730

Anaesthesia, day-case, Cognitive failures after general anaesthesia for day-case surgery, Tzabar, Y., *et al.* 194–197

——, Day-case cataract surgery, Goold, J. E., (*C*) 333

——, Day-case cataract surgery, Maltby, J. R., *et al.*, (*C*) 333

——, Naproxen after day-case laparoscopic sterilization, Dunn, T. J., *et al.*, (*C*) 168

——, Naproxen after day-case laparoscopic sterilization, Williams, P. I., (*C*) 168

——, Regional anaesthesia for outpatient nasal surgery, Molliex, S., *et al.* 151–153

Anaesthesia, depth, Double-blind, randomized trial of cessation of smoking after audiotape suggestion during anaesthesia, Myles, P. S., *et al.* 694–698

——, EEG arousal during laryngoscopy and intubation, Shannon, C., *et al.*, (*C*) 472

——, EEG arousal during laryngoscopy and intubation, Wilder-Smith, O. H. G., *et al.*, (*C*) 472–473

——, Effect of neuromuscular block on depth of anaesthesia as measured by the auditory evoked response, Richmond, C. E., *et al.* 446–448

——, Effect of tramadol on depth of anaesthesia, Coetzee, J. F., *et al.* 415–418

——, Heart rate variability in patients recovering from general anaesthesia, Ireland, N., *et al.* 657–662

——, Is there implicit memory after propofol sedation? Cork, R. C., *et al.* 492–498

——, Isolated forearm technique, Healy, T. E. J., *et al.*, (*C*) 885–886

——, Isolated forearm technique, Russell, I. F., *et al.*, (*C*) 884–885

——, Omitting nitrous oxide in general anaesthesia: meta-analysis of intraoperative awareness and postoperative emesis in randomized controlled trials, Tramèr, M., *et al.* 186–193

——, Recall during intermittent propofol anaesthesia, Nordström, O., *et al.* 699–701

Anaesthesia, emergency service, Prehospital monitoring of trauma patients: experience of a helicopter emergency medical service, Morley, A. P. 726–730

Anaesthesia for Surgery of the Spine, Porter, S. S., (editor), (*R*) 892

Anaesthesia, general, Changes in pineal and pituitary hormone secretion under general anaesthesia, Reber, A., *et al.*, (*ARS*) 584P

——, Heart rate variability in patients recovering from general anaesthesia, Ireland, N., *et al.* 657–662

——, Midazolam before induction improves conditions for laryngeal mask insertion, Driver, I., *et al.*, (*e*) 175

——, Volumetric analysis of aeration in the lungs during general anaesthesia, Reber, A., *et al.* 760–766

Anaesthesia, geriatric, Day-case cataract surgery, Goold, J. E., (*C*) 333

——, Day-case cataract surgery, Maltby, J. R., *et al.*, (*C*) 333

Anaesthesia, journals, Impact factors in anaesthesia journals, Smith, G., (*E*) 753–754

——, The 11th World Congress of Anaesthesiology, Smith, G., (*E*) 479–480

Anaesthesia, obstetric, A double-blind comparison of 0.25% ropivacaine and 0.25% bupivacaine for extradural analgesia in labour, Eddleston, J. M., *et al.* 66–71

——, Accidental insertion of an extradural catheter, Fox, A., *et al.*, (*C*) 336

——, Cardiac arrest at induction of anaesthesia for Caesarean section, McIndoe, A. K., *et al.*, (*C*) 332–333

——, Cardiac arrest at induction of anaesthesia for Caesarean section, Wilson, J. A., (*C*) 332

——, CSF progesterone concentrations in pregnancy, Baliga, N., (*C*) 886

——, CSF progesterone concentrations in pregnancy, Hirabayashi, Y., *et al.*, (*C*) 886

——, Elective forceps delivery and extradural anaesthesia in a primigravida with portal hypertension and oesophageal varices, Heriot, J. A., *et al.* 325–327

——, Failed intubation revisited: 17-yr experience in a teaching maternity unit, Hawthorne, L., *et al.* 680–684

——, Hydroxyethylstarch compared with modified gelatin as volume preload before spinal anaesthesia for Caesarean section, Vercauteren, M. P., *et al.* 731–733
——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, Camann, W., (*C*) 169
——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, Lee, J. S., *et al.*, (*C*) 169–170
——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, Robbins, P. M., *et al.*, (*C*) 170
——, Maternal and uteroplacental haemodynamic state in pre-eclamptic patients during spinal anaesthesia for Caesarean section, Karinen, J., *et al.* 616–620
——, Patient-controlled extradural analgesia with bupivacaine, fentanyl, or a mixture of both, after Caesarean section, Cooper, D. W., *et al.* 611–615

——, Ventilatory response to carbon dioxide, Dahan, A., *et al.*, (*C*) 747
——, Ventilatory response to carbon dioxide, Saito, Y., *et al.*, (*C*) 747–748
Anaesthetic techniques, extubation, Haemodynamic effects of continued sedation during tracheal extubation, Conti, J., *et al.*, (*EACTA*) A.72
Anaesthetic techniques, hypotensive, Metabolic and hormonal responses to induced hypotension for middle ear surgery, Newton, M. C., *et al.* 352–357
Anaesthetic techniques, hypotensive, nitroprusside, Haemodynamic effects of sodium nitroprusside *versus* prostaglandin E_1 in heart transplant candidates, Coddens, J., *et al.*, (*EACTA*) A.26
Anaesthetic techniques, induction, EEG arousal during laryngoscopy and intubation, Shannon, C., *et al.*, (*C*) 472
——, EEG arousal during laryngoscopy and intubation, Wilder-Smith, O. H. G., *et al.*, (*C*) 472–473
Anaesthetic techniques, i.v., Prospective evaluation of pharmacokinetic model-controlled infusion of propofol in adult patients, Short, T. G., *et al.* 313–315
Anaesthetic techniques, laryngoscopy, Airway management in cleft lip and palate surgery, Hatch, D. J., (*E*) 755–756
——, Difficult laryngoscopy in cleft lip and palate surgery, Gunawardana, R. H. 757–759
——, EEG arousal during laryngoscopy and intubation, Shannon, C., *et al.*, (*C*) 472
——, EEG arousal during laryngoscopy and intubation, Wilder-Smith, O. H. G., *et al.*, (*C*) 472–473
Anaesthetic techniques, low flow, Fuzzy logic control of inspired isoflurane and oxygen concentrations using minimal flow anaesthesia, Curatolo, M., *et al.* 245–250
Anaesthetic techniques, preoxygenation, Improving preoxygenation, McGowan, P., (*C*) 748
——, Improving preoxygenation, Smith, A. F., (*C*) 748
Anaesthetic techniques, regional, Haemostatic changes caused by i.v. regional anaesthesia with lignocaine, Niemi, T. T., *et al.* 822–828
——, Isolated forearm technique, Healy, T. E. J., *et al.*, (*C*) 885–886
——, Isolated forearm technique, Russell, I. F., *et al.*, (*C*) 884–885
——, Regional anaesthesia for outpatient nasal surgery, Molliex, S., *et al.* 151–153
——, Ulnar and common peroneal nerve block revisited, Souter, A. J., *et al.*, (*C*) 595–596
Anaesthetic techniques, regional, brachial plexus, Effect of the addition of alfentanil to lignocaine during axillary brachial plexus anaesthesia, Gormley, W. P., *et al.* 802–805

Anaesthetic techniques, regional, inguinal, Smaller children have greater bupivacaine plasma concentrations after ilioinguinal block, Smith, T., *et al.* 452–455
Anaesthetic techniques, regional, interpleural, Interpleural local anaesthesia: anatomical basis for mechanism of action, McKenzie, A. G., *et al.* 297–299
Anaesthetic techniques, regional, paravertebral, Continuous extrapleural paravertebral infusion of bupivacaine for post-thoracotomy analgesia in young infants, Karmakar, M. K., *et al.* 811–815
Anaesthetic techniques, regional, peribulbar, Prilocaine 3% is superior to a mixture of bupivacaine and lignocaine for peribulbar anaesthesia, Döpfmer, U. R., *et al.* 77–80
Anaesthetic techniques, subarachnoid, Accidental insertion of an extradural catheter, Fox, A., *et al.*, (*C*) 336
——, Anatomical configuration of the spinal column in the supine position. III. Comparison of adolescent and adult volunteers, Hirabayashi, Y., *et al.* 508–510
——, Bilateral severe pain at L3–4 after spinal anaesthesia with hyperbaric 5% lignocaine, Rodríguez-Chinchilla, R., *et al.* 328–329
——, CSF progesterone concentrations in pregnancy, Baliga, N., (*C*) 886
——, CSF progesterone concentrations in pregnancy, Hirabayashi, Y., *et al.*, (*C*) 886
——, Extradural and subarachnoid catheterization using the Seldinger technique, Delhaas, E. M. 149–150
——, Hydroxyethylstarch compared with modified gelatin as volume preload before spinal anaesthesia for Caesarean section, Vercauteren, M. P., *et al.* 731–733
——, Hypotension during subarachnoid anaesthesia: haemodynamic effects of colloid and metaraminol, Critchley, L. A. H., *et al.* 734–736
——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, Camann, W., (*C*) 169
——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, Lee, J. S., *et al.*, (*C*) 169–170
——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, Robbins, P. M., *et al.*, (*C*) 170
——, Maternal and uteroplacental haemodynamic state in pre-eclamptic patients during spinal anaesthesia for Caesarean section, Karinen, J., *et al.* 616–620
——, Randomized trial of bolus phenylephrine or ephedrine for maintenance of arterial pressure during spinal anaesthesia for Caesarean section, Thomas, D. G., *et al.* 61–65
——, Spinal anaesthesia for Caesarean section in women with incomplete extradural analgesia, Stoneham, M., *et al.*, (*C*) 476
——, Spinal clonidine produces less urinary retention than spinal morphine, Gentili, M., *et al.* 872–873
——, Visceral pain during Caesarean section, Fairfield, M. C., (*C*) 167
——, Visceral pain during Caesarean section, Hirabayashi, Y., *et al.*, (*C*) 167
——, Volume preloading, spinal anaesthesia and Caesarean section, Lawes, E. G., (*C*) 334–335
——, Volume preloading, spinal anaesthesia and Caesarean section, Mallick, A., *et al.*, (*C*) 335
——, Volume preloading, spinal anaesthesia and Caesarean section, Reid, J., *et al.*, (*C*) 335–336
Anaesthetic techniques, topical, nitroglycerine, Nitroglycerin induced hypoxaemia does not produce myocardial ischaemia, Toraman, F., *et al.*, (*EACTA*) A.21
——, Topical nitroglycerin dilates the radial artery, Gota, M., *et al.*, (*EACTA*) A.20
Anaesthetics gases, Effect of age on MAC in humans: a meta-analysis, Mapleson, W. W. 179–185
Anaesthetics gases, nitrous oxide, Auditory evoked responses, median frequency and 95% spectral edge during anaesthesia with desflurane and nitrous oxide, Pal, S. K., *et al.*, (*ARS*) 577P
——, Effects of carbon dioxide embolism with nitrous oxide in the inspired gas in piglets, Nyarwaya, J.-B., *et al.* 428–434
——, Nitrous oxide and the rate of gas uptake from an unventilated lung in dogs, Joyce, C. J., *et al.* 292–296
——, Nitrous oxide or halothane, or both, fail to suppress c-*fos* expression in rat spinal cord dorsal horn neurones after subcutaneous formalin, Sun, W. Z., *et al.* 99–105
——, Omitting nitrous oxide in general anaesthesia: meta-analysis of intraoperative awareness and postoperative emesis in randomized controlled trials, Tramèr, M., *et al.* 186–193
——, Volatile anaesthetics antagonize nitrous oxide and morphine-induced analgesia in the rat, Goto, T., *et al.* 702–706
Anaesthetics i.v., Flow cytometry evaluation of the *in vitro* effects of four i.v. anaesthetics on the respiratory burst of human neutrophils, Leuwer, M., *et al.*, (*ARS*) 585P
——, Interaction of i.v. anaesthetic agents with 5-HT_3 receptors, Appadu, B. L., *et al.* 271–273
——, Is the dihydropyridine binding site on neuronal L-type calcium channels a target for i.v. anaesthetic agents? Hirota, K., *et al.*, (*ARS*) 591P
——, Org 21465 a new i.v. anaesthetic agent, Daniell, C. J., *et al.*, (*ARS*) 586–587P
——, Total i.v. anaesthesia for transcranial magnetic evoked potential spinal cord monitoring, Watt, J. W. H., *et al.* 870–871
Anaesthetics i.v., eltanolone, Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone, Spens, H. J., *et al.* 369–373
Anaesthetics i.v., etomidate, Day-case cataract surgery, Goold, J. E., (*C*) 333
——, Day-case cataract surgery, Maltby, J. R., *et al.*, (*C*) 333
Anaesthetics i.v., fentanyl, Nitrous oxide or halothane, or both, fail to suppress c-*fos* expression in rat spinal cord dorsal horn neurones after subcutaneous formalin, Sun, W. Z., *et al.* 99–105
Anaesthetics i.v., ketamine, Central nuclei and spinal pathways in feedback inhibitory spinal cord potentials in ketamine-anaesthetized rats, Denda, S., *et al.* 258–265
——, Comparison of sedation with midazolam and ketamine: effects on airway muscle activity, Drummond, G. B. 663–667
——, Effect of systemic *N*-methyl-D-aspartate receptor antagonist (ketamine) on primary and secondary hyperalgesia in humans, Ilkjaer, S., *et al.* 829–834
——, Relaxant effect of ketamine and its isomers on histamine-induced contraction of tracheal smooth muscle, Hirota, K., *et al.* 266–270
Anaesthetics i.v., propofol, A perfusion system for *in vitro* measurement of human cilia beat frequency, Selwyn, D. A., *et al.* 111–115
——, Activation of the electrocorticogram by propofol during surgery for epilepsy, Smith, M., *et al.* 499–502
——, Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone, Spens, H. J., *et al.* 369–373
——, Comparison of arterialized venous with arterial blood propofol concentrations during sub-anaesthetic infusions in volunteers, Johnston, K. R., *et al.* 401–404
——, Day-case cataract surgery, Goold, J. E., (*C*) 333
——, Day-case cataract surgery, Maltby, J. R., *et al.*, (*C*) 333
——, Does propofol change the phenotype of monocytes in thoracic surgery? Laßnigg, A., *et al.*, (*EACTA*) A.18

——, Volatile anaesthetics antagonize nitrous oxide and morphine-induced analgesia in the rat, Goto, T., *et al.* 702–706

Analgesics opioid, pethidine, Dose requirements, efficacy and side effects of morphine and pethidine delivered by patient-controlled analgesia after gynaecological surgery, Stanley, G., *et al.* 484–486

Analgesics opioid, remifentanil, Remifentanil by infusion achieves predictable blood concentrations, Poulton, B. B., *et al.*, (*EACTA*) A.15

——, Remifentanil reduces auditory and somatosensory evoked responses during isoflurane anaesthesia in a dose-dependent manner, Crabb, I., *et al.* 795–801

——, Remifentanil—an opioid for the 21st century, Thompson, J. P., *et al.*, (*E*) 341–343

Analgesics opioid, sufentanil, Pulmonary uptake of sufentanil during and after constant rate infusion, Boer, F., *et al.* 203–208

Analgesics opioid, tramadol, Effect of tramadol on depth of anaesthesia, Coetzee, J. F., *et al.* 415–418

——, Is tramadol better than ketorolac after day-case laparoscopy? Sabar, M. A., *et al.*, (*ARS*) 584P

Anatomy, spinal column, Anatomical configuration of the spinal column in the supine position. III. Comparison of adolescent and adult volunteers, Hirabayashi, Y., *et al.* 508–510

Anesthesia and Intensive Care for Patients with Liver Disease, Park, G. R., *et al.*, (editors), (*R*) 338

Anesthesiology, House Officer Series, Berry, A. J., *et al.*, (editors), (*R*) 891

Antacids, omeprazole, Comparison of the effect of two dose schedules of oral omeprazole with oral ranitidine on gastric aspirate pH and volume in patients undergoing elective surgery, Levack, I. D., *et al.* 567–569

Antacids, ranitidine, Comparison of the effect of two dose schedules of oral omeprazole with oral ranitidine on gastric aspirate pH and volume in patients undergoing elective surgery, Levack, I. D., *et al.* 567–569

Antagonists benzodiazepine, flumazenil, Periodic cardiovascular and ventilatory activity during midazolam sedation, Galletly, D. C., *et al.* 503–507

Antagonists neuromuscular block, edrophonium, Edrophonium antagonism of intense mivacurium-induced neuromuscular block in children, Abdulatif, M., *et al.* 239–244

Antagonists neuromuscular block, neostigmine, Change in neostigmine ampoules, Mackersie, A. M., (*C*) 334

Antagonists serotonin, tropisetron, Single dose i.v. tropisetron in the prevention of postoperative nausea and vomiting after gynaecological surgery, Capouet, V., *et al.* 54–60

Antibiotics, Management of pre-eclampsia, Mushambi, M. C., *et al.*, (*C*) 889–890

——, Management of pre-eclampsia, Ward, J. E. H., *et al.*, (*C*) 889

Arterial pressure, Haemodynamic effects of continued sedation during tracheal extubation, Conti, J., *et al.*, (*EACTA*) A.72

Arterial pressure, Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement, Weiss, B. M., *et al.* 405–411

Arterial pressure, drug effects, Periodic cardiovascular and ventilatory activity during midazolam sedation, Galletly, D. C., *et al.* 503–507

Arterial pressure, hypertension, Management of pre-eclampsia, Mushambi, M. C., *et al.*, (*C*) 889–890

——, Management of pre-eclampsia, Ward, J. E. H., *et al.*, (*C*) 889

——, Recent developments in the pathophysiology and management of pre-eclampsia, Mushambi, M. C., *et al.* 133–148

Arterial pressure, hypotension, Volume preloading, spinal anaesthesia and Caesarean section, Lawes, E. G., (*C*) 334–335

——, Volume preloading, spinal anaesthesia and Caesarean section, Mallick, A., *et al.*, (*C*) 335

——, Volume preloading, spinal anaesthesia and Caesarean section, Reid, J., *et al.*, (*C*) 335–336

Arterial pressure, measurement, Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement, Weiss, B. M., *et al.* 405–411

Arteries, Effects of propofol on rabbit mesenteric arteries and veins, Kamitani, K., (*C*) 333–334

——, Effects of propofol on rabbit mesenteric arteries and veins, Stratford, N., (*C*) 333

——, Methylprednisolone inhibits endotoxin-induced depression of contractile function in human arteries *in vitro*, Tsuneyoshi, I., *et al.* 251–257

Arteries, aorta, Aortic stent surgery, Baranowski, A. P., *et al.*, (*C*) 882–883

——, Aortic stent surgery, Thompson, M. M., *et al.*, (*C*) 883

Arteries, mammary artery, Use of internal mammary artery improves prognosis in patients under 70 undergoing combined valve and coronary artery surgery, Herijgers, P., *et al.*, (*EACTA*) A.79

Arteries, radial, Topical nitroglycerin dilates the radial artery, Gota, M., *et al.*, (*EACTA*) A.20

Arteries, relaxation, Effect of phosphodiesterase inhibitors on human arteries *in vitro*, Vroom, M. B., *et al.* 122–129

Ataractics, cannabis, Cannabis as a medicine, West, M. E., *et al.*, (*C*) 167

Baillière's Clinical Anaesthesiology: New Pharmacological Vistas, Fink, E. J. jr, *et al.*, (editors), (*R*) 173

Basics of Transoesophageal Echocardiography, Rafferty, T. D., (editor), (*R*) 173

Beta blockers, Comparison of sotalol and digoxin in the prevention of early supraventricular arrhythmias after coronary artery bypass graft (CABG), Jadoul, J. L., *et al.*, (*EACTA*) A.67

——, Effect of β-blockers *versus* calcium channel blockers in myocardial revascularization without cardiopulmonary bypass in pigs, Rajek, A., *et al.*, (*EACTA*) A.39

Blood, haemodilution, Haemodynamic effects of moderate normovolaemic haemodilution in conscious and anaesthetized patients, Biboulet, P., *et al.* 81–84

Biocompatibility, Comparative assessment of the biocompatibility of 4 types of tubing for cardiopulmonary bypass, Briquet, F., *et al.*, (*EACTA*) A.31

Blood, anaemia, Anaemia and transfusion; major determinants of pressure sores after cardiac surgery, Baele, Ph., *et al.*, (*EACTA*) A.60

Blood, anticoagulants, heparin, Venous thromboembolism and cardiovascular surgery, Bullingham, A., *et al.*, (*C*) 473

——, Venous thromboembolism and cardiovascular surgery, McDonald, D. S., (*C*) 473

Blood, antifibrinolytics, High dose aprotinin *vs* tranexamic acid in elective cardiac surgery: effects on bleeding and necessity of transfusion, Casati, V., *et al.*, (*EACTA*) A.53

——, Plasma levels of tranexamic acid after two injections during cardiac surgery with cardiopulmonary bypass, Isetta, C., *et al.*, (*EACTA*) A.52

——, Very low dose aprotinin in cardiac surgery, Pétrie, J., *et al.*, (*EACTA*) A.54

Blood, autotransfusion, Autologous blood processing during cardiac surgery: haemofiltration *versus* cell washing, Walpoth, B. H., *et al.*, (*EACTA*) A.58

——, Autotransfusion of unwashed shed blood after CABG, using the Atrium 2052® blood recovery system, Gouwy, S., *et al.*, (*EACTA*) A.59

Blood, coagulation, Autotransfusion of unwashed shed blood after CABG, using the Atrium 2052® blood recovery system, Gouwy, S., *et al.*, (*EACTA*) A.59

——, Effect of aspirin in single first coronary artery bypass grafting, Vuylsteke, A., *et al.*, (*EACTA*) A.51

——, Haemodilution induces a hypercoagulable state, Ruttmann, T. G., *et al.* 412–414

——, Haemostatic changes caused by i.v. regional anaesthesia with lignocaine, Niemi, T. T., *et al.* 822–828

——, High dose aprotinin *vs* tranexamic acid in elective cardiac surgery: effects on bleeding and necessity of transfusion, Casati, V., *et al.*, (*EACTA*) A.53

——, Plasma levels of tranexamic acid after two injections during cardiac surgery with cardiopulmonary bypass, Isetta, C., *et al.*, (*EACTA*) A.52

——, Very low dose aprotinin in cardiac surgery, Pétrie, J., *et al.*, (*EACTA*) A.54

Blood, colloid oncotic pressure, Cardiopulmonary bypass with modified fluid gelatin and heparin-coated circuits, Jansen, P. G. M., *et al.* 13–19

Blood, conservation, Autologous blood processing during cardiac surgery: haemofiltration *versus* cell washing, Walpoth, B. H., *et al.*, (*EACTA*) A.58

——, Pilot evaluation of RMI haemoconcentrator during cardiopulmonary bypass, Dhond, G., *et al.*, (*EACTA*) A.57

Blood, erythrocytes, Effect of propofol and thiopentone on free radical mediated oxidative stress of the erythrocyte, Murphy, P. G., *et al.* 536–543

Blood, erythropoietin, Use of recombinant human erythropoietin to facilitate liver transplantation in a Jehovah's Witness, Snook, N. J., *et al.* 740–743

Blood, flow, A new method for cerebral blood flow measurement, Mielck, F., *et al.*, (*EACTA*) A.12

——, Effects of dopamine and dopexamine on splanchnic microcirculation during major surgery in humans, Bellamy, M. C., *et al.*, (*ARS*) 587P

——, Experimental evaluation of a single breath inert gas technique for measurement of myocardial blood flow, Kazmaier, S., *et al.*, (*EACTA*) A.5

——, Quality control of coronary bypass surgery: intraoperative transit time flow measurement, Walpoth, B. H., *et al.*, (*EACTA*) A.7

——, Splanchnic blood flow during cardiopulmonary bypass assessed by indicator dilution technique, Gårdebäck, M., *et al.*, (*EACTA*) A.36

——, The effects of propofol on cerebral blood flow velocity and oxygenation during cardiopulmonary bypass, Ederberg, S., *et al.*, (*EACTA*) A.17

Blood, flow, feto-uteroplacental, Maternal and uteroplacental haemodynamic state in pre-eclamptic patients during spinal anaesthesia for Caesarean section, Karinen, J., *et al.* 616–620

Blood, flow, mucosal, Effect of low-dose dopamine on intestinal villus microcirculation during normotensive endotoxaemia in rats, Schmidt, H., *et al.* 707–712

Blood, flow, splanchnic, Effects of desflurane and isoflurane on splanchnic microcirculation during surgery, O'Beirne, H., *et al.*, (*ARS*) 592P

Blood, glucose, Patient-controlled analgesia and the plasma glucose response to surgery, O'Keefe, V., *et al.*, (*ARS*) 585P

——, Rheological properties of commonly used plasma substitutes during preoperative normovolaemic acute haemodilution, Freyburger, G., *et al.* 519–525

Blood, haemofiltration, Autologous blood processing during cardiac surgery: haemofiltration *versus* cell washing, Walpoth, B. H., *et al.*, (*EACTA*) A.58

Blood, haemoglobin, Continuous temperature and O_2 saturation monitoring of jugular blood during DHCA procedures for aortic surgery, Paino, R., *et al.*, (*EACTA*) A.40

——, Does Parsonnet score predict the usefulness of Sv_{O_2} pulmonary artery catheter (Sv_{O_2}PAC) during heart surgery? Vedrinne, C., *et al.*, (*EACTA*) A.85

——, Effect of propofol and thiopentone on free radical mediated oxidative stress of the erythrocyte, Murphy, P. G., *et al.* 536–543

——, Kinetics of methaemoglobin and serum nitrogen oxide production during inhalation of nitric oxide in volunteers, Young, J. D., *et al.* 652–656

Blood, haemolysis, Effect of propofol and thiopentone on free radical mediated oxidative stress of the erythrocyte, Murphy, P. G., *et al.* 536–543

Blood, haemostasis, Haemostatic changes caused by i.v. regional anaesthesia with lignocaine, Niemi, T. T., *et al.* 822–828

Blood, monocytes, Does propofol change the phenotype of monocytes in thoracic surgery? Laßnigg, A., *et al.*, (*EACTA*) A.18

Blood, neutrophils, Flow cytometry evaluation of the *in vitro* effects of four i.v. anaesthetics on the respiratory burst of human neutrophils, Leuwer, M., *et al.*, (*ARS*) 585P

Blood, products, Use of blood products in cardiovascular surgery 4 years after the Sanguis study, Deneys, V., *et al.*, (*EACTA*) A.56

Blood, replacement, Consensus statement on autologous transfusion, Royal College of Physicians of Edinburgh, 470

——, Rheological properties of commonly used plasma substitutes during preoperative normovolaemic acute haemodilution, Freyburger, G., *et al.* 519–525

Blood, substitutes, Rheological properties of commonly used plasma substitutes during preoperative normovolaemic acute haemodilution, Freyburger, G., *et al.* 519–525

Blood, transfusion, Consensus statement on autologous transfusion, Royal College of Physicians of Edinburgh, 470

Blood, volume, Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function, Dalmas, S., *et al.* 419–427

Principles and Practice Series: Respiratory Support, Sykes, K., (*R*) 338
Regional Anesthesia: An Atlas of Anatomy and Techniques, Hahn, M. B., *et al.*, (editors), (*R*) 751
Sedation and Analgesia in the Critically Ill, Park, G. R., *et al.*, (editors), (*R*) 174
The ABC of Resuscitation, 3rd Edn, Colquhoun, M. C., *et al.*, (editors), (*R*) 338–339
Understanding Anaesthesia, 3rd Edn, Carrie, L. E. S., *et al.*, (*R*) 892–893
Wylie & Churchill-Davidson's A Practice of Anaesthesia, 6th Edn. Healy, T. E. J., *et al.*, (editors), (*R*) 477
Brain, Continuous temperature and O_2 saturation monitoring of jugular blood during DHCA procedures for aortic surgery, Paino, R., *et al.*, (*EACTA*) A.40
——, The effects of propofol on cerebral blood flow velocity and oxygenation during cardiopulmonary bypass, Ederberg, S., *et al.*, (*EACTA*) A.17
Brain, blood flow, Cerebral blood flow response to changes in CO_2 at hypothermia and normothermia. A controlled, randomized crossover study, Weyland, A., *et al.*, (*EACTA*) A.35
——, Sepsis-induced vasoparalysis does not involve the cerebral vasculature: indirect evidence from autoregulation and carbon dioxide reactivity studies, Matta, B. F., *et al.* 790–794
——, Use of near infrared spectroscopy to estimate cerebral blood flow in conscious and anaesthetized adult subjects, Owen-Reece, H., *et al.* 43–48
Brain, carbon dioxide reactivity, Sepsis-induced vasoparalysis does not involve the cerebral vasculature: indirect evidence from autoregulation and carbon dioxide reactivity studies, Matta, B. F., *et al.* 790–794
Brain, cerebral cortex, Is the dihydropyridine binding site on neuronal L-type calcium channels a target for i.v. anaesthetic agents? Hirota, K., *et al.*, (*ARS*) 591P
Brain, damage, Epiaortic scanning of the ascending aorta identifies arteriosclerotic plaques and changes surgical practice during CABG? van der Linden, J., *et al.*, (*EACTA*) A.82
Brain, electroencephalography, Auditory evoked responses, median frequency and 95% spectral edge during anaesthesia with desflurane and nitrous oxide, Pal, S. K., *et al.*, (*ARS*) 577P
——, Evaluation of bispectral index as an objective sedation score in the intensive care unit, Pearson, A. J., *et al.*, (*ARS*) 577–578P
——, Sevoflurane, enflurane and isoflurane have no persistent postanaesthetic effects on the central nervous system in cats, Kurata, J., *et al.* 721–725
Brain, evoked potentials, Auditory evoked responses, median frequency and 95% spectral edge during anaesthesia with desflurane and nitrous oxide, Pal, S. K., *et al.*, (*ARS*) 577P
——, Effect of suxamethonium on the auditory evoked response in humans, Brunner, M. D., *et al.* 34–37
——, Remifentanil reduces auditory and somatosensory evoked responses during isoflurane anaesthesia in a dose-dependent manner, Crabb, I., *et al.* 795–801
——, Suxamethonium and auditory evoked potentials, Brunner, M. D., *et al.*, (*C*) 881
——, Suxamethonium and auditory evoked potentials, Ponte, J., (*C*) 881
Brain, injury, Validation of the Edslab dual lumen oximetry catheter for continuous monitoring of jugular bulb oxygen saturation after severe head injury, Souter, M. J., *et al.* 744–746
Brain, ischaemia, Validation of the Edslab dual lumen oximetry catheter for continuous monitoring of jugular bulb oxygen saturation after severe head injury, Souter, M. J., *et al.* 744–746
Burns, Analgesic and anti-inflammatory effects of lignocaine–prilocaine (EMLA) cream in human burn injury, Pedersen, J. L., *et al.* 806–810
——, Effect of systemic *N*-methyl-D-aspartate receptor antagonist (ketamine) on primary and secondary hyperalgesia in humans, Ilkjaer, S., *et al.* 829–834

Calcium antagonists, Effect of β-blockers *versus* calcium channel blockers in myocardial revascularization without cardiopulmonary bypass in pigs, Rajek, A., *et al.*, (*EACTA*) A.39
——, Pharmacokinetics and haemodynamic effects of an ultrashort-acting calcium antagonist, Nordlander, M., *et al.*, (*EACTA*) A.24
Calcium channel block, diltiazem, Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation, Mikawa, K., *et al.* 221–226
Calcium channel block, nicardipine, Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation, Mikawa, K., *et al.* 221–226
Calcium channel block, verapamil, Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation, Mikawa, K., *et al.* 221–226
Calcium sensitizer, levosimendan, Levosimendan is a more potent inotropic agent than amrinone after ischaemia in isolated perfused guinea pig hearts, Süzer, Ö., *et al.*, (*EACTA*) A.9
——, The effect of the calcium sensitizer levosimendan on normal and stunned left ventricular myocardium, Weterings, C. J., *et al.*, (*EACTA*) A.8
Carbon dioxide, embolism, Effects of carbon dioxide embolism with nitrous oxide in the inspired gas in piglets, Nyarwaya, J.-B., *et al.* 428–434
Cardiac surgery, Anaemia and transfusion; major determinants of pressure sores after cardiac surgery, Baele, Ph., *et al.*, (*EACTA*) A.60
——, Aprotinin treatment does not impair renal function during and after cardiac surgery, Schweizer, A., *et al.*, (*EACTA*) A.55
——, Arrhythmias after valvular surgery: a randomized double-blind Holter comparative trial of St Thomas' (*ST*) *vs* CPS cardioplegia, Vedrinne, C., *et al.*, (*EACTA*) A.66
——, Autologous blood processing during cardiac surgery: haemofiltration *versus* cell washing, Walpoth, B. H., *et al.*, (*EACTA*) A.58
——, Autotransfusion of unwashed shed blood after CABG, using the Atrium 2052® blood recovery system, Gouwy, S., *et al.*, (*EACTA*) A.59
——, Cardiac surgical practices in the United States of America and Europe: striking similarities and minor differences, Vuylsteke, A., *et al.*, (*EACTA*) A.77
——, Changes of mitral inflow patterns as assessed by transoesophageal echocardiography following cardiac surgery: are they of clinical significance? Schmidlin, D., *et al.*, (*EACTA*) A.48
——, Comparison of caudally administered morphine *vs* hydromorphone in paediatric cardiac surgical patients, Lavoie, J., *et al.*, (*EACTA*) A.70
——, Comparison of sotalol and digoxin in the prevention of early supraventricular arrhythmias after coronary artery bypass graft (CABG), Jadoul, J. L., *et al.*, (*EACTA*) A.67
——, Correlation of predicted and recorded concentrations of nitric oxide during long-term inhalation in infants after cardiac surgery, Knapik, P., *et al.*, (*EACTA*) A.28
——, Does Parsonnet score predict the usefulness of Sv_{O_2} pulmonary artery catheter (Sv_{O_2}PAC) during heart surgery? Vedrinne, C., *et al.*, (*EACTA*) A.85
——, Does perioperative transoesophageal echocardiography change the therapy of cardiothoracic patients? Brase, R., *et al.*, (*EACTA*) A.47
——, Double blind, placebo controlled study of the effects of remacemide HCl on neuropsychological deficits following coronary artery surgery, Arowsmith, J. E., *et al.*, (*EACTA*) A.83
——, Effect of aspirin in single first coronary artery bypass grafting, Vuylsteke, A., *et al.*, (*EACTA*) A.51
——, Effects of lidoflazine on left ventricular function, Dhirue, G. L., *et al.*, (*EACTA*) A.10
——, Free fatty acid (FFA) uptake immediately after routine coronary artery bypass surgery (CABG), Pietersen, H. G., *et al.*, (*EACTA*) A.2
——, Haemodynamic effects of continued sedation during tracheal extubation, Conti, J., *et al.*, (*EACTA*) A.72

——, Convective warming overcomes effects of cooling after cardiopulmonary bypass, Knowles, P. R., *et al.*, (*EACTA*) A.42
——, Effect of β-blockers *versus* calcium channel blockers in myocardial revascularization without cardiopulmonary bypass in pigs, Rajek, A., *et al.*, (*EACTA*) A.39
——, Perioperative changes in receptors for ICAM-1/CD54 and immunglobulin G on monocytes by extracorporeal circulation (ECC), Hiesmayr, M., *et al.*, (*EACTA*) A.32
——, Splanchnic blood flow during cardiopulmonary bypass assessed by indicator dilution technique, Gårdebäck, M., *et al.*, (*EACTA*) A.36
——, Standard pump flow rate and Sv_{O_2} above 60% do not imply adequate oxygen delivery during CPB, Ryckwaert, F., *et al.*, (*EACTA*) A.34
Cardiovascular system, effects, Aprotinin during liver transplantation, Cottam, S., *et al.*, (*C*) 882
——, Aprotinin during liver transplantation, Lentschener, C., *et al.*, (*C*) 882
——, Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation, Mikawa, K., *et al.* 221–226
——, Comparison of the effects of urapidil and sodium nitroprusside on haemodynamic state, myocardial metabolism and function in patients during coronary artery surgery, van der Stroom, J. G., *et al.* 645–651
——, Effects of sevoflurane and isoflurane on systemic vascular resistance: use of cardiopulmonary bypass as a study model, Rödig, G., *et al.* 9–12
——, Haemodynamic effects of moderate normovolaemic haemodilution in conscious and anaesthetized patients, Biboulet, P., *et al.* 81–84
——, Haemodynamic responses to incision and sternotomy in relation to the auditory evoked potential and spontaneous EEG, de Beer, N. A. M., *et al.* 685–693
——, Laparoscopic cholecystectomy: haemodynamic and neuroendocrine responses after pneumoperitoneum and changes in position, O'Leary, E., *et al.* 640–644
Central nervous system, A new method for cerebral blood flow measurement, Mielck, F., *et al.*, (*EACTA*) A.12
——, Double blind, placebo controlled study of the effects of remacemide HCl on neuropsychological deficits following coronary artery surgery, Arowsmith, J. E., *et al.*, (*EACTA*) A.83
——, Epiaortic scanning of the ascending aorta identifies arteriosclerotic plaques and changes surgical practice during CABG? van der Linden, J., *et al.*, (*EACTA*) A.82
Central nervous system, damage, Brain death induced haemodynamic failure in the rat is solely due to autonomic denervation, Herijgers, P., *et al.*, (*EACTA*) A.13
——, Serotonin induces coronary spasms after brain death in dogs, Herijgers, P., *et al.*, (*EACTA*) A.14
Cerebrospinal fluid, Reducing the potential morbidity of an unintentional spinal anaesthetic by aspirating cerebrospinal fluid, Southorn, P., *et al.* 467–469
Children, Dose of propofol for laryngeal mask airway insertion in children: effect of premedication with midazolam, Martlew, R. A., *et al.* 308–309
——, Edrophonium antagonism of intense mivacurium-induced neuromuscular block in children, Abdulatif, M., *et al.* 239–244
——, Midazolam *vs* trimeprazine premedication for children during day-care surgery, Nathwani, D., *et al.*, (*ARS*) 589P
——, Parental or anaesthetist's ability to predict a 'stormy' induction in young children, Lyons, B., *et al.*, (*ARS*) 589P
——, Removal of the laryngeal mask airway in children: anaesthetized compared with awake, Kitching, A. J., *et al.* 874–876
——, Sevoflurane–nitrous oxide or halothane–nitrous oxide for paediatric bronchoscopy and gastroscopy, Meretoja, O. A., *et al.* 767–771
——, Smaller children have greater bupivacaine plasma concentrations after ilioinguinal block, Smith, T., *et al.* 452–455
——, Suxamethonium in children, Farrell, P. T., (*C*) 883–884
——, Suxamethonium in children, Fiacchino, F., *et al.*, (*C*) 883
——, Suxamethonium in children, Hopkins, P. M., (*C*) 884
Complications, A multifactorial analysis to explain inadequate surgical analgesia after extradural block, Curatolo, M., *et al.*, (*e*) 598
——, Anaemia and transfusion; major determinants of pressure sores after cardiac surgery, Baele, Ph., *et al.*, (*EACTA*) A.60
——, Double blind, placebo controlled study of the effects of remacemide HCl on neuropsychological deficits following coronary artery surgery, Arowsmith, J. E., *et al.*, (*EACTA*) A.83
——, Heparin-coated circuits reduce postoperative lung complications in high-risk cardiac patients, Ranucci, M., *et al.*, (*EACTA*) A.71
——, Nausea and vomiting after cardiac surgery, Grebenik, C., *et al.*, (*EACTA*) A.76
——, Organ dysfunctions after cardiac surgery: definitions and prognosis, Calvert, B., *et al.*, (*EACTA*) A.78
Complications, abscess, Extradurals and infection, Brosnan, C. M., *et al.*, (*C*) 887–888
Complications, airway obstruction, Airway problems after carotid endarterectomy, Munro, F. J., *et al.* 156–159
——, Cervical haematoma and airway obstruction, Calder, I., *et al.*, (*C*) 888
——, Cervical haematoma and airway obstruction, Munro, F. J., *et al.*, (*C*) 888–889
Complications, awareness, Recall during intermittent propofol anaesthesia, Nordström, O., *et al.* 699–701
Complications, brain death, Oxygen consumption and delivery relationship in brain-dead organ donors, Langeron, O., *et al.* 783–789
Complications, cardiac arrest, Systolic pressure variation—a way to recognize dynamic hyperinflation, Myles, P. S., (*C*) 169
——, Systolic pressure variation—a way to recognize dynamic hyperinflation, Perel, A., *et al.*, (*C*) 168–169
Complications, cardiomyopathy, Cardiac arrest at induction of anaesthesia for Caesarean section, McIndoe, A. K., *et al.*, (*C*) 332–333
——, Cardiac arrest at induction of anaesthesia for Caesarean section, Wilson, J. A., (*C*) 332
Complications, cardioplegia, Arrhythmias after valvular surgery: a randomized double-blind Holter comparative

trial of St Thomas' (ST) *vs* CPS cardioplegia, VEDRINNE, C., *et al.*, (*EACTA*) A.66

Complications, catheter misplacement, Accidental insertion of an extradural catheter, FOX, A., *et al.*, (*C*) 336

——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, CAMANN, W., (*C*) 169

——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, LEE, J. S., *et al.*, (*C*) 169–170

——, Intrathecal insertion of an extradural catheter during combined spinal–extradural anaesthesia, ROBBINS, P. M., *et al.*, (*C*) 170

Complications, convulsions, Sevoflurane, enflurane and isoflurane have no persistent postanaesthetic effects on the central nervous system in cats, KURATA, J., *et al.* 721–725

Complications, diabetes, Blood lactate during cardiopulmonary bypass with a lactated priming solution, HETT, D., *et al.*, (*EACTA*) A.33

——, Use of i.v. insulin in well-controlled non-insulin-dependent diabetics undergoing major surgery, RAUCOULES-AIMÉ, M., *et al.* 198–202

Complications, Ehlers–Danlos syndrome, Myocardial ischaemia associated with Ehlers–Danlos syndrome, PRICE, C. M., *et al.* 464–466

Complications, embolism, Pulsed saline lavage causing venous air embolism in a patient with Paget's disease, SIDES, C. A. 330–331

——, Venous thromboembolism and cardiovascular surgery, BULLINGHAM, A., *et al.*, (*C*) 473

——, Venous thromboembolism and cardiovascular surgery, MCDONALD, D. S., (*C*) 473

Complications, emphysema, Stable right ventricular pressure-volume relation during lung volume reducing surgery for diffuse emphysema, GELINDER, S., *et al.*, (*EACTA*) A.80

Complications, endotoxaemia, Effect of low-dose dopamine on intestinal villus microcirculation during normotensive endotoxaemia in rats, SCHMIDT, H., *et al.* 707–712

Complications, fractured cricoid cartilage, Fracture of the cricoid cartilage after Sellick's manoeuvre, HEATH, K. J., *et al.* 877–878

Complications, haematoma, Venous thromboembolism and cardiovascular surgery, BULLINGHAM, A., *et al.*, (*C*) 473

——, Venous thromboembolism and cardiovascular surgery, MCDONALD, D. S., (*C*) 473

Complications, hypertension, Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation, MIKAWA, K., *et al.* 221–226

——, Elective forceps delivery and extradural anaesthesia in a primigravida with portal hypertension and oesophageal varices, HERIOT, J. A., *et al.* 325–327

Complications, hypotension, Hydroxyethylstarch compared with modified gelatin as volume preload before spinal anaesthesia for Caesarean section, VERCAUTEREN, M. P., *et al.* 731–733

——, Hypotension during subarachnoid anaesthesia: haemodynamic effects of colloid and metaraminol, CRITCHLEY, L. A. H., *et al.* 734–736

——, Randomized trial of bolus phenylephrine or ephedrine for maintenance of arterial pressure during spinal anaesthesia for Caesarean section, THOMAS, D. G., *et al.* 61–65

Complications, hypothermia, Cerebral blood flow response to changes in CO$_2$ at hypothermia and normothermia. A controlled, randomized crossover study, WEYLAND, A., *et al.*, (*EACTA*) A.35

——, Continuous temperature and O$_2$ saturation monitoring of jugular blood during DHCA procedures for aortic surgery, PAINO, R., *et al.*, (*EACTA*) A.40

——, Effect of cooling on the force of contraction of rat and guineapig phrenic nerve hemidiaphragm preparations, ENGLAND, A. J., *et al.*, (*ARS*) 592–593P

——, Elevated serum levels of S-100 after deep hypothermic circulatory arrest correlate with duration of circulatory arrest, VAN DER LINDEN, J., *et al.*, (*EACTA*) A.84

Complications, inflammation, Phospholipase A$_2$ in cardiac surgery, HÅKANSON, E., *et al.*, (*EACTA*) A.1

Complications, Jehovah's Witness, Use of recombinant human erythropoietin to facilitate liver transplantation in a Jehovah's Witness, SNOOK, N. J., *et al.* 740–743

Complications, juvenile hyaline fibromatosis, Anaesthesia and juvenile hyaline fibromatosis, NORMAN, B., *et al.* 163–166

Complications, lung, Minimal incidence of reperfusion pulmonary oedema after pulmonary thromboendarterectomy, MARES, P., *et al.*, (*EACTA*) A.75

——, Non-invasive pressure support ventilation (NPSV) as an alternative to reintubation, PAULUS, S., *et al.*, (*EACTA*) A.73

Complications, morbidity, Reducing the potential morbidity of an unintentional spinal anaesthetic by aspirating cerebrospinal fluid, SOUTHORN, P., *et al.* 467–469

Complications, mucosal pressure, Laryngeal mask airway performance: effect of cuff deflation during anaesthesia, MORRIS, G. N., *et al.* 456–458

Complications, multiple organ dysfunction syndrome, Soluble E-cadherin concentrations in patients with systemic inflammatory response syndrome and multiorgan dysfunction syndrome, PITTARD, A. J., *et al.* 629–631

Complications, myalgia, Rocuronium pretreatment reduces suxamethonium-induced myalgia: comparison with vecuronium, FINDLAY, G. P., *et al.* 526–529

Complications, myopathy, Mivacurium chloride and late onset congenital myopathy, PARMAR, M., *et al.* 160–162

——, Suxamethonium in children, FARRELL, P. T., (*C*) 883–884

——, Suxamethonium in children, FIACCHINO, F., *et al.*, (*C*) 883

——, Suxamethonium in children, HOPKINS, P. M., (*C*) 884

Complications, neurological, Bilateral severe pain at L3–4 after spinal anaesthesia with hyperbaric 5% lignocaine, RODRÍGUEZ-CHINCHILLA, R., *et al.* 328–329

——, Maternal sequelae of childbirth, HUTTER, C. D. D., (*C*) 474

——, Maternal sequelae of childbirth, REYNOLDS, F., (*C*) 474–475

Complications, oesophageal varices, Elective forceps delivery and extradural anaesthesia in a primigravida with portal hypertension and oesophageal varices, HERIOT, J. A., *et al.* 325–327

Complications, overdose, Observations on patient-controlled administration of propofol, THORPE, S. J., *et al.*, (*ARS*) 576P

——, Patient-controlled propofol: randomized, double-blind dose refinement, SMITH, A. F., *et al.*, (*ARS*) 577P

Complications, Paget's disease, Pulsed saline lavage causing venous air embolism in a patient with Paget's disease, SIDES, C. A. 330–331

Complications, porphyria, Porphyria, propofol and rats, BÖHRER, H., (*C*) 172

——, Porphyria, propofol and rats, GORCHEIN, A., (*C*) 172

——, Porphyria, propofol and rats, TIDMARSH, M. D., (*C*) 171–172

Complications, pre-eclampsia, Management of pre-eclampsia, MUSHAMBI, M. C., *et al.*, (*C*) 889–890

——, Management of pre-eclampsia, WARD, J. E. H., *et al.*, (*C*) 889

——, Recent developments in the pathophysiology and management of pre-eclampsia, MUSHAMBI, M. C., *et al.* 133–148

——, Serotonin in pre-eclampsia, GAJRAJ, N. M., *et al.*, (*C*) 748–749

Complications, pressure sores, Anaemia and transfusion; major determinants of pressure sores after cardiac surgery, BAELE, PH., *et al.*, (*EACTA*) A.60

Complications, pulmonary oedema, Balloon mitral valve dilatation as an aid to weaning from ventilatory support in patients with intractable pulmonary oedema caused by severe mitral stenosis, DAVIS, G., *et al.* 879–880

Complications, regurgitation, Effect of pneumoperitoneum and Trendelenburg position on gastro–oesophageal reflux and lower oesophageal sphincter pressure, TOURNADRE, J. P., *et al.* 130–132

Complications, reperfusion syndrome, White blood cell cytosolic calcium changes during human orthotopic liver transplantation, ENRIGHT, S., *et al.*, (*ARS*) 587–588P

Complications, respiratory, Nebulized lignocaine before gaseous induction with desflurane, BUNTING, H. E., *et al.*, (*C*) 596

——, Nebulized lignocaine before gaseous induction with desflurane, NAY, P. G., (*C*) 596

Complications, sepsis syndrome, Sepsis-induced vasoparalysis does not involve the cerebral vasculature: indirect evidence from autoregulation and carbon dioxide reactivity studies, MATTA, B. F., *et al.* 790–794

Complications, septic shock, Prospects for management of peripheral vascular failure in septic shock, ALLEN, J. D., *et al.*, (*E*) 177–178

Complications, septicaemia, Soluble E-cadherin concentrations in patients with systemic inflammatory response syndrome and multiorgan dysfunction syndrome, PITTARD, A. J., *et al.* 629–631

Complications, smokers, Double-blind, randomized trial of cessation of smoking after audiotape suggestion during anaesthesia, MYLES, P. S., *et al.* 694–698

——, Effect of smoking on dose requirements for vecuronium, Teiriá, H., *et al.* 154–155

Complications, spontaneous excitatory movement, Unilateral convulsion after induction of anaesthesia with propofol, Cochran, D., *et al.* 570–572

Complications, stenosis, Balloon mitral valve dilatation as an aid to weaning from ventilatory support in patients with intractable pulmonary oedema caused by severe mitral stenosis, Davis, G., *et al.* 879–880

Complications, subarachnoid block, Sudden onset of subarachnoid block after subdural catheterization: a case of arachnoid rupture? Elliott, D. W., *et al.* 322–324

Complications, thrombosis, Venous thromboembolism and cardiovascular surgery, Bullingham, A., *et al.*, (*C*) 473

——, Venous thromboembolism and cardiovascular surgery, McDonald, D. S., (*C*) 473

Complications, tracheal bronchus, Airway management for patients with a tracheal bronchus, Ikeno, S., *et al.* 573–575

Complications, trauma, Prehospital monitoring of trauma patients: experience of a helicopter emergency medical service, Morley, A. P. 726–730

——, Transoesophageal echocardiography in chest trauma, George, S. J., (*C*) 336–337

——, Transoesophageal echocardiography in chest trauma, Kennedy, N., *et al.*, (*C*) 337

Complications, urinary retention, Spinal clonidine produces less urinary retention than spinal morphine, Gentili, M., *et al.* 872–873

Computers, Fuzzy logic control of inspired isoflurane and oxygen concentrations using minimal flow anaesthesia, Curatolo, M., *et al.* 245–250

Computers, fuzzy logic, Performance assessment of a fuzzy controller for atracurium-induced neuromuscular block, Mason, D. G., *et al.* 396–400

Coronary artery bypass surgery, Atrial natriuretic peptide (ANP) and N-terminal ANP: relationship to right ventricular function in patients undergoing coronary artery bypass surgery, Honkonen, E. L., *et al.*, (*EACTA*) A.6

Coronary artery disease, Assessment of right and left heart volume indices in patients undergoing coronary artery bypass surgery, Buhre, W., *et al.*, (*EACTA*) A.37

——, Effect of β-blockers *versus* calcium channel blockers in myocardial revascularization without cardiopulmonary bypass in pigs, Rajek, A., *et al.*, (*EACTA*) A.39

——, Free fatty acid (FFA) uptake immediately after routine coronary artery bypass surgery (CABG), Pietersen, H. G., *et al.*, (*EACTA*) A.2

——, Postoperative diastolic dysfunction. Incidence, natural history and prognosis, Oppizzi, M., *et al.*, (*EACTA*) A.46

——, Quality control of coronary bypass surgery: intraoperative transit time flow measurement, Walpoth, B. H., *et al.*, (*EACTA*) A.7

——, Transoesophageal echocardiography and haemodynamic monitoring in emergency surgical revascularization for extensive acute myocardial infarction, Guarracino, F., *et al.*, (*EACTA*) A.45

Diabetes, Use of i.v. insulin in well-controlled non-insulin-dependent diabetics undergoing major surgery, Raucoules-Aimé, M., *et al.* 198–202

Difficult Hypertension: Practical Management and Decision Making, Kendall, M. J., *et al.*, (editors), (*R*) 891–892

Dog, Differential effects of desflurane and halothane on peripheral airway smooth muscle, Mazzeo, A. J., *et al.* 841–846

——, Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function, Dalmas, S., *et al.* 419–427

——, Nitrous oxide and the rate of gas uptake from an unventilated lung in dogs, Joyce, C. J., *et al.* 292–296

Drug delivery, computerized, Prospective evaluation of pharmacokinetic model-controlled infusion of propofol in adult patients, Short, T. G., *et al.* 313–315

Drug delivery, transdermal, Effect of transdermal hyoscine on nausea and vomiting, Foster, R. N., (*C*) 749

——, Effect of transdermal hyoscine on nausea and vomiting, Honkavaara, P., (*C*) 749–750

——, Effect of transdermal hyoscine on nausea and vomiting during and after middle ear surgery under local anaesthesia, Honkavaara, P. 49–53

Ehlers–Danlos syndrome, Myocardial ischaemia associated with Ehlers–Danlos syndrome, Price, C. M., *et al.* 464–466

Embolism, air, Pulsed saline lavage causing venous air embolism in a patient with Paget's disease, Sides, C. A. 330–331

——, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? Kyttä, J., *et al.*, (*C*) 475–476

——, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? Mallick, A., *et al.*, (*C*) 475

Embolism, carbon dioxide, Effects of carbon dioxide embolism with nitrous oxide in the inspired gas in piglets, Nyarwaya, J.-B., *et al.* 428–434

Embolism, thromboembolism, Venous thromboembolism and cardiovascular surgery, Bullingham, A., *et al.*, (*C*) 473

——, Venous thromboembolism and cardiovascular surgery, McDonald, D. S., (*C*) 473

Enzymes, Elevated serum levels of S-100 after deep hypothermic circulatory arrest correlate with duration of circulatory arrest, van der Linden, J., *et al.*, (*EACTA*) A.84

Enzymes, phosphodiesterase, inhibition, Levosimendan is a more potent inotropic agent than amrinone after ischaemia in isolated perfused guinea pig hearts, Süzer, Ö., *et al.*, (*EACTA*) A.9

——, The efficacy of enoximone in improving the postoperative course of cardiac patients with severe myocardial dysfunction, Oppizzi, M., *et al.*, (*EACTA*) A.81

Enzymes, phospholipase C, Phospholipase A_2 in cardiac surgery, Håkanson, E., *et al.*, (*EACTA*) A.1

Enzymes, troponin I, Time course of serial serum troponin I levels after coronary artery bypass surgery (CABG), Filley, S., *et al.*, (*EACTA*) A.63

Enzymes, troponin T, Troponin-T for asessment of myocardial damage in CABG surgery, Dahlin, L. G., *et al.*, (*EACTA*) A.62

Epilepsy, Activation of the electrocorticogram by propofol during surgery for epilepsy, Smith, M., *et al.* 499–502

Equipment, Perioperative changes in receptors for ICAM-1/CD54 and immunglobulin G on monocytes by extracorporeal circulation (ECC), Hiesmayr, M., *et al.*, (*EACTA*) A.32

Equipment, assist device, The hemopump as left ventricular assist device in postcardiotomy heart failure, Meyns, B., *et al.*, (*EACTA*) A.38

Equipment, blankets, Convective warming combined with vasodilator therapy accelerates core rewarming after coronary artery bypass surgery, Harrison, S. J., *et al.* 511–514

Equipment, breathing systems, Accumulation of foreign gases during closed-system anaesthesia, Versichelen, L., *et al.* 668–672

——, Effect of apparatus on functional residual capacity, Drummond, G. B. 560–562

——, Efficiency of a circle system for short surgical cases: comparison of desflurane with isoflurane, Lee, D. J. H., *et al.* 780–782

——, Performance of vaporizers in circle systems (II), Royston, B., *et al.*, (*ARS*) 582–583P

Equipment, catheters extradural, Extradural and subarachnoid catheterization using the Seldinger technique, Delhaas, E. M. 149–150

——, Extradurals and infection, Brosnan, C. M., *et al.*, (*C*) 887–888

Equipment, catheters oximetry, Validation of the Edslab dual lumen oximetry catheter for continuous monitoring of jugular bulb oxygen saturation after severe head injury, Souter, M. J., *et al.* 744–746

Equipment, catheters subarachnoid, Extradural and subarachnoid catheterization using the Seldinger technique, Delhaas, E. M. 149–150

Equipment, gas analysers, Interference of volatile anaesthetics with infrared analysis of carbon dioxide and nitrous oxide tested in the Dräger Cicero EM using sevoflurane, Wilkes, A. R., *et al.* 737–739

Equipment, heart-lung machine, Comparative assessment of the biocompatibility of 4 types of tubing for cardiopulmonary bypass, Briquet, F., *et al.*, (*EACTA*) A.31

Equipment, hemopump, The hemopump as left ventricular assist device in postcardiotomy heart failure, Meyns, B., *et al.*, (*EACTA*) A.38

Equipment, masks anaesthesia, Cricoid pressure applied after placement of the laryngeal mask prevents gastric insufflation but inhibits ventilation, Asai, T., *et al.* 772–776

——, Dose of propofol for laryngeal mask airway insertion in children: effect of premedication with midazolam, Martlew, R. A., *et al.* 308–309

——, Effect of apparatus on functional residual capacity, Drummond, G. B. 560–562

——, Improving preoxygenation, McGowan, P., (*C*) 748

——, Improving preoxygenation, Smith, A. F., (*C*) 748
——, Laryngeal mask airway performance: effect of cuff deflation during anaesthesia, Morris, G. N., *et al.* 456–458
——, Midazolam before induction improves conditions for laryngeal mask insertion, Driver, I., *et al.*, (*e*) 175
——, Removal of the laryngeal mask airway in children: anaesthetized compared with awake, Kitching, A. J., *et al.* 874–876
Equipment, monitors, Prehospital monitoring of trauma patients: experience of a helicopter emergency medical service, Morley, A. P. 726–730
Equipment, perfusion system, A perfusion system for *in vitro* measurement of human cilia beat frequency, Selwyn, D. A., *et al.* 111–115
Equipment, pupillometer, Pupil changes during cardiopulmonary bypass, Fletcher, G. C., *et al.* 20–22
Equipment, temperature probes, Use of i.m. temperature probes during cardiopulmonary bypass in humans, Benson, J. P., *et al.*, (*C*) 472
——, Use of i.m. temperature probes during cardiopulmonary bypass in humans, Manners, J. M., (*C*) 471–472
Equipment, tubes tracheal, A new tracheal tube for difficult intubation, West, M. R. J., *et al.* 673–679
——, RAE tube obstruction during tonsil dissection, Graham, D., *et al.*, (*C*) 170–171
Equipment, vaporizers, Performance of vaporizers in circle systems (II), Royston, B., *et al.*, (*ARS*) 582–583P
Equipment, warming devices, Convective warming combined with vasodilator therapy accelerates core rewarming after coronary artery bypass surgery, Harrison, S. J., *et al.* 511–514
——, Delayed forced air warming prevents hypothermia during abdominal aortic surgery, Karayan, J., *et al.* 459–460
Errata, A model to describe the rate of oxyhaemoglobin desaturation during apnoea, Farmery, A. D., *et al.*, (*e*) 890
——, A multifactorial analysis to explain inadequate surgical analgesia after extradural block, Curatolo, M., *et al.*, (*e*) 598
——, Histamine-release haemodynamic changes produced by rocuronium, vecuronium, mivacurium, atracurium and tubocurarine, Naguib, M., *et al.*, (*e*) 339
——, Midazolam before induction improves conditions for laryngeal mask insertion, Driver, I., *et al.*, (*e*) 175
Essentials of Anaesthetic Equipment, Al-Shaikh, B., *et al.*, (*R*) 751
Ethanol, Analysis of ethanol in expired air during low-flow isoflurane anaesthesia, Olsson, J., *et al.* 85–89
Eye, extraocular muscles, Effect of antagonism of mivacurium on recovery of extraocular muscle function, Mellor, D. J., *et al.* 621–623

Fluids, i.v., Haemodilution induces a hypercoagulable state, Ruttmann, T. G., *et al.* 412–414
——, Hydroxyethylstarch compared with modified gelatin as volume preload before spinal anaesthesia for Caesarean section, Vercauteren, M. P., *et al.* 731–733
——, Hypotension during subarachnoid anaesthesia: haemodynamic effects of colloid and metaraminol, Critchley, L. A. H., *et al.* 734–736
——, Inadvertent infusion of glucose saline into the extradural space, Mphanza, T., (*C*) 332
Free fatty acids, Free fatty acid (FFA) uptake immediately after routine coronary artery bypass surgery (CABG), Pietersen, H. G., *et al.*, (*EACTA*) A.2

Gases, non-anaesthetic, Kinetics of methaemoglobin and serum nitrogen oxide production during inhalation of nitric oxide in volunteers, Young, J. D., *et al.* 652–656
Gases non-anaesthetic, acetone, Accumulation of foreign gases during closed-system anaesthesia, Versichelen, L., *et al.* 668–672
Gases non-anaesthetic, carbon monoxide, Accumulation of foreign gases during closed-system anaesthesia, Versichelen, L., *et al.* 668–672
Gases non-anaesthetic, methane, Accumulation of foreign gases during closed-system anaesthesia, Versichelen, L., *et al.* 668–672
Gastrointestinal tract, antacids, Comparison of the effect of two dose schedules of oral omeprazole with oral ranitidine on gastric aspirate pH and volume in patients undergoing elective surgery, Levack, I. D., *et al.* 567–569
Gastrointestinal tract, circulation, Splanchnic blood flow during cardiopulmonary bypass assessed by indicator dilution technique, Gårdebäck, M., *et al.*, (*EACTA*) A.36
Gastrointestinal tract, intestine, Effect of low-dose dopamine on intestinal villus microcirculation during normotensive endotoxaemia in rats, Schmidt, H., *et al.* 707–712
Gastrointestinal tract, lower oesophageal sphincter, Effect of pneumoperitoneum and Trendelenburg position on gastro–oesophageal reflux and lower oesophageal sphincter pressure, Tournadre, J. P., *et al.* 130–132
Gastrointestinal tract, perfusion, The influence of dopaminergic agents on liver venous and mixed venous O_2-saturation in MODS – a preliminary report, Lampert, R., *et al.*, (*EACTA*) A.11
Gastrointestinal tract, pH, Comparison of the effect of two dose schedules of oral omeprazole with oral ranitidine on gastric aspirate pH and volume in patients undergoing elective surgery, Levack, I. D., *et al.* 567–569
——, Gastric tonometry, Boyd, O., *et al.*, (*C*) 750
——, Gastric tonometry to monitor tissue oxygenation: more than a gut feeling? Oh, T. E., (*E*) 604–605
——, Measurement technique and variation in intramucosal pH, Wood, P. R., *et al.* 563–564
——, Perioperative mucosal pH and splanchnic endotoxin concentration in orthotopic liver transplantation, Welte, M., *et al.* 90–98
Gastrointestinal tract, volume, Comparison of the effect of two dose schedules of oral omeprazole with oral ranitidine on gastric aspirate pH and volume in patients undergoing elective surgery, Levack, I. D., *et al.* 567–569
Genetic factors, proto-oncogenes, Nitrous oxide or halothane, or both, fail to suppress c-*fos* expression in rat spinal cord dorsal horn neurones after subcutaneous formalin, Sun, W. Z., *et al.* 99–105
——, Remembrance of times past: the significance of c-*fos* in pain, Munglani, R., *et al.*, (*E*) 1–4
Guineapig, Effect of cooling on the force of contraction of rat and guineapig phrenic nerve hemidiaphragm preparations, England, A. J., *et al.*, (*ARS*) 592–593P

Haemodynamics, Brain death induced haemodynamic failure in the rat is solely due to autonomic denervation, Herijgers, P., *et al.*, (*EACTA*) A.13
Haemofiltration, Pilot evaluation of RMI haemoconcentrator during cardiopulmonary bypass, Dhond, G., *et al.*, (*EACTA*) A.57
Haemoglobin, Standard pump flow rate and Sv_{O_2} above 60% do not imply adequate oxygen delivery during CPB, Ryckwaert, F., *et al.*, (*EACTA*) A.34
Handbook of Neonatal Anaesthesia, Hughes, D. G., *et al.*, (editors), (*R*) 599
Heart, Long chain triglycerides but not glucose–insulin, administered during reperfusion, improve recovery from stunning in isolated rabbit hearts, Van de Velde, M., *et al.*, (*EACTA*) A.3
——, Oxfenicine blocks the beneficial effects of intravenous long chain triglyceride (LCT) administration on regional myocardial stunning in conscious dogs, Van de Velde, M., *et al.*, (*EACTA*) A.4
Heart, arrhythmia, Arrhythmias after valvular surgery: a randomized double-blind Holter comparative trial of St Thomas' (ST) *vs* CPS cardioplegia, Vedrinne, C., *et al.*, (*EACTA*) A.66
——, Comparison of sotalol and digoxin in the prevention of early supraventricular arrhythmias after coronary artery bypass graft (CABG), Jadoul, J. L., *et al.*, (*EACTA*) A.67
——, QTc-dispersion in patients undergoing CABG surgery, Fruhwald, S., *et al.*, (*EACTA*) A.65
——, Trimetazidine does not reduce ischaemia-reperfusion induced arrhythmias in isolated perfused rat hearts, Süzer, Ö, *et al.*, (*EACTA*) A.68
Heart, cardiac output, Haemodynamic effects of air travel, Malagon, I., (*ARS*) 590P
Heart, cardiopulmonary bypass, Cardiopulmonary bypass with modified fluid gelatin and heparin-coated circuits, Jansen, P. G. M., *et al.* 13–19
——, Dobutamine increases oxygen consumption during constant flow cardiopulmonary bypass, Karzai, W., *et al.* 5–8
——, Effects of sevoflurane and isoflurane on systemic vascular resistance: use of cardiopulmonary bypass as a study model, Rödig, G., *et al.* 9–12
——, Plasma concentration and protein binding of propofol during cardiac surgery, Hammarén, E., *et al.*, (*EACTA*) A.16
——, Pupil changes during cardiopulmonary bypass, Fletcher, G. C., *et al.* 20–22
——, Remifentanil by infusion achieves predictable blood concentrations, Poulton, B. B., *et al.*, (*EACTA*) A.15
——, The effects of propofol on cerebral blood flow velocity and oxygenation during cardiopulmonary bypass, Ederberg, S., *et al.*, (*EACTA*) A.17
——, Use of i.m. temperature probes during cardiopulmonary bypass in humans, Benson, J. P., *et al.*, (*C*) 472

——, Use of i.m. temperature probes during cardiopulmonary bypass in humans, Manners, J. M., (*C*) 471–472
Heart, circulation, Serotonin induces coronary spasms after brain death in dogs, Herijgers, P., *et al.*, (*EACTA*) A.14
Heart, coronary artery disease, Effect of anaesthetic agents on pulmonary shunt during coronary artery surgery, Sindjelic, R., *et al.*, (*EACTA*) A.19
——, QTc-dispersion in patients undergoing CABG surgery, Fruhwald, S., *et al.*, (*EACTA*) A.65
Heart, diastolic function, Postoperative diastolic dysfunction. Incidence, natural history and prognosis, Oppizzi, M., *et al.*, (*EACTA*) A.46
Heart, digoxin, Comparison of sotalol and digoxin in the prevention of early supraventricular arrhythmias after coronary artery bypass graft (CABG), Jadoul, J. L., *et al.*, (*EACTA*) A.67
Heart, dobutamine, Dobutamine increases oxygen consumption during constant flow cardiopulmonary bypass, Karzai, W., *et al.* 5–8
Heart, dopamine, The influence of dopaminergic agents on liver venous and mixed venous O_2-saturation in MODS – a preliminary report, Lampert, R., *et al.*, (*EACTA*) A.11
Heart, dysfunction, The efficacy of enoximone in improving the postoperative course of cardiac patients with severe myocardial dysfunction, Oppizzi, M., *et al.*, (*EACTA*) A.81
Heart, failure, The hemopump as left ventricular assist device in postcardiotomy heart failure, Meyns, B., *et al.*, (*EACTA*) A.38
Heart, function, Assessment of right and left heart volume indices in patients undergoing coronary artery bypass surgery, Buhre, W., *et al.*, (*EACTA*) A.37
——, Postoperative diastolic dysfunction. Incidence, natural history and prognosis, Oppizzi, M., *et al.*, (*EACTA*) A.46
Heart, heart rate, Heart rate variability in patients recovering from general anaesthesia, Ireland, N., *et al.* 657–662
——, Periodic cardiovascular and ventilatory activity during midazolam sedation, Galletly, D. C., *et al.* 503–507
Heart, ischaemia, Effect of halothane on myocardial reoxygenation injury in the isolated rat heart, Schlack, W., *et al.* 860–867
——, Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function, Dalmas, S., *et al.* 419–427
——, Levosimendan is a more potent inotropic agent than amrinone after ischaemia in isolated perfused guinea pig hearts, Süzer, Ö., *et al.*, (*EACTA*) A.9
——, Myocardial ischaemia and heart rate variability after coronary bypass surgery, Kentala, E., *et al.*, (*EACTA*) A.64
——, Myocardial ischaemia associated with Ehlers–Danlos syndrome, Price, C. M., *et al.* 464–466
——, Nitroglycerin induced hypoxaemia does not produce myocardial ischaemia, Toraman, F., *et al.*, (*EACTA*) A.21
Heart, isolated preparation, Effect of halothane on myocardial reoxygenation injury in the isolated rat heart, Schlack, W., *et al.* 860–867
——, Effects of morphine on atrial preparations obtained from non-failing and failing human hearts, Llobel, F., *et al.* 106–110
Heart, mitral valve, Changes of mitral inflow patterns as assessed by transoesophageal echocardiography following cardiac surgery: are they of clinical significance? Schmidlin, D., *et al.*, (*EACTA*) A.48
Heart, myocardial function, Comparison of the effects of urapidil and sodium nitroprusside on haemodynamic state, myocardial metabolism and function in patients during coronary artery surgery, van der Stroom, J. G., *et al.* 645–651
——, Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function, Dalmas, S., *et al.* 419–427
——, Effects of morphine on atrial preparations obtained from non-failing and failing human hearts, Llobel, F., *et al.* 106–110
——, Effects of propofol and isoflurane on right ventricular function, Boyd, O., *et al.*, (*C*) 598
Heart, myocardial infarction, Perioperative myocardial infarction (PMI) in cardiac surgery—risk factors and clinical outcome, Svedjeholm, P., *et al.*, (*EACTA*) A.61
——, Time course of serial serum troponin I levels after coronary artery bypass surgery (CABG), Filley, S., *et al.*, (*EACTA*) A.63
Heart, myocardial injury, Effect of halothane on myocardial reoxygenation injury in the isolated rat heart, Schlack, W., *et al.* 860–867
Heart, myocardial protection, Effects of lidoflazine on left ventricular function, Deirue, G. L., *et al.*, (*EACTA*) A.10
Heart, myocardium, Experimental evaluation of a single breath inert gas technique for measurement of myocardial blood flow, Kazmaier, S., *et al.*, (*EACTA*) A.5
——, Nitroglycerin induced hypoxaemia does not produce myocardial ischaemia, Toraman, F., *et al.*, (*EACTA*) A.21
——, The effect of the calcium sensitizer levosimendan on normal and stunned left ventricular myocardium, Wetterings, C. J., *et al.*, (*EACTA*) A.8
Heart, rate, Myocardial ischaemia and heart rate variability after coronary bypass surgery, Kentala, E., *et al.*, (*EACTA*) A.64
Heart, right ventricular function, Atrial natriuretic peptide (ANP) and N-terminal ANP: relationship to right ventricular function in patients undergoing coronary artery bypass surgery, Honkonen, E. L., *et al.*, (*EACTA*) A.6
Heart, transplant, Haemodynamic effects of sodium nitroprusside *versus* prostaglandin E_1 in heart transplant candidates, Coddens, J., *et al.*, (*EACTA*) A.26
Heart, valve surgery, Use of internal mammary artery improves prognosis in patients under 70 undergoing combined valve and coronary artery surgery, Herijgers, P., *et al.*, (*EACTA*) A.79
Heart, ventricles, Effects and interactions of myocardial ischaemia and alterations in circulating blood volume on canine left ventricular diastolic function, Dalmas, S., *et al.* 419–427
Heart, ventricular function, Stable right ventricular pressure-volume relation during lung volume reducing surgery for diffuse emphysema, Gelinder, S., *et al.*, (*EACTA*) A.80
HELLP syndrome, Management of pre-eclampsia, Mushambi, M. C., *et al.*, (*C*) 889–890
——, Management of pre-eclampsia, Ward, J. E. H., *et al.*, (*C*) 889
——, Recent developments in the pathophysiology and management of pre-eclampsia, Mushambi, M. C., *et al.* 133–148
Histamine, Histamine release by neuromuscular blocking agents, Naguib, M., (*C*) 471
——, Histamine release by neuromuscular blocking agents, Todd, D. B., (*C*) 471
——, Histamine-release haemodynamic changes produced by rocuronium, vecuronium, mivacurium, atracurium and tubocurarine, Naguib, M., *et al.*, (*e*) 339
——, Relaxant effect of ketamine and its isomers on histamine-induced contraction of tracheal smooth muscle, Hirota, K., *et al.* 266–270
Hormones, aldosterone, Laparoscopic cholecystectomy: haemodynamic and neuroendocrine responses after pneumoperitoneum and changes in position, O'Leary, E., *et al.* 640–644
Hormones, glucocorticoid, Metabolic and hormonal responses to induced hypotension for middle ear surgery, Newton, M. C., *et al.* 352–357
——, Methylprednisolone inhibits endotoxin-induced depression of contractile function in human arteries *in vitro*, Tsuneyoshi, I., *et al.* 251–257
Hormones, melatonin, Changes in pineal and pituitary hormone secretion under general anaesthesia, Reber, A., *et al.*, (*ARS*) 584P
Hormones, progesterone, CSF progesterone concentrations in pregnancy, Baliga, N., (*C*) 886
——, CSF progesterone concentrations in pregnancy, Hirabayashi, Y., *et al.*, (*C*) 886
Hormones, prostaglandins, Haemodynamic effects of sodium nitroprusside *versus* prostaglandin E_1 in heart transplant candidates, Coddens, J., *et al.*, (*EACTA*) A.26
——, Inhaled prostacyclin compared to inhaled nitric oxide in the evaluation of heart transplant candidates with elevated pulmonary vascular resistance, Haraldsson, A., *et al.*, (*EACTA*) A.27
Hormones, renin, Laparoscopic cholecystectomy: haemodynamic and neuroendocrine responses after pneumoperitoneum and changes in position, O'Leary, E., *et al.* 640–644
Hypertension, Pharmacokinetics and haemodynamic effects of an ultrashort-acting calcium antagonist, Nordlander, M., *et al.*, (*EACTA*) A.24
Hypnotics benzodiazepine, diazepam, Hypotension following the administration of fentanyl-diazepam combination in chronic ACE inhibitor users, Özyurt, A., *et al.*, (*EACTA*) A.25
Hypnotics benzodiazepine, midazolam, Comparison of sedation with midazolam and ketamine: effects on airway muscle activity, Drummond, G. B. 663–667
——, Midazolam *vs* trimeprazine premedication for children during day-care surgery, Nathwani, D., *et al.*, (*ARS*) 589P
——, Periodic cardiovascular and ventilatory activity during midazolam sedation, Galletly, D. C., *et al.* 503–507

Hypnotics benzodiazepine, trimeprazine, Midazolam *vs* trimeprazine premedication for children during day-care surgery, Nathwani, D., *et al.*, (*ARS*) 589P
Hypnotics benzodiazepines, midazolam, Investigation into the effects of midazolam and propofol on human respiratory cilia beat frequency *in vitro*, Hann, H. C. L., *et al.*, (*ARS*) 591P
Hypotension, Relative effects of three hypotensive agents on pulmonary gas exchange, Van Oldenbeek, C., *et al.*, (*EACTA*) A.22
Hypothermia, Delayed forced air warming prevents hypothermia during abdominal aortic surgery, Karayan, J., *et al.* 459–460
——, Perioperative inadvertent hypothermia: what do we need to prevent? Carli, F., *et al.*, (*E*) 601–603
——, Preoperative infusion of amino acids prevents postoperative hypothermia, Selldén, E., *et al.* 227–234
Hypoxaemia, Postoperative sleep disturbances: mechanisms and clinical implications, Rosenberg-Adamsen, S., *et al.* 552–559
Hypoxia, Influence of oral clonidine on the ventilatory response to acute and sustained isocapnic hypoxia in human males, Foo, I. T., *et al.* 214–220
——, Slow ventilatory dynamics after isocapnic hypoxia and voluntary hyperventilation in humans: effects of isoflurane, Dahan, A., *et al.* 374–381

Immune response, Immunoglobulin and interleukin 2 production *ex vivo/in vitro* during treatment with oral retarded morphine, Palm, S., *et al.*, (*ARS*) 588–589P
Immune system, Perioperative changes in receptors for ICAM-1/CD54 and immunglobulin G on monocytes by extracorporeal circulation (ECC), Hiesmayr, M., *et al.*, (*EACTA*) A.32
Infants, Continuous extrapleural paravertebral infusion of bupivacaine for post-thoracotomy analgesia in young infants, Karmakar, M. K., *et al.* 811–815
——, Perioperative changes in α_1-acid glycoprotein concentrations in infants undergoing major surgery, Booker, P. D., *et al.* 365–368
——, Sevoflurane–nitrous oxide or halothane–nitrous oxide for paediatric bronchoscopy and gastroscopy, Meretoja, O. A., *et al.* 767–771
——, Vecuronium infusion requirements in paediatric patients in intensive care units: the use of acceleromyography, Hodges, U. M. 23–28
Infertility, Infertility among female hospital doctors in the UK, Maran, N. J., *et al.*, (*ARS*) 581P
Intensive care, A comparison of core temperature with thermal energy balance in predicting adequacy of rewarming from hypothermic cardiopulmonary bypass, Deakin, C. D., *et al.*, (*EACTA*) A.41

——, RAE tube obstruction during tonsil dissection, Graham, D., *et al.*, (*C*) 170–171
Intubation tracheal, complications, A new tracheal tube for difficult intubation, West, M. R. J., *et al.* 673–679
Intubation tracheal, responses, Comparison of nicardipine, diltiazem and verapamil for controlling the cardiovascular responses to tracheal intubation, Mikawa, K., *et al.* 221–226
——, EEG arousal during laryngoscopy and intubation, Shannon, C., *et al.*, (*C*) 472
——, EEG arousal during laryngoscopy and intubation, Wilder-Smith, O. H. G., *et al.*, (*C*) 472–473
Intubation tracheal, training, A new tracheal tube for difficult intubation, West, M. R. J., *et al.* 673–679
Ions, calcium, Fentanyl increases intracellular Ca^{2+} concentrations in SH-SY5Y cells, Wandless, A. L., *et al.* 461–463
——, Is the dihydropyridine binding site on neuronal L-type calcium channels a target for i.v. anaesthetic agents? Hirota, K., *et al.*, (*ARS*) 591P
——, Voltage-sensitive Ca^{2+} channels and anaesthesia, Hirota, K., *et al.*, (*E*) 344–346
——, White blood cell cytosolic calcium changes during human orthotopic liver transplantation, Enright, S., *et al.*, (*ARS*) 587–588P
Ions, ion channels, Halothane and potassium channels in airway smooth muscle, Fukushima, T., *et al.* 847–853
——, Is the dihydropyridine binding site on neuronal L-type calcium channels a target for i.v. anaesthetic agents? Hirota, K., *et al.*, (*ARS*) 591P
Ions, ion channels, voltage-gated, Voltage-sensitive Ca^{2+} channels and anaesthesia, Hirota, K., *et al.*, (*E*) 344–346
Ions, magnesium, Electromyographic and mechanomyographic characteristics of neuromuscular block by magnesium sulphate in the pig, Lee, C., *et al.* 278–283
——, Magnesium sulphate enhances residual neuromuscular block induced by vecuronium, Fuchs-Buder, T., *et al.* 565–566
Ions, potassium, Halothane and potassium channels in airway smooth muscle, Fukushima, T., *et al.* 847–853

Kidney, blood flow, Preoperative inhibition of angiotensin-converting enzyme improves systemic and renal haemodynamic changes during aortic abdominal surgery, Licker, M., *et al.* 632–639
Kidney, function, Aprotinin treatment does not impair renal function during and after cardiac surgery, Schweizer, A., *et al.*, (*EACTA*) A.55
——, Preoperative inhibition of angiotensin-converting enzyme improves systemic and renal haemodynamic changes during aortic abdominal surgery, Licker, M., *et al.* 632–639

Lactate, Nitroglycerin induced hypoxaemia does not produce myocardial ischaemia, Toraman, F., *et al.*, (*EACTA*) A.21
Larynx, cricoid pressure, Cricoid pressure applied after placement of the laryngeal mask prevents gastric insufflation but inhibits ventilation, Asai, T., *et al.* 772–776
——, Fracture of the cricoid cartilage after Sellick's manoeuvre, Heath, K. J., *et al.* 877–878
Larynx, laryngoscopy, Airway management in cleft lip and palate surgery, Hatch, D. J., (*E*) 755–756
——, Difficult laryngoscopy in cleft lip and palate surgery, Gunawardana, R. H. 757–759
——, Effect of neuromuscular block on depth of anaesthesia as measured by the auditory evoked response, Richmond, C. E., *et al.* 446–448
Liver, Effects of dopamine and dopexamine on splanchnic microcirculation during major surgery in humans, Bellamy, M. C., *et al.*, (*ARS*) 587P
Liver, disease, Pharmacokinetics and pharmacodynamics of cisatracurium in patients with end-stage liver disease undergoing liver transplantation, De Wolf, A. M., *et al.* 624–628
Liver, failure, Early effects of total hepatectomy on haemodynamic state and organ uptake of catecholamines in the pig, James, M. F. M., *et al.* 713–720
Liver, oxygen, The influence of dopaminergic agents on liver venous and mixed venous O_2-saturation in MODS – a preliminary report, Lampert, R., *et al.*, (*EACTA*) A.11
Liver, transplantation, Aprotinin during liver transplantation, Cottam, S., *et al.*, (*C*) 882
——, Aprotinin during liver transplantation, Lentschener, C., *et al.*, (*C*) 882
——, Perioperative mucosal pH and splanchnic endotoxin

concentration in orthotopic liver transplantation, Welte, M., *et al.* 90–98
——, Pharmacokinetics and pharmacodynamics of cisatracurium in patients with end-stage liver disease undergoing liver transplantation, De Wolf, A. M., *et al.* 624–628
——, Use of recombinant human erythropoietin to facilitate liver transplantation in a Jehovah's Witness, Snook, N. J., *et al.* 740–743
Lung, atelectasis, Volumetric analysis of aeration in the lungs during general anaesthesia, Reber, A., *et al.* 760–766
Lung, circulation, Nitric oxide and pulmonary impedance, Poulton, B. B., *et al.*, (*EACTA*) A.29
Lung, compliance, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? Kyttä, J., *et al.*, (*C*) 475–476
——, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? Mallick, A., *et al.*, (*C*) 475
Lung, complications, Heparin-coated circuits reduce postoperative lung complications in high-risk cardiac patients, Ranucci, M., *et al.*, (*EACTA*) A.71
Lung, function, Nitric oxide and pulmonary impedance, Poulton, B. B., *et al.*, (*EACTA*) A.29
——, Relative effects of three hypotensive agents on pulmonary gas exchange, Van Oldenbeek, C., *et al.*, (*EACTA*) A.22
Lung, functional residual capacity, Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone, Spens, H. J., *et al.* 369–373
——, Effect of apparatus on functional residual capacity, Drummond, G. B. 560–562
Lung, gas exchange, Nitrous oxide and the rate of gas uptake from an unventilated lung in dogs, Joyce, C. J., *et al.* 292–296
Lung, hyperinflation, Systolic pressure variation—a way to recognize dynamic hyperinflation, Myles, P. S., (*C*) 169
——, Systolic pressure variation—a way to recognize dynamic hyperinflation, Perel, A., *et al.*, (*C*) 168–169
Lung, hypertension, Correlation of predicted and recorded concentrations of nitric oxide during long-term inhalation in infants after cardiac surgery, Knapik, P., *et al.*, (*EACTA*) A.28
——, Inhaled prostacyclin compared to inhaled nitric oxide in the evaluation of heart transplant candidates with elevated pulmonary vascular resistance, Haraldsson, Å., *et al.*, (*EACTA*) A.27
Lung, metabolic function, Pulmonary uptake of sufentanil during and after constant rate infusion, Boer, F., *et al.* 203–208
Lung, pathophysiology, Investigation into the effects of midazolam and propofol on human respiratory cilia beat frequency *in vitro*, Hann, H. C. L., *et al.*, (*ARS*) 591P
——, Pulmonary lactate flux after cardiopulmonary bypass, Kulkarni, V., *et al.*, (*ARS*) 586P
Lung, shunt, Effect of anaesthetic agents on pulmonary shunt during coronary artery surgery, Sindjelic, R., *et al.*, (*EACTA*) A.19
Lung, surgery, Minimal incidence of reperfusion pulmonary oedema after pulmonary thromboendarterectomy, Mares, P., *et al.*, (*EACTA*) A.75
Lung, trachea, A perfusion system for *in vitro* measurement of human cilia beat frequency, Selwyn, D. A., *et al.* 111–115
——, Effects of 3 MAC of halothane, enflurane and isoflurane on cilia beat frequency of human nasal epithelium *in vitro*, Raphael, J. H., *et al.* 116–121
——, Effects of morphine on human nasal cilia beat frequency *in vitro*, Selwyn, D. A., *et al.* 274–277
——, Halothane and potassium channels in airway smooth muscle, Fukushima, T., *et al.* 847–853
——, Recovery of respiratory ciliary function after depression by inhalation anaesthetic agents: an *in vitro* study using nasal turbinate explants, Raphael, J. H., *et al.* 854–859
Lung, volume, Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone, Spens, H. J., *et al.* 369–373
——, Effect of apparatus on functional residual capacity, Drummond, G. B. 560–562
600 MCQs in Anaesthesia: Clinical Practice, 2nd Edn, Goodman, N. W., *et al.*, (*R*) 751

Measurement techniques, Assessment of right and left heart volume indices in patients undergoing coronary artery bypass surgery, Buhre, W., *et al.*, (*EACTA*) A.37
——, Splanchnic blood flow during cardiopulmonary bypass assessed by indicator dilution technique, Gårdebäck, M., *et al.*, (*EACTA*) A.36
Measurement techniques, acceleromyography, Vecuronium infusion requirements in paediatric patients in intensive care units: the use of acceleromyography, Hodges, U. M. 23–28
Measurement techniques, arterial pressure, Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement, Weiss, B. M., *et al.* 405–411
Measurement techniques, blood flow, A new method for cerebral blood flow measurement, Mielck, F., *et al.*, (*EACTA*) A.12
Measurement techniques, calorimetry, Oxygen consumption and delivery relationship in brain-dead organ donors, Langeron, O., *et al.* 783–789
Measurement techniques, Doppler ultrasound, Randomized trial of bolus phenylephrine or ephedrine for maintenance of arterial pressure during spinal anaesthesia for Caesarean section, Thomas, D. G., *et al.* 61–65
Measurement techniques, drug concentration, Comparison of arterialized venous with arterial blood propofol concentrations during sub-anaesthetic infusions in volunteers, Johnston, K. R., *et al.* 401–404
Measurement techniques, echocardiography, Randomized trial of bolus phenylephrine or ephedrine for maintenance of arterial pressure during spinal anaesthesia for Caesarean section, Thomas, D. G., *et al.* 61–65
Measurement techniques, electromyography, Effect of isoflurane and sevoflurane on the magnitude and time course of neuromuscular block produced by vecuronium, pancuronium and atracurium, Vanlinthout, L. E. H., *et al.* 389–395
——, Electromyographic and mechanomyographic characteristics of neuromuscular block by magnesium sulphate in the pig, Lee, C., *et al.* 278–283
——, Evoked EMG response during inhalation of a subanaesthetic concentration of isoflurane, Polhill, S. L., *et al.*, (*ARS*) 578P
——, Magnesium sulphate enhances residual neuromuscular block induced by vecuronium, Fuchs-Buder, T., *et al.* 565–566
——, Post-tetanic constant stimulus train patterns during neuromuscular block with atracurium and vecuronium, Bryan, A., *et al.*, (*ARS*) 579P
Measurement techniques, gas exchange, Experimental evaluation of a single breath inert gas technique for measurement of myocardial blood flow, Kazmaier, S., *et al.*, (*EACTA*) A.5
Measurement techniques, mechanomyography, Effect of isoflurane and sevoflurane on the magnitude and time course of neuromuscular block produced by vecuronium, pancuronium and atracurium, Vanlinthout, L. E. H., *et al.* 389–395
——, Electromyographic and mechanomyographic characteristics of neuromuscular block by magnesium sulphate in the pig, Lee, C., *et al.* 278–283
Measurement techniques, near infrared spectroscopy, Use of near infrared spectroscopy to estimate cerebral blood flow in conscious and anaesthetized adult subjects, Owen-Reece, H., *et al.* 43–48
Measurement techniques, nuclear magnetic resonance, Anatomical configuration of the spinal column in the supine position. III. Comparison of adolescent and adult volunteers, Hirabayashi, Y., *et al.* 508–510
——, Magnetic resonance imaging of the superior vena cava during spontaneous respiration with continuous positive airway pressure via a facemask in normal subjects, Mayor, A. H., *et al.*, (*ARS*) 578–579P
Measurement techniques, oscillometry, Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement, Weiss, B. M., *et al.* 405–411
Measurement techniques, oximetry, Validation of the Edslab dual lumen oximetry catheter for continuous monitoring of jugular bulb oxygen saturation after severe head injury, Souter, M. J., *et al.* 744–746
Measurement techniques, plethysmography, Periodic cardiovascular and ventilatory activity during midazolam sedation, Galletly, D. C., *et al.* 503–507
Measurement techniques, pupil diameter, Pupil changes during cardiopulmonary bypass, Fletcher, G. C., *et al.* 20–22
Measurement techniques, spectrometry, Accumulation of foreign gases during closed-system anaesthesia, Versichelen, L., *et al.* 668–672
Measurement techniques, spectrophotometry, Interference of volatile anaesthetics with infrared analysis of carbon dioxide and nitrous oxide tested in the Dräger Cicero EM using sevoflurane, Wilkes, A. R., *et al.* 737–739

Measurement techniques, thrombelastography, Haemodilution induces a hypercoagulable state, Ruttmann, T. G., *et al.* 412–414

Measurement techniques, tomography, Volumetric analysis of aeration in the lungs during general anaesthesia, Reber, A., *et al.* 760–766

Measurement techniques, tonometry, Radial artery tonometry: moderately accurate but unpredictable technique of continuous non-invasive arterial pressure measurement, Weiss, B. M., *et al.* 405–411

Measurement techniques, transit time flow, Quality control of coronary bypass surgery: intraoperative transit time flow measurement, Walpoth, B. H., *et al.*, (*EACTA*) A.7

Measurement techniques, transoesophageal echocardiography, Changes of mitral inflow patterns as assessed by transoesophageal echocardiography following cardiac surgery: are they of clinical significance? Schmidlin, D., *et al.*, (*EACTA*) A.48

——, Does perioperative transoesophageal echocardiography change the therapy of cardiothoracic patients? Brase, R., *et al.*, (*EACTA*) A.47

——, Doppler-derived left ventricular DP/DT: peroperative feasibility of the method during mitral valve surgery, Broka, S., *et al.*, (*EACTA*) A.44

——, Echocardiography by the anaesthetist: a French survey, Lehot, J. J., *et al.*, (*EACTA*) A.43

——, Epiaortic scanning of the ascending aorta identifies arteriosclerotic plaques and changes surgical practice during CABG? van der Linden, J., *et al.*, (*EACTA*) A.82

——, Postoperative diastolic dysfunction. Incidence, natural history and prognosis, Oppizzi, M., *et al.*, (*EACTA*) A.46

——, Transoesophageal echocardiography and haemodynamic monitoring in emergency surgical revascularization for extensive acute myocardial infarction, Guarracino, F., *et al.*, (*EACTA*) A.45

——, Transoesophageal echocardiography and intraoperative evaluation of left ventricular performance, Jovic, M., *et al.*, (*EACTA*) A.49

Measurement techniques, transthoracic electrical impedance, Haemodynamic effects of moderate normovolaemic haemodilution in conscious and anaesthetized patients, Biboulet, P., *et al.* 81–84

——, Hypotension during subarachnoid anaesthesia: haemodynamic effects of colloid and metaraminol, Critchley, L. A. H., *et al.* 734–736

Measurement techniques, ultrasound, Sepsis-induced vasoparalysis does not involve the cerebral vasculature: indirect evidence from autoregulation and carbon dioxide reactivity studies, Matta, B. F., *et al.* 790–794

Memory, Double-blind, randomized trial of cessation of smoking after audiotape suggestion during anaesthesia, Myles, P. S., *et al.* 694–698

——, Effect of tramadol on depth of anaesthesia, Coetzee, J. F., *et al.* 415–418

——, Recall during intermittent propofol anaesthesia, Nordström, O., *et al.* 699–701

Metabolism, Oxygen consumption during early mobilization after CABG surgery in patients with normal cardiac function, Kirkeby-Garstad, I., *et al.*, (*EACTA*) A.74

Metabolism, fasting, Preoperative fasting for paediatric anaesthesia, Hopp, M., (*C*) 471

——, Preoperative fasting for paediatric anaesthesia, Phillips, S., *et al.*, (*C*) 471

Metabolism, glucose, Metabolic and hormonal responses to induced hypotension for middle ear surgery, Newton, M. C., *et al.* 352–357

——, Use of i.v. insulin in well-controlled non-insulin-dependent diabetics undergoing major surgery, Raucoules-Aimé, M., *et al.* 198–202

Metabolism, insulin, Use of i.v. insulin in well-controlled non-insulin-dependent diabetics undergoing major surgery, Raucoules-Aimé, M., *et al.* 198–202

Metabolism, lactate, Blood lactate during cardiopulmonary bypass with a lactated priming solution, Hett, D., *et al.*, (*EACTA*) A.33

——, Pulmonary lactate flux after cardiopulmonary bypass, Kulkarni, V., *et al.*, (*ARS*) 586P

Metabolism, myocardial, Free fatty acid (FFA) uptake immediately after routine coronary artery bypass surgery (CABG), Pietersen, H. G., *et al.*, (*EACTA*) A.2

Metabolism, triglycerides, Long chain triglycerides but not glucose–insulin, administered during reperfusion, improve recovery from stunning in isolated rabbit hearts, Van de Velde, M., *et al.*, (*EACTA*) A.3

——, Oxfenicine blocks the beneficial effects of intravenous long chain triglyceride (LCT) administration on regional myocardial stunning in conscious dogs, Van de Velde, M., *et al.*, (*EACTA*) A.4

Mitral valve, Doppler-derived left ventricular DP/DT: peroperative feasibility of the method during mitral valve surgery, Broka, S., *et al.*, (*EACTA*) A.44

Model, computer simulation, Fuzzy logic control of inspired isoflurane and oxygen concentrations using minimal flow anaesthesia, Curatolo, M., *et al.* 245–250

Model, dog, Oxfenicine blocks the beneficial effects of intravenous long chain triglyceride (LCT) administration on regional myocardial stunning in conscious dogs, Van de Velde, M., *et al.*, (*EACTA*) A.4

——, Serotonin induces coronary spasms after brain death in dogs, Herijgers, P., *et al.*, (*EACTA*) A.14

Model, guineapig, Levosimendan is a more potent inotropic agent than amrinone after ischaemia in isolated perfused guinea pig hearts, Süzer, Ö., *et al.*, (*EACTA*) A.9

Model, heart, Effect of halothane on myocardial reoxygenation injury in the isolated rat heart, Schlack, W., *et al.* 860–867

Model, logistic regression, Prediction of postoperative nausea and vomiting using a logistic regression model, Toner, C. C., *et al.* 347–351

Model, neuroblastoma cells, Fentanyl increases intracellular Ca^{2+} concentrations in SH-SY5Y cells, Wandless, A. L., *et al.* 461–463

——, Interaction of i.v. anaesthetic agents with 5-HT_3 receptors, Appadu, B. L., *et al.* 271–273

Model, pharmaco-physiological, A model to describe the rate of oxyhaemoglobin desaturation during apnoea, Farmery, A. D., *et al.* 284–291

——, A model to describe the rate of oxyhaemoglobin desaturation during apnoea, Farmery, A. D., *et al.*, (*e*) 890

Model, rabbit, Long chain triglycerides but not glucose–insulin, administered during reperfusion, improve recovery from stunning in isolated rabbit hearts, Van de Velde, M., *et al.*, (*EACTA*) A.3

Model, rat, Brain death induced haemodynamic failure in the rat is solely due to autonomic denervation, Herijgers, P., *et al.*, (*EACTA*) A.13

——, Is the dihydropyridine binding site on neuronal L-type calcium channels a target for i.v. anaesthetic agents? Hirota, K., *et al.*, (*ARS*) 591P

——, Porphyria, propofol and rats, Böhrer, H., (*C*) 172

——, Porphyria, propofol and rats, Gorchein, A., (*C*) 172

——, Porphyria, propofol and rats, Tidmarsh, M. D., (*C*) 171–172

——, Trimetazidine does not reduce ischaemia-reperfusion induced arrhythmias in isolated perfused rat hearts, Süzer, Ö, *et al.*, (*EACTA*) A.68

Modulation of the Inflammatory Response in Severe Sepsis, Tellado, J. M., *et al.*, (editors), (*R*) 173–174

Monitoring, Transoesophageal echocardiography and haemodynamic monitoring in emergency surgical revascularization for extensive acute myocardial infarction, Guarracino, F., *et al.*, (*EACTA*) A.45

Monitoring, echocardiography, Balloon mitral valve dilatation as an aid to weaning from ventilatory support in patients with intractable pulmonary oedema caused by severe mitral stenosis, Davis, G., *et al.* 879–880

——, Transoesophageal echocardiography in chest trauma, George, S. J., (*C*) 336–337

——, Transoesophageal echocardiography in chest trauma, Kennedy, N., *et al.*, (*C*) 337

Monitoring, electrocardiography, Laparoscopic cholecystectomy: haemodynamic and neuroendocrine responses after pneumoperitoneum and changes in position, O'Leary, E., *et al.* 640–644

Monitoring, electrocorticography, Activation of the electrocorticogram by propofol during surgery for epilepsy, Smith, M., *et al.* 499–502

Monitoring, electroencephalography, EEG arousal during laryngoscopy and intubation, Shannon, C., *et al.*, (*C*) 472

——, EEG arousal during laryngoscopy and intubation, Wilder-Smith, O. H. G., *et al.*, (*C*) 472–473

——, Haemodynamic responses to incision and sternotomy in relation to the auditory evoked potential and spontaneous EEG, DE BEER, N. A. M., *et al.* 685–693

Monitoring, evoked potentials, Analgesic effect in humans of subanaesthetic isoflurane concentrations evaluated by evoked potentials, ROTH, D., *et al.* 38–42

——, Central nuclei and spinal pathways in feedback inhibitory spinal cord potentials in ketamine-anaesthetized rats, DENDA, S., *et al.* 258–265

——, Remifentanil reduces auditory and somatosensory evoked responses during isoflurane anaesthesia in a dose-dependent manner, CRABB, I., *et al.* 795–801

——, Suxamethonium and auditory evoked potentials, BRUNNER, M. D., *et al.*, (*C*) 881

——, Suxamethonium and auditory evoked potentials, PONTE, J., (*C*) 881

——, Total i.v. anaesthesia for transcranial magnetic evoked potential spinal cord monitoring, WATT, J. W. H., *et al.* 870–871

Monitoring, neuromuscular function, Vecuronium infusion requirements in paediatric patients in intensive care units: the use of acceleromyography, HODGES, U. M. 23–28

Monitoring, oxygen, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? KYTTÄ, J., *et al.*, (*C*) 475–476

——, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? MALLICK, A., *et al.*, (*C*) 475

Monitoring, oxygen saturation, Validation of the Edslab dual lumen oximetry catheter for continuous monitoring of jugular bulb oxygen saturation after severe head injury, SOUTER, M. J., *et al.* 744–746

Monitoring, pH gastric, Gastric tonometry, BOYD, O., *et al.*, (*C*) 750

Monitoring, pH oesophageal, Gastric tonometry to monitor tissue oxygenation: more than a gut feeling? OH, T. E., (*E*) 604–605

——, Measurement technique and variation in intramucosal pH, WOOD, P. R., *et al.* 563–564

——, Perioperative mucosal pH and splanchnic endotoxin concentration in orthotopic liver transplantation, WELTE, M., *et al.* 90–98

Monitoring, spirometry, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? KYTTÄ, J., *et al.*, (*C*) 475–476

——, Venous air embolism: is end-tidal oxygen monitoring more informative than end-tidal carbon dioxide? MALLICK, A., *et al.*, (*C*) 475

Monitoring, temperature, Convective warming combined with vasodilator therapy accelerates core rewarming after coronary artery bypass surgery, HARRISON, S. J., *et al.* 511–514

——, Delayed forced air warming prevents hypothermia during abdominal aortic surgery, KARAYAN, J., *et al.* 459–460

——, Perioperative inadvertent hypothermia: what do we need to prevent? CARLI, F., *et al.*, (*E*) 601–603

Monitoring, temperature, rewarming, Convective warming overcomes effects of cooling after cardiopulmonary bypass, KNOWLES, P. R., *et al.*, (*EACTA*) A.42

Monitoring, tonometry, Gastric tonometry to monitor tissue oxygenation: more than a gut feeling? OH, T. E., (*E*) 604–605

Monocytes, Perioperative changes in receptors for ICAM-1/CD54 and immunglobulin G on monocytes by extracorporeal circulation (ECC), HIESMAYR, M., *et al.*, (*EACTA*) A.32

Muscle respiratory, Changes in chest wall compartment volumes on induction of anaesthesia with eltanolone, propofol and thiopentone, SPENS, H. J., *et al.* 369–373

Muscle vascular, responses, Effects of propofol on rabbit mesenteric arteries and veins, KAMITANI, K., (*C*) 333–334

——, Effects of propofol on rabbit mesenteric arteries and veins, STRATFORD, N., (*C*) 333

Nerve, Effect of stimulation rate on force of contraction in partially paralysed rat phrenic nerve hemidiaphragm preparations, RICHARDS, K., *et al.*, (*ARS*) 579–580P

Nerve, damage, Ulnar and common peroneal nerve block revisited, SOUTER, A. J., *et al.*, (*C*) 595–596

Neuro-anaesthetic Practice, VAN AKEN, H., (editor), (*R*) 599

Neuromuscular Block, FELDMAN, S., (*R*) 893

Neuromuscular block, Effect of neuromuscular block on depth of anaesthesia as measured by the auditory evoked response, RICHMOND, C. E., *et al.* 446–448

——, Effect of stimulation rate on force of contraction in partially paralysed rat phrenic nerve hemidiaphragm preparations, RICHARDS, K., *et al.*, (*ARS*) 579–580P

Neuromuscular block, 51W89, Comparison of the pharmacodynamics and pharmacokinetics of an infusion of *cis*-atracurium (51W89) or atracurium in critically ill patients undergoing mechanical ventilation in an intensive therapy unit, BOYD, A. H., *et al.* 382–388

——, Pharmacokinetics and pharmacodynamics of cisatracurium in patients with end-stage liver disease undergoing liver transplantation, DE WOLF, A. M., *et al.* 624–628

Neuromuscular block, α-bungarotoxin, Effect of stimulation rate on force of contraction in partially paralysed rat phrenic nerve hemidiaphragm preparations, RICHARDS, K., *et al.*, (*ARS*) 579–580P

Neuromuscular block, antagonism, Effect of antagonism of mivacurium on recovery of extraocular muscle function, MELLOR, D. J., *et al.* 621–623

Neuromuscular block, atracurium, Comparison of the pharmacodynamics and pharmacokinetics of an infusion of *cis*-atracurium (51W89) or atracurium in critically ill patients undergoing mechanical ventilation in an intensive therapy unit, BOYD, A. H., *et al.* 382–388

——, Effect of isoflurane and sevoflurane on the magnitude and time course of neuromuscular block produced by vecuronium, pancuronium and atracurium, VANLINTHOUT, L. E. H., *et al.* 389–395
